CHAPTER 9

Supplementary Material

SUPPLEMENTARY TABLE 9.1 List of HSV genes and their functions

Open reading frames (ORFs):
RL1 (248 codons, E/L, nonessential) encodes ICP34.5, sometimes called a neurovirulence factor. ICP34.5 binds protein phosphatase 1α and directs it to dephosphorylate the α subunit of the eukaryotic translation initiation factor 2 (eIF-2), thereby preventing the inhibition of protein synthesis due to activation of eIF-2α kinases like PKR. ICP34.5 interacts with Beclin and blocks autophagy, and the ICP34.5 protein also plays a dual role in blocking both innate and adaptive immunity, the latter through evasion of MHC class II responses.[60,61,131,132,173,294]
ORF-P (233 codons, Pre-IE, nonessential) encodes the ORF-P protein, which binds p32 and localizes in spliceosomes. ORF-P is encoded on the strand complementary to RL1. Transcription of ORF-P is blocked by ICP4 bound to a high-affinity binding site at the transcription initiation site of ORF-P. Derepression of ORF-P results in decreased expression of ICP34.5. Overexpression of ORF-P results in decreased expression of viral products of spliced RNAs.[41,167,168]
ORF-O (117 codons, Pre-IE, nonessential) encodes the ORF-O protein, which blocks the binding of ICP4 to its cognate high-affinity DNA binding sites *in vitro*. The N-terminus is identical to that of ORF-P. The amino acid sequence beyond residue 35 is in an alternate reading frame. Expression of ORF-O is repressed by ICP4.[243]
RL2 (775 codons, IE, nonessential at high multiplicities in certain cells) encodes ICP0, an E3 ubiquitin ligase that promotes viral gene expression and inhibits host cell responses. ICP0 promotes the degradation of certain host restriction factors, thereby reversing or preventing epigenetic silencing and acting to enhance viral transcription. Also inhibits innate immune pathways by promoting degradation of signaling components.[37,43,57,66,170,187,226,277,302]
U_L1 (224 codons, E/L, essential) encodes glycoprotein L (gL), which binds gH (UL22) and is required for its proper folding and trafficking through the Golgi to the plasma membrane. gL lacks a membrane anchor and localizes to the envelope surface through its interaction with gH. The gH/gL heterodimer is thought to regulate the fusogenic activity of gB.[63,139,251]
U_L2 (334 codons, E or E/L, nonessential) encodes a uracil-DNA glycosylase, which removes uracil in G:U base pairs resulting from deamination of cytosine residues in DNA.[47,316]
U_L3 (224 codons, L, nonessential) encodes a nuclear nonstructural protein of unknown function that is phosphorylated by the UL13 protein kinase. UL3 colocalizes with ICP22-US1.5 proteins in small dense nuclear structures.[16,193–195,317,319]
U_L4 (199 codons, L, nonessential) encodes a nuclear nonstructural protein of unknown function. UL4 colocalizes with ICP22/US1.5 in small dense nuclear structures that are formed prior to the onset of viral DNA synthesis. In the absence of other viral proteins, it remains in the cytoplasm.[143,152,319,322]
U_L5 (882 codons, E, essential) encodes a subunit of the heterotrimeric helicase–primase complex essential for viral DNA synthesis. The UL5–UL52 complex has DNA-dependent ATPase and GTPase, DNA primase, and DNA helicase activities.[74,88,126,333]
U_L6 (676 codons, L, essential) encodes the capsid portal protein. UL6 forms a dodecameric ring located at one vertex of the HSV capsid. UL6 interacts with UL15 and UL28 (the putative terminase) proteins.[217,313,326]

U_L7 (296 codons, E/L, nonessential) encodes a virion tegument protein that binds UL51. The UL7–UL51 complex maintains cell morphology and attachment of infected cells by stabilizing focal adhesions. UL7-null HSV-1 has a reduced titer and small-plaque phenotype. Nonenveloped capsids accumulate in the cytoplasm following infection with a ΔUL7ΔUL51 mutant virus, hinting at a role for UL7 in secondary envelopment.[7,221,249]

U_L8 (750 codons, E, essential) encodes a subunit of the heterotrimeric helicase primase complex and is required for the transport of UL52 and UL5 into the nucleus. UL8 is required for optimal helicase and primase activity of the UL5/UL52 complex and for the unwinding of ICP8-bound DNA.[103,196,197,267,290]

$U_L8.5$ (281 codons, E/L, nonessential) encodes a protein corresponding to the C-terminal domain of UL9 protein. It was reported to be transcribed with delayed early kinetics and to bind to the origins of DNA synthesis. In transient assays, the UL8.5 protein inhibited DNA synthesis and may play a role in shifting the pattern of synthesis for de novo initiation at origins to a rolling circle model of viral DNA synthesis.[21,22,176]

U_L9 (851 codons, E, essential) encodes the viral origin–binding protein. UL9 binds to specific sites within the origins of viral DNA synthesis. It acts as an ATPase and helicase and is required for initiation and early but not for later viral DNA synthesis. NFB42, an F box component of the SCF E3 enzyme, binds phosphorylated UL9 and targets it for ubiquitin–proteasomal degradation. The phosphorylation and degradation of UL9 may enable the switch from *de novo* initiation of DNA synthesis at origins to a rolling circle type of DNA replication.[98,101,106,160,224]

$U_L9.5$ (477 codons, L, unknown) encodes a protein of unknown function but may be the same as the UL8.5 protein because the transcript of *$U_L9.5$* is coterminal with those of *U_L8*, *$U_L8.5$*, and *U_L9*.[21]

U_L10 (473 codons, L, nonessential) encodes glycoprotein M (apparent M, 53-63,000). gM forms a complex with UL49.5 (gN). Although a ΔgM HSV mutant showed no major impairment of growth, coexpression of gM with UL49.5 altered the localization and decreased the fusogenic activity of HSV glycoproteins.[18,73,97]

U_L11 (96 codons, L, nonessential) encodes a myristoylated, palmitoylated tegument protein that accumulates on Golgi-derived membranes and is likely involved in secondary envelopment in the cytoplasm and budding.[17,163,185,189]

U_L12 (626 codons, E, nonessential) encodes an alkaline nuclease that potentially functions as a resolvase, an enzyme required for processing of replication intermediates that would interfere with the packaging of viral DNA into capsids. It forms a complex with ICP8 that has recombinase activity.[123,199,246]

$U_L12.5$ (~500 codons, E, nonessential) encodes a protein that corresponds to the C-terminal portion of the UL12 protein. The protein accumulates in the cytoplasm, contains a mitochondrial localization signal, and degrades mitochondrial DNA.[71,200,245,246,257]

U_L13 (518 codons, E, nonessential) encodes a tegument serine/tyrosine protein kinase that phosphorylates many viral and cellular proteins. UL13 appears to regulate multifunctional proteins and disrupt nuclear lamins.[9,46,80,242,271]

U_L14 (219 codons, L, nonessential) encodes a virion tegument protein that has been shown to interact with UL51 and is involved in viral egress.[76,138]

U_L15 (735 codons, L, essential) encodes a subunit of the HSV DNA-packaging terminase that hydrolyzes ATP to drive DNA packaging. The UL15 protein is required for the cleavage of replicated viral DNA into unit-length molecules and subsequent packaging into viral capsids. The transcript is one of the few HSV RNAs that are spliced.[15,72,238,261,327]

$U_L15.5$ (293 codons, L, unknown) encodes a protein of unknown function from exon 2 of UL15.[13]

U_L16 (373 codons, L, nonessential) encodes a tegument protein. The UL16 ORF is encoded in a sequence antisense to the UL15 intron. UL16-null virus has a reduced titer and accumulates nonenveloped capsids in the cytoplasm, hinting at a role in secondary envelopment. In HSV-2, but not in HSV-1, UL16 has also been reported to be necessary for efficient nuclear egress.[16,117,130,214]

U_L17 (703 codons, L, essential) encodes a capsid-associated protein that is required for DNA cleavage and packaging. This ORF is encoded in sequences antisense to exon 2 of UL15. Along with UL25 and the C terminus of UL36, UL17 forms a capsid-associated complex that localizes to the vertices and serves as a hub for tegument recruitment. Along with UL25, UL17 mechanically reinforces the capsid so that it can withstand the high internal pressure of the packaged gen ome.[77,259,260,272]

U_L18 (318 codons, E/L, essential) encodes VP23 (M, 34,000) or capsid triplex subunit 2.[218,296]

U_L19 (1311 codons, E/L, essential) encodes VP5 or ICP5 (M, 149,000), the major capsid protein present on the capsid in hexons and pentons.[38,218,315]

U_L20 (222 codons, E/L, nonessential) encodes a virion envelope protein that, when coexpressed with gK, localizes to the Golgi and inhibits cell–cell fusion. Its postulated role is to prevent fusion of infected cells with adjacent cells. UL20 interacts with gK and gB.[11,19,62,111]

$U_L20.5$ (160 codons, L, nonessential) encodes a protein of unknown function that localizes to small dense nuclear structures containing ICP22, US1.5, UL3, and UL4. The *$U_L20.5$* ORF is located upstream of the *U_L20* ORF.[310]

U_L21 (535 codons, L, nonessential) encodes a nucleotidylylated tegument protein weakly associated with capsids. During HSV-2 infection, but not HSV-1 or pseudorabies virus infection, UL21 is essential for the exit of viral capsids from the nucl eus.[14,34,171,283]

U_L22 (838 codons, L, essential) encodes glycoprotein H (gH), which is essential for virion infectivity and cell–cell fusion. Transport of gH from the endoplasmic reticulum to the Golgi and plasma membrane requires the interaction with glycoprotein L (gL). The gH/gL heterodimer is thought to regulate the fusogenic activity of gB.[10,63,85,110,139]

U_L23 (376 codons, E, nonessential) encodes the viral gene product called thymidine kinase (TK); however, it is a wide-spectrum nucleoside kinase capable of phosphorylating both purine and pyrimidine nucleosides and their analogs. TK plays a crucial role in activating nucleoside analogs used for the treatment of HSV infections.[58,94,99,144]

U_L24 (269 codons, E/L, nonessential) encodes a membrane-associated nuclear protein (M, of 30,000). Mutant viruses defective for *U_L24* form small polykaryocytes in cell culture, yield less virus, and exhibit decreased virulence in mice. UL24 is associated with dispersal of nucleolin. Other functions remain to be determined. The *U_L24* ORF partly overlaps the *TK* gene on the opposite strand.[31,128,141,188,229,292]

U_L25 (580 codons, L, essential) encodes a capsid protein involved in the retention of viral DNA after cleavage and that, along with UL17, stabilizes the DNA-filled viral capsid. UL25 is also involved in the release of DNA from the capsid after virus penetration. UL25, with UL17 and the C terminus of UL36, form a capsid vertex-specific complex (CVSC), also referred to as capsid-associated tegument complex (CATC), that localizes to the vertices and serves as a hub for tegument recruitment.[77,207,216,223,256,272]

U_L26 (635 codons, L, essential) encodes the capsid scaffold proteins/protease involved in capsid assembly. The UL26 product is cleaved in *cis*- or *trans*- by itself at two sites. The N-terminal polypeptide is a serine protease (VP24) required for assembly of scaffolding within capsids for DNA packaging and the larger, middle cleavage product (VP21) is a component of the scaffolding.[118,178,179,291]

$U_L26.5$ (326 codons, L, nonessential) encodes a capsid scaffold protein that is identical to the C-terminal sequence of the UL26 protein. The promoter and coding domain of the *$U_L26.5$* gene is contained in its entirety within the *U_L26* ORF. UL26.5 is cleaved by the protease at its C-terminus at the same site as the UL26 protein.[179,202]

U_L27 (904 codons, E/L, essential) encodes the viral fusogen glycoprotein B (gB), which interacts with gH/gL and with gD during an essential step for viral entry: fusion of the viral envelope with the plasma membrane. Virions lacking gB egress the cell but are noninfectious. gB has been shown to interact with CD1d in infected cells and, along with US3, is required for down-regulation of CD1d expression and inhibition of NK T-cell function.[10,44,133,284]

$U_L27.5$ (undefined but not less than 575 codons, L, unknown) encodes a cytoplasmic protein of unknown function with an apparent M, of 43,000. The ORF maps antisense to *U_L27*.[54]

U_L28 (785 codons, L, essential) encodes a subunit of the DNA-packaging HSV terminase, along with UL15 and UL33. UL28 binds *pac1* sequences and is required for both cleavage and encapsidation of the replicated viral genome.[4,5,29,289,324]

U_L29 (1196 codons, E, essential) encodes ICP8, the viral major DNA-binding protein, which unwinds and binds single-stranded DNA. ICP8 plays a key role in viral gene expression and an essential role in synthesis of viral DNA. ICP8 enables the unwinding of the DNA at the origin by UL9 and allows the entry of the machinery that replicates the DNA. ICP8 may also serve as a scaffold for organization of the replication complex. ICP8 in combination with UL12 or another nuclease has recombinase activity.[35,59,70,177,246,254]

U_L30 (1235 codons, E, essential) encodes the catalytic subunit of the viral DNA polymerase. UL30 has intrinsic RNase H and 3′-to-5′ exonuclease activities.[180,241,311,312]

U_L31 (306 codons, L, essential) encodes a nuclear phosphoprotein that, together with UL34, is required for nuclear egress. Proper localization of UL31 at the inner nuclear membrane (INM) requires UL34. UL31 and UL34 form a heterodimeric nuclear egress complex (NEC) that is anchored in the INM and mediates capsid budding at the INM. The NEC vesiculates nuclear membranes in uninfected cells expressing UL31 and UL34 and synthetic membranes *in vitro*. UL31 facilitates disruption of the nuclear lamina by recruiting kinases and participates in capsid docking by binding UL25. UL31 is present in perinuclear enveloped virions but not in extracellular virions.[32,56,159,248,270,284,325]

U_L32 (596 codons, L, essential) encodes a nuclear protein that plays an essential role in the cleavage of concatemeric viral DNA into monomeric genomes and their packaging into preformed capsids.[8,55,169]

U_L33 (130 codons, L, essential) encodes a nuclear protein that is required for packaging of viral DNA into preformed capsids. UL33 forms a complex with the HSV terminase subunits UL15 and UL28.[28,29,247]

U_L34 (275 codons, E/L, essential) encodes a type II membrane protein that localizes to the nuclear envelope and, together with UL31, is required for nuclear egress. Proper localization of UL34 at the inner nuclear membrane (INM) requires UL31. UL31 and UL34 form a heterodimeric nuclear egress complex (NEC) that is anchored in the INM and mediates capsid budding at the INM. The NEC vesiculates nuclear membranes in uninfected cells expressing UL31 and UL34 and synthetic membranes *in vitro*. UL34 is present in perinuclear enveloped virions but not in extracellular virions.[32,159,248,268,323]

U_L35 (112 codons, L, nonessential) encodes the VP26 capsid protein (also called small capsid protein), which forms a hexameric structure located on the outer surface of each hexon. It interacts with dynein light chains RP3 and Tetex1.[69,83,91,332]

U_L36 (3165 codons, L, essential) encodes a tegument protein designated VP1-2 (M, >270,000), the largest protein encoded by HSV. It is required for transport of virions through the cytoplasm, with possible roles in entry and in egress. VP1-2 also functions as a deubiquitinase.[26,156]

U_L37 (1123 codons, E/L, essential) encodes a tegument phosphoprotein that interacts with VP1-2, associates with capsids through binding of VP1-2, and promotes envelopment.[42,48,84,263]

U_L38 (465 codons, L, essential) encodes the capsid protein VP19C (capsid triplex subunit 1).[274,296]

U_L39 (1137 codons, E, nonessential) encodes the multifunctional ICP6 polypeptide, first identified as the large subunit of the viral ribonucleotide reductase holoenzyme. The ICP6 C-terminus is required for ribonucleotide reductase activity when partnered with the small subunit encoded by UL40.[12,142]

U_L40 (340 codons, E, unknown) encodes the small subunit of ribonucleotide kinase.[140]

U_L41 (489 codons, E/L, nonessential) encodes a tegument protein with an endoribonuclease activity with a substrate specificity similar to that of RNase A. This is termed the *vhs* (virion host shutoff) function and protein. Vhs introduced into cells during infection degrades (a) stable mRNAs in polyribosomes from 5′ to 3′ and (b) mRNAs containing A-U–rich elements by deadenylation and endonucleolytic cleavage in the 3′ UTR. Other features suggest that the degradation of mRNA is selective. Newly made vhs is neutralized by VP16 (UL48) and VP22 (UL49).[102,264,278,279,281,282]

U_L42 (488 codons, E, essential) encodes the DNA polymerase processivity factor, which binds double-stranded DNA and tethers the polymerase to its template and increases its processivity.[125,334]

U_L43 (434 codons, E, nonessential) encodes a hydrophobic, myristylated integral membrane protein of unknown function.[52,190]

$U_L43.5$ (91 codons, L, nonessential) encodes a hydrophilic protein localizing in nuclear structures containing capsid proteins. The ORF is encoded antisense to U_L43.[309]

U_L44 (511 codons, L, nonessential) encodes glycoprotein C (gC), which mediates the attachment of virions to cells by binding to glycosaminoglycans of heparan sulphate or to chondroitin sulfate at a site near its N-terminus. ΔgC mutants attach to cells with reduced efficiency. HSV-1 gC binds complement component C3b and inhibits the interaction of the next components of the pathway, C5 and properdin, thereby preventing activation of the classical and alternative pathways.[115,116,134,164,191]

U_L45 (172 codons, L, nonessential) encodes a type II membrane protein of unknown function.[89,304]

U_L46 (718 codons, L, nonessential) encodes tegument proteins VP11 and VP12, differentiated solely by their migration in denaturing gels. VP11-12 associates with capsids and membranes, binds VP13-14 (UL47) in stoichiometric amounts with VP16 (UL48) and enhances the latter's activity. In the absence of UL48 protein, UL46 inhibits activation of IE promoters. VP11-12 is stabilized by US3 kinase and activates Lck kinase.[24,201,206,213,305,306,329]

U_L47 (693 codons, L, nonessential) encodes the VP13 and VP14 tegument proteins, which along with UL46, enhance the activity of VP16 (UL48). VP13-14, in conjunction with ICP27, binds and displaces PABC1 from the PABP binding complex on the cap structure. It is reported to shuttle between the cytoplasm and nucleus and to bind RNA.[24,87,90,329]

U_L48 (491 codons, L, essential) encodes VP16 or α-TIF (α-trans–inducing factor), a multifunctional tegument protein. VP16 induces IE genes by interacting with two cellular proteins, HCF and Oct-1. The VP16–HCF–Oct-1 complex binds to specific sequences with the consensus GyATGnTAATGArATTCy-NC. VP16 is also required for virion assembly and, together with VP22 (UL49), it interacts with and blocks the RNase activity of UL41.[181,210,230,295,314]

U_L49 (301 codons, E/L, nonessential) encodes one of the most abundant tegument proteins, VP22 (UL49). In infected cells, VP22 localizes both to the cytoplasm and to the nucleus. It contributes to tegument assembly and secondary envelopment through its interactions with UL16, VP16 (UL48), ICP0, gE, and gM, presumably, by helping bridge the tegument to the glycoproteins but is not required for virion assembly. VP22 also controls the endonuclease activity of vhs (UL41). VP22 has been reported to bind RNA and translocate it from infected to adjacent, noninfected cells. It has been shown to interact with chromatin-remodeling proteins and to block nucleosome assembly in transfected cells. It is a putative microtubule-associated protein and has been reported to induce the stabilization and hyperacetylation of microtubules. VP22 also has a role in regulating viral protein synthesis.[34,95,100,192,198,204,235,237,265,275,280,301]

$U_L49.5$ (91 codons, L, essential) encodes the membrane-associated glycoprotein N (apparent M, of 6,700), which is abundant in virions. It interacts with gM (UL10) and gM may be required for localization of UL49.5 to the Golgi. UL49.5 is reported to block endogenous antigen presentation.[3,25,97,225]

U_L50 (371 codons, E, nonessential) encodes a monomeric dUTPase.[20,24,107]

U_L51 (244 codons, L, nonessential) encodes a palmitoylated tegument protein that localizes to the Golgi and is involved in virus egress. UL51 binds UL7 and the UL7–UL51 complex stabilizes focal adhesions to maintain the morphology and attachment of infected cells. *U_L51* deletion results in reduced viral titers and the accumulation of nonenveloped capsids in the cytoplasm, suggesting a role for UL51 in secondary envelopment.[7,24,79,222]

U_L52 (1058 codons, E, essential) encodes the primase subunit of the HSV helicase–primase complex formed together with UL5 and UL8. Both UL5 and UL52 contribute to DNA binding.[33,92,158]

U_L53 (338 codons, L, nonessential) encodes glycoprotein K (gK) that has three extracellular and two intracellular domains connected by four transmembrane segments. In infected cells, gK localizes to the Golgi apparatus. gK is a frequent locus of syncytial (syn) mutations. gK interacts with unglycosylated transmembrane protein UL20, and these interactions are important for intracellular trafficking, virus-induced cell fusion, and viral egress. gK interaction with gB also modulates virus-induced cell fusion and virion egress. HSV-1 lacking gK or its N-terminal 39 amino acids has an entry defect into neuronal axons but not fibroblasts or epithelial cells.[62,81,111–114,258]

U_L54 (512 codons, IE, essential) encodes the ICP27 multifunctional regulatory protein. Early in infection, ICP27 blocks pre-mRNA splicing and thereby contributes to the shutoff of host protein synthesis. ICP27 recruits cellular RNA polymerase II to the viral genome to promote efficient viral transcription and is required for transcription of certain E and E/L genes and possibly all L genes. ICP27 interacts with numerous cellular and viral proteins and binds RNA. It shuttles between the nucleus and the cytoplasm and is implicated in the nuclear export and translation of viral mRNAs.[78,109,129,145,150,262,330]

U_L55 (186 codons, L, nonessential) encodes a nonstructural protein of unknown function that is associated with sites of virion assembly.[215,321]

U_L56 (234 codons, L, nonessential) encodes a phosphorylated type II virion membrane protein. It was reported to interact with and relocalize members of the Nedd4 family of ubiquitin ligases and to bind kinesin motor protein KIF1A. It was reported to be required for virulence in mice.[161,162,252,300]

R_S1 (1298 codons, IE, essential) encodes ICP4, a protein that acts mainly as a transactivator of viral transcription but also as a repressor. ICP4 represses transcription from viral genes in which high-affinity ICP4-binding sites overlap the transcription initiation sites, such as *LAT*, *ORF-P*, *ORF-O*, and its own *ICP4* gene. Promoters activated by ICP4 lack high-affinity binding sites and instead contain low-affinity ICP4-binding sites with sequences significantly different from those at high-affinity sites. The role of low affinity sites remains unclear, but the interaction of ICP4 together with transcription factors (e.g., TFIID) at low-affinity sites may account for the transactivating function of ICP4. ICP4 is also present in transcriptional complexes containing ICP22, ICP27, and the CLOCK histone acetyl transferase.[40,82,154,175,228]

U_S1 (420 codons, IE, essential in cell type–dependent manner) encodes the ICP22 regulatory protein, which is required for efficient virus replication in experimental animal systems and some human and nonhuman cell lines but not in Vero, HeLa, or HEp-2 cells. The properties of US1.5 (described below) are similar to those encoded in the ICP22 C-terminal domain and are principally manifested by reduced accumulation of a subset of L genes and inhibition of ICP0-mediated gene expression. Deletion of the entire *U_S1* ORF, however, exacerbates the attenuation phenotype. ICP22 is extensively phosphorylated by viral and cellular kinases and nucleotidylylated by casein kinase II. ICP22 and UL13 are required for the activation of cdc2 and degradation of its partners, cyclin A and B. cdc2 subsequently acquires a new partner, the UL42 polymerase processivity factor, and together they recruit topoisomerase II to enable the expression of the subset of L genes exemplified by *U_L41*, *U_S11*, and *U_L38*. UL13 and ICP22 mediate the phosphorylation of the C-terminal domain of RNA polymerase II. In addition, ICP22 interacts with cdk9 in a US3 kinase–dependent fashion to phosphorylate RNA polymerase II. ICP22 is necessary and sufficient for reduced CD4+ T-cell clone proliferation and cytokine expression and also renders infected cells less susceptible to CD4+ T-cell–mediated lysis.[6,23,96,182,208,233,236,266]

$U_S1.5$ (250 codons, IE, nonessential) is expressed from a promoter and coding domain contained within the *ICP22* ORF, and the *ICP22* methionine 90 codon acts as the initiation codon of the *$U_S1.5$* ORF. Most of the known functions of ICP22 map to the *$U_S1.5$* ORF.[39,51,184,233]

U_S2 (291 codons, L, nonessential) encodes a tegument protein reported to interact with cytokeratin 18.[124,147]

U_S3 (481 codons, E/L, nonessential) encodes a multifunctional serine–threonine protein kinase (PK) that phosphorylates numerous viral and cellular proteins. Its substrate specificity is similar to that of cellular protein kinase A and Akt. It promotes egress of capsids from nuclei and is essential for blocking apoptosis induced by viral or exogenous inducers. A key function of the US3 PK is to alter the structure of nuclear membranes so as to enable budding of capsids into the lumen between the inner and outer nuclear membranes. US3 can also repress autophagy and stimulate viral protein synthesis. In addition, US3 functions along with gB to suppress CD1d antigen presentation and inhibit NK T-cell function during infection.[30,64,155,174,211,244,253,255]

$U_S3.5$ (405 codons, E/L, nonessential) encodes a truncated US3 PK enzyme initiated at the *U_S3* methionine 71 codon on an mRNA that is smaller than that encoding US3. US3.5 mediates the phosphorylation of HDAC1 but does not block apoptosis.[239]

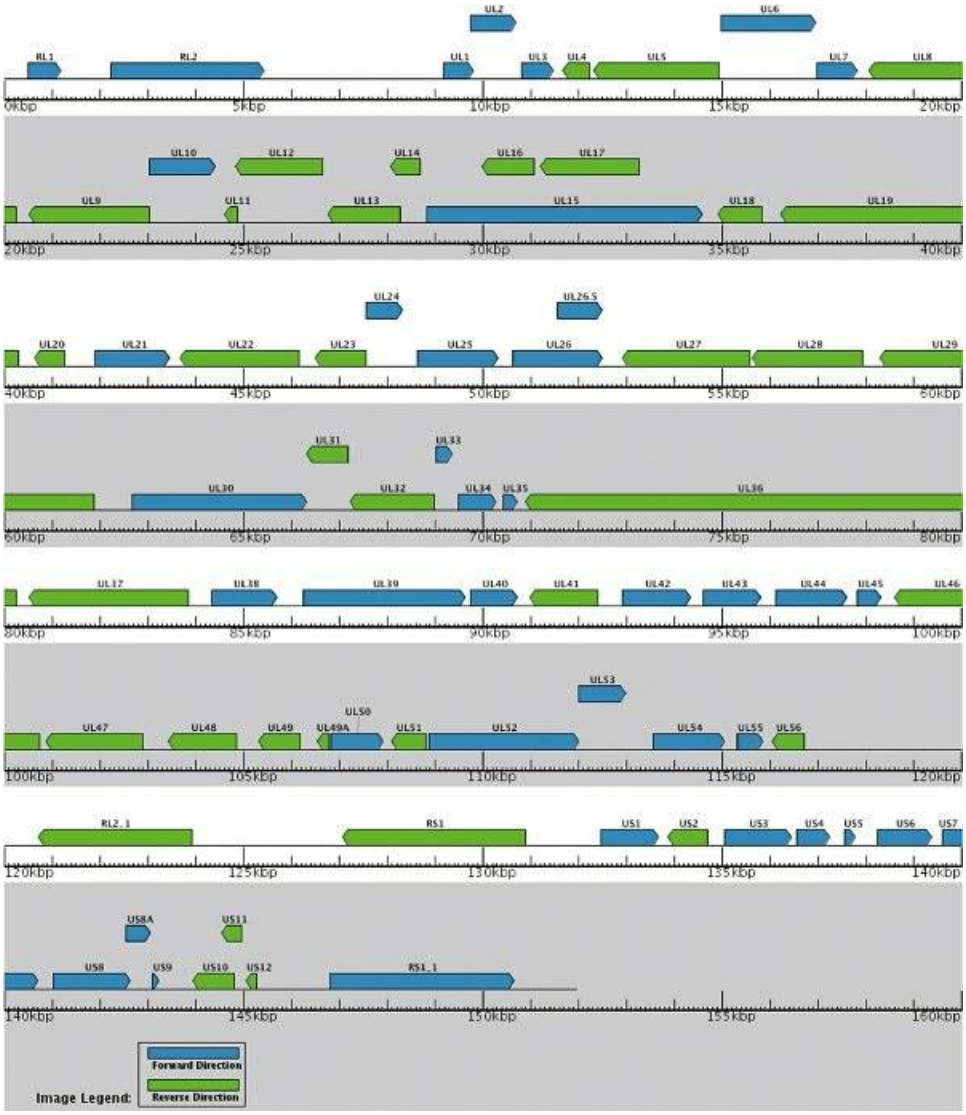
U_S4 (283 codons, E/L, nonessential) encodes glycoprotein G (gG). While the precise function of gG is not known, it has been shown to bind to chemokines and to heparin. The HSV-2 gG is larger than HSV-1 gG; thus, gG can be used to differentiate HSV-1 from HSV-2 antibody responses.[1,2,172,303]

U_S5 (92 codons, L, nonessential) encodes glycoprotein J (gJ), which blocks apoptosis induced by granzyme B, by Fas, or by infection of cells with glycoprotein D (*U_S6*)–minus viruses and other agents.[146,331]

U_S6 (394 codons, E/L, essential) encodes glycoprotein D (gD), a major determinant of viral tropism, that interacts with three different cellular receptors that promote entry: HVEM, nectin-1, and 3-O-sulfated heparan sulfate. Receptor binding causes conformational changes in gD that enable it to interact with and presumably activate the gH/gL heterodimer and subsequently gB to complete fusion of the viral envelope with the cell membrane.[45,49,67,68,86,104,121,166,209,269]

U_S7 (390 codons, E/L, nonessential) encodes glycoprotein I (gI), which forms a heterodimer with gE. The gE–gI complex constitutes a viral Fc receptor for monomeric IgG. The gE–gI complex localizes to basolateral surfaces in epithelial cells and facilitates virion transport and basolateral cell-to-cell spread of progeny virus in polarized cells, including neurons. US7 is dispensable in transformed cells, but critical in nontransformed cells.[136,148,149,183]

U_S8 (550 codons, E/L, nonessential) encodes glycoprotein E (gE), the major component of the viral F_C receptor. It is phosphorylated by the UL13 kinase and forms a heterodimer with gI (US7). US8 has been implicated in cell-to-cell spread and in virion transport in neurons and polarized epithelial cells. US8 also contributes to antihost defenses.[27,136,149,186,219,307]



$U_S8.5$ (159 codons, E/L, nonessential) encodes a nuclear protein of unknown function that localizes to nucleoli.[120,184]

U_S9 (90 codons, L, nonessential) encodes a type II membrane-associated protein. US9 may play a role in axonal spread.[184,205,220,273]

U_S10 (312 codons, L, nonessential) encodes a tegument phosphoprotein of unknown function.[184,220,320]

U_S11 (161 codons, L, nonessential) encodes an RNA-binding protein with multiple functions. It binds RNA in a sequence- and conformation-dependent fashion and binds dsRNA. US11 is a virion component and is in part responsible for the packaging of RNA in virions. Virion-associated US11 binds to ribosomes and localizes to polyribosomes. Late in infection US11 is also found in nucleoli. US11 blocks activation of protein kinase R and interacts with and blocks homeodomain-interacting protein kinase 2 (HIPK2).[53,122,157,184,240,250,265]

U_S12 (88 codons, IE, nonessential) encodes ICP47, which selectively binds to human TAP1/TAP2 and blocks the transport of antigenic peptides into the ER for presentation at the cell surface.[135,203,293,328]

SUPPLEMENTARY FIGURE 9.1 Map of the open reading frames on the HSV-1 genome. Forward denotes transcripts from left to right on the prototype arrangement of the HSV-1 genome, and reverse denotes transcripts from right to left on the prototype arrangement. Perspective

HISTORY

Herpes simplex viruses (HSVs) were the first of the human herpesviruses to be discovered and are among the most intensively investigated of all viruses. Attractions are their biologic properties, particularly their abilities to cause a variety of infections, to remain latent in their host for life, and to reactivate to cause lesions at or near the site of initial infection. They serve as models and tools for the study of translocation of proteins, synaptic connections in the nervous system, membrane structure, gene regulation, gene therapy, cancer therapy, and a myriad of other biological problems, both general to viruses and specific to HSV. For years, their size and complexity served as formidable obstacles to intensive research. More than 40 years passed from the time of their isolation until Schneweis demonstrated that there were two serotypes of HSV: HSV-1 and HSV-2. For a detailed history of HSV infections, the reviewer is referred to a prior edition of this chapter.

The field has grown enormously since the dawn of the molecular biology of HSV. Studies on HSV are elaborating “structure and function,” and its gene products have become powerful probes for the study of cellular metabolic pathways. Host factors crucial to virus multiplication and, potentially, to latency are being identified. Notably, only a fraction of viral gene products are extensively studied and for many products their reason for existence has not been established.

PATHOGENESIS

Entry Into the Host

Transmission of HSV is dependent on intimate, personal contact between a seronegative (susceptible) individual and someone excreting HSV from skin or mucosal surfaces. Virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. Following oropharyngeal infection, usually caused by HSV-1, the trigeminal ganglion becomes infected and harbors latent virus. Although HSV-1 efficiently reactivates from the trigeminal ganglion, it can also infect the genital tract and become latent in the sacral ganglion. Acquisition of HSV-2 infection is usually the consequence of transmission by genital contact. Virus replicates in the genital, perigenital, or anal skin sites with seeding of the sacral ganglia. By comparison, HSV-2 is more pathogenic in the genital track than HSV-1, causing more frequent recurrences and reactivation from sacral ganglia than HSV-1.

Site of Primary Replication

Accumulated clinical experience suggests that after primary infection, replication of virus at the portal of entry, usually oral or genital mucosa, results in infection of sensory nerve endings; virus is transported to dorsal root ganglia.[16,17,276] The more severe the primary infection, as reflected by the size, number, and extent of lesions, the more likely it is that recurrences will ensue. This notion is attributed to the large quantity of virus present when primary disease is extensive as compared with asymptomatic infections. Primary infection can spread beyond the dorsal root ganglia, thereby becoming systemic. For example, studies of children with primary gingivostomatitis demonstrated HSV DNA in the blood by polymerase chain reaction (PCR) in about one-third of patients. Similarly, 24% of adults with primary genital herpes had viral DNA detected by PCR in the blood.[140]

Cell and Tissue Tropism

Fundamental to disease pathogenesis is the propensity of virus to replicate at mucosal surfaces, to be transported to dorsal root ganglia, and to become latent. Although replication can sometimes lead to disease and infrequently result in life-threatening central nervous system (CNS) infection, the host–virus balance between latency and reactivation predominates. With reactivation, virus travels through peripheral nerves to epithelial cells, where it replicates and is detected at mucocutaneous sites. Vesicles or pustules that coalesce into painful mucosal ulcers are classic clinical signs, but the virus can also simply be excreted in the absence of symptoms (asymptomatic shedding).

The first exposure to either HSV-1 or HSV-2 results in primary infection. Patients with primary infection may present with multiple ulcerations of the oral or genital tract, as well as systemic symptoms such as fevers, chills, or myalgias and headaches. Reactivation of HSV is known as recurrent infection and clinically results in a limited number of vesicular lesions as occurs with HSV labialis or recurrent HSV genitalis or can result in asymptomatic shedding. An individual with preexisting antibodies to one type of HSV (i.e., HSV-1) can experience a first infection with the opposite virus type (i.e., HSV-2) at a different site. Under such circumstances, the infection is known as an initial infection rather than as a primary or recurrent infection. For example, an initial infection occurs in those individuals who have preexisting HSV-1 antibodies who then acquire a genital HSV-2 infection. HSV-1 antibodies do not protect against HSV-2 infection, but those with prior HSV-1 infection may have a less severe HSV-2 initial infection.[61] While not proven, prior HSV infections may ameliorate subsequent infection with different HSV types. Because many individuals are infected with HSV and do not experience a primary infection, the first recurrence has been identified as first-episode infection. Reinfection with a different strain of HSV can occur, but it is uncommon in the normal host.[122]

Pathology

The pathologic changes induced by HSV replication are similar for both primary and recurrent infection but vary in the extent. The histopathologic characteristics of HSV skin lesions are shown in Figure 10.1,[236] representing a combination of virus-mediated cell death and associated inflammation. Viral infection induces ballooning of cells and the appearance of condensed chromatin within the nuclei, followed by subsequent degeneration of the cellular nuclei,

generally within parabasal and intermediate cells of the epithelium. Cells lose intact plasma membranes and form multinucleated giant cells. With cell lysis, clear (referred to as vesicular) fluid containing virus appears between the epidermis and dermal layer. The vesicular fluid contains cell debris, inflammatory cells, and, often, multinucleated giant cells. In dermal substructures, there is an intense inflammatory response with infiltration of CD4+ and CD8+ T cells, usually in the corium of the skin. With healing, the vesicular fluid becomes pustular with the recruitment of inflammatory cells, and then it forms a wet and painful ulceration. The dry crust, or healing phase, is characterized by formation of a scab and typically occurs in the absence of viral shedding. Scarring is uncommon but has been noted in some patients with frequent recurrences. When mucous membranes are involved, vesicles are less likely to be prominent. Instead, shallow ulcers are more common because the vesicles rapidly rupture as a result of the very thin cornified epithelium.

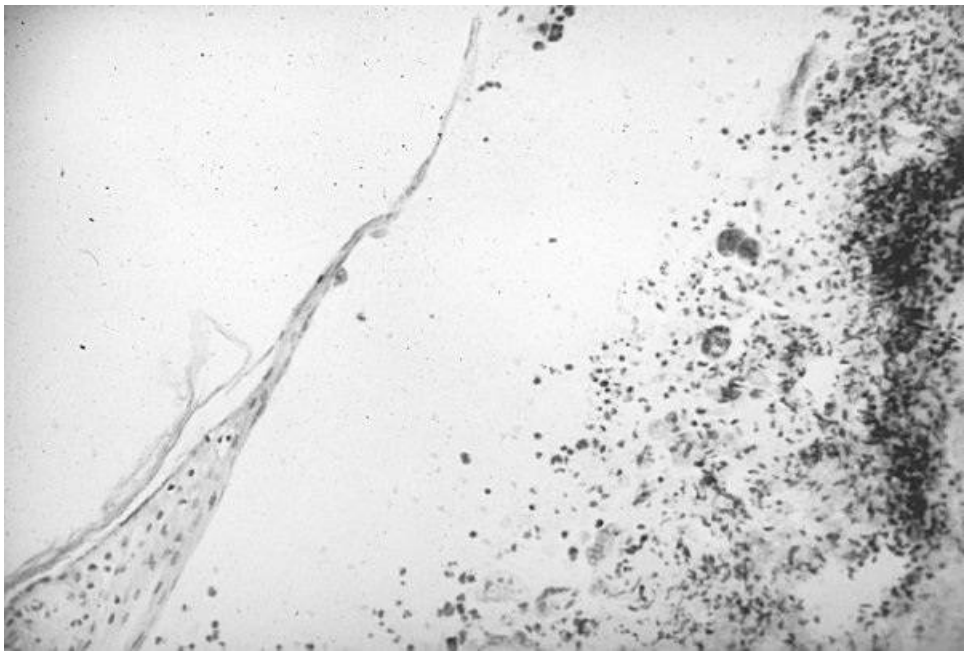

FIGURE 10.1 Histopathology of herpes simplex virus infection.

Vascular changes in infected tissue include perivascular cuffing and areas of hemorrhagic necrosis. These histopathologic findings become particularly prominent when organs other than skin are involved, for example, HSV encephalitis or disseminated neonatal HSV infection. In such cases, widespread areas of hemorrhagic necrosis, mirroring the area of infection, are prominent. With HSV encephalitis, oligodendrocytic involvement and gliosis are common, as is astrocytosis, but these changes develop late in the disease course. Local lymphatics can show evidence of infection with intrusion of inflammatory cells, draining infected secretions from the area of viral replication. The intensity of the inflammatory response is significantly less with recurrent disease. As host defenses develop, an influx of mononuclear cells is detected in infected tissue.

MODELS OF DISEASE PATHOGENESIS

Animal models allow study of the pathogenesis of infection but with fundamental problems. The animal species (indicative of susceptibility), virus type, route of infection, state of immune competence, and specific viral strain all influence disease pathogenesis. Both HSV-1 encephalitis (virulence) and latency models have been established in animals following inoculation by the eye route. However, the end points of virulence and latency do not routinely correlate with human disease. After ocular inoculation by corneal scarification, replication of virus in the eye peaks within 48 hours and declines over the next 6 days. Virus appears in the trigeminal ganglia approximately 1 day after inoculation, with peak replication occurring 4 to 6 days later. If sufficient quantities of virus and/or a virulent strain of virus are inoculated onto the eye, encephalitis follows virus replication within the trigeminal ganglia.

For HSV-1 cutaneous infections, mice (particularly the hairless mouse)[298] and rabbits or guinea pigs with abraded or punctured skin are used to study replication and disease pathogenesis as well as to evaluate antiviral therapies. The hairless mouse, guinea pig, and rabbit are all artificial models of human cutaneous infections, particularly for recurrent infections of humans.

HSV-2 mucosal infections have been studied most extensively in an intravaginal guinea pig model. Both HSV-1 and HSV-2 have been used in this model. These animals tend to experience continual recurrences of lesions, but retrieval of HSV from these lesions is variable. The guinea pig genital infection model has been used extensively in the assessment of vaccines and antiviral. The development of an intravaginal infection in rhesus macaques in which HSV-2 DNA is detected in sacral ganglia and spontaneous vaginal shedding is found up to 40 days after inoculation may also be useful to study interventions to prevent HSV-2 infection.[163]

Models of life-threatening disease include the intranasal inoculation of HSV-1 or HSV-2 in young (3-week-old) Balb/ C mice, resulting in CNS and visceral (usually lung) disease (mimicking neonatal HSV infection). However, inoculation of older mice with similar quantities of either virus type may fail to cause disease, or, if it does lead to disease, it might be encephalitis but not multiorgan disease. Intracerebral inoculation of virus provides an unnatural route of infection even for the study of antiviral therapeutics; however, it is used to screen new drugs.

Accurate and predictive models of human HSV encephalitis have been described using rabbit[250,251] and mouse models. The resultant disease leads to focal localization of infection in the rabbit brain, as compared with diffuse pancortical infection of the mouse brain. Virus is inoculated directly into the olfactory bulb or upon abraded nasal epithelium of the rabbit over the nerves from the olfactory bulb.[278]

Human models of both labial and genital herpes have been reported. Induced reactivation of HSV labialis occurs by exposure of the vermilion border of the lip of seropositive individuals to UV light.[237] The resulting lesions and course of infection are similar to those that occur naturally. Lesions develop in approximately 70% of UV-exposed volunteers after approximately 3 days. This model has been exploited for the evaluation of antiviral therapies.[237,238] Similarly, UV exposure of the buttocks and thigh in HSV-2–infected individuals results in reactivation in

approximately 35%, and the incubation period is longer, about 5 days.[238]

IMMUNE RESPONSE

Primary Immune Responses

The natural history of HSV infections is influenced by both innate and induced host defense mechanisms. Historically, animal models provided the majority of data that address the relationship between host defense and disease pathogenesis. Host genetic background, innate immune responses, macrophages, natural killer cells, specific T-cell subpopulations, specific antibodies, and cytokine responses are important host defenses against HSV infections. Human studies have been insightful.[273] Local control mechanisms of viral spread aim to neutralize the infectious agent and lead to viral clearance. Following primary HSV infection, the initial, local immunological responses involve both nonspecific defense mechanisms, namely interferons (IFNs) alpha and beta, activated natural killer (NK) cells, and macrophages, and HSV-specific responses, such as cytotoxic T cells (CTLs).[223] The role of T cells has attracted increasing attention, particularly as it relates to vaccine development, particularly for therapeutic, as opposed to prophylactic, vaccines.[111,116,142,156,224,241]

In response to a viral infection, the initial cellular response is synthesis and secretion of type I IFNs (α and β). IFNs induce an antiviral state in infected and surrounding cells. The antiviral activity is modulated in part by IFN-mediated activation of cellular enzymes such as 2′-5′ oligoadenylate synthetase (2′-5′ AS) and double-stranded RNA-dependent protein kinase, as well as intracellular signaling molecules through the activation of the JAK/STAT kinase pathway. More specific to HSV infection, IFN-α appears to inhibit immediate-early (IE) gene expression (see Chapter 9 for HSV cycle of replication). Thus, the antiviral mechanisms directly affect transactivation of the IE responsive element necessary for synthesis of viral proteins.

In addition to antiviral activity, IFNs are potent immunomodulators. As such, they mediate macrophage and NK cell activation, activate CTLs, induce MHC class I and MHC class II antigens, stimulate cytokine secretion, and induce local inflammation. IFN gamma may aid the control of HSV infection. Evidence that γδ T cells, NK cells, CD4+ T cells, and possibly neurons produce IFN-γ and TNF in response to HSV infection in the nervous system has been reported. IFN-γ down-regulates priming of CD4+ Th2 cells, which are responsible for inducing Ig isotype B cell switching from IgA to IgG, thereby exerting a major effect on humoral immune responses.[108]

NK cells lyse pathogen-infected cells before virus-specific T-cell immunity is generated and constitute first-line defense against infection. *In vitro* and *in vivo* experiments have demonstrated that NK cells protect from HSV challenge in a murine model. Severe herpetic disease has been correlated with low *in vitro* NK activity in newborns, as well as in a patient lacking NK cells.[28] Other mononuclear cells, such as macrophages, are recruited to the site of infection and, upon activation, release immune cell mediators such as TNF and interleukins. Macrophages play a major role in mediating antibody-dependent cellular cytotoxicity (ADCC) for viral clearance and antigen presentation.

Dendritic cells (DCs) travel from mucosal or skin areas of infection and prime antigen-specific, naive T cells in draining lymph nodes (DLN). Studies using HSV-1 footpad infection and fractionating DC subpopulations in the DLN show that classic, CD8α+ dermal DC, rather than specialized epidermal Langerhans cells (LCs), are able to prime naive $CD8^+$ T cells.[19] In the case of vaginal HSV-2 infection, dermal DCs rather than LCs again seem to be the physiologically active cell population in a similar DLN investigation.[351] LCs are able to present HSV antigens to memory HSV-specific T cells and may participate in primary or recurrent immune reactions. Plasmacytoid DCs (pDCs) react to HSV by producing IFN-α.[266] pDCs are recruited to sites of infection, participate in viral clearance, and express relevant Toll-like receptors (TLRs) including TLR 7, 8, and 9.[170,245] Low pDC number or poor pDC reactivity is associated with severe human HSV infection.[68]

As infection progresses, virus-specific immune responses are detected. On days 4 and 5 postinfection, HSV-specific $CD4^+$ Th1 lymphocytes are detected in genital lymph nodes and in smaller numbers in peripheral blood; they can subsequently be found in the genital mucosa. $CD8^+$ responses also occur quite quickly in the mouse.[196]

Humoral immune responses follow initial HSV infection. The predominant mucosal antibodies are of the IgA isotype, being secreted by plasma cells. Antibodies can be detected as early as day 3 following infection, peaking within the first 6 weeks after disease onset, and are followed by appearance of IgG1 and IgG3 subclasses of antibodies, which are typically found following viral infections. HSV-specific IgA antibodies are present for at least 6 weeks, gradually decreasing to undetectable levels. IgM-secreting B cells have also been detected in secretions of the female genital mucosa. Analyses of antibody responses by immunoblot and immunoprecipitation to infected cell polypeptides have been correlated with the development of neutralizing antibodies.[356] Soon after the onset of infection, antibodies to structural proteins are followed by those directed against gD, gB, ICP-4, gE, gG-1 or gG-2, and gC. Both IgM and IgG antibodies can be detected, depending on the time of assessment after infection.

Recurrent HSV Infection

Early on, cytokine production was incriminated in the pathogenesis of frequently recurrent genital and labial HSV infection. A decrease in both IFN-γ production and NK cells has been reported during the disease prodrome.[66] HSV-specific CD8 and CD4 T cells infiltrate latently infected trigeminal ganglia in mice and humans,[132,302] acting via IFN-γ. Neuronal loss is not seen clinically, and inhibitory receptor–ligand pairings can be documented in the ganglia that may modulate their cytotoxic activity.[283] HSV-2–specific $CD4^+$ and $CD8^+$ T cells localize to sites of recurrent HSV-2 infection and to the cervix.[144,145] Using *in situ* staining, HSV-2–specific CD8 CTLs persist at the epidermal/dermal junction adjacent to sensory nerve endings.[139,354] In human genital tissue, tissue resident memory CD8+ T cells remain at the dermal–epidermal junction in the mucosa after the resolution of lesions and are thought to play a role in immune surveillance.[355] Repeated subclinical episodes of HSV excretion may be a source of antigenic stimulation leading to long-term HSV-specific immune memory. In recurrent HSV-2 infections, NK and HSV-specific $CD4^+$ cells are detected earlier than $CD8^+$ cells in genital lesions.[108] $CD4^+$ T cells and, more recently, $CD8^+$ T cells have been highlighted as major mediators of viral clearance from mucocutaneous lesions in recurrent episodes.[144,223] Low IFN-γ titers in vesicle

fluid have been associated with a shorter time to the next recurrence in patients with frequent recurrences. T-cell proliferation is decreased in these patients in comparison to patients with less-frequent recurrences. IFN-γ is associated with viral clearance from mucocutaneous sites, whereas altered cytokine production appears to correlate with recurrence.

A shorter duration of viral shedding occurs in women with recurrent genital herpes who have detectable secretory IgA in vaginal secretions. IgA, IgG1, and IgG3 antibodies develop in the sera of all patients with recurrent HSV-2 episodes, while IgM and IgG4 antibodies were detected in 70% to 80% of these patients.

Persistence of Immune Responses

The host's immune responses persist and partially control HSV disease; recurrent episodes are generally less severe and of shorter duration over the years, perhaps due to progressive enhancement of long-term immunity.[21] Differences in host immune response between episodes of symptomatic versus asymptomatic shedding have not been detected. Furthermore, some degree of cross-protection exists between HSV-1 and HSV-2, as best evidenced by partial protection of newborns by maternal antibodies.[327] HSV-specific T-cell infiltrates appear in lesions during early disease resolution.[223]

Studies indicate that persistent cell-mediated immune responses are more important than humoral immune responses in disease resolution.[26] NK cells, macrophages, and T lymphocytes as well as cytokines such as IFN-α and -γ, IL-2, and IL-12 all contribute to resolving HSV disease.[234] HSV-specific $CD4^+$ and $CD8^+$ cells are detected in lesions from recurrent episodes, suggesting a role in controlling HSV disease.[144,223] By contrast, agammaglobulinemic patients do not experience more severe or more frequent herpetic recurrences than the general population.[151] Several vaccine trials have demonstrated that the presence of neutralizing antibodies, albeit of varying titers, to HSV-2 glycoproteins do not provide protection against HSV-2 infection or disease.[275] However, a prophylactic vaccine study did suggest benefit for prevention of genital HSV-1 infection,[18] implying that with selection of the correct antigen and adjuvant, antibody responses may be protective against HSV infection.

Relationship Between Immune Response and Disease

Humoral immunity has been evaluated exhaustively in disease pathogenesis. In animal models, polyclonal antibodies have been used to alter disease lethality, particularly in the newborn mouse, or to limit progression of both neurologic and ocular disease. Monoclonal antibodies to selected specific infected cell polypeptides, especially the envelope glycoproteins gB and gD, confer protection from lethality.[73,232] gD2 is a known target of neutralizing antibodies, ADCC and CD4 and CD8 T-cell mediated responses[102,120,192,346]: thus, this antigen has been a prime component of subunit vaccines.

Efforts to correlate the frequency of recurrences with immune responses have failed to identify any specific humoral response to specified polypeptides.[23,126] Thus, further efforts have focused, in large part, on cell-mediated immune responses. As noted, lymphocyte blastogenic responses are demonstrable within 4 to 6 weeks after the onset of infection and sometimes as early as 2 weeks.[63,214,231,279] These responses are typically mediated by CD4 T cells. With recurrences, boosts in blastogenic responses occur; however, these responses, as after primary

infection, decrease with time. Nonspecific blastogenic responses do not correlate with a history of recurrences. HSV-1 and 2 are cross-reactive in these assays at the whole virus levels, although individual T-cell clonotypic responses can be either type common or type specific.[140]

Lymphokine production has been incriminated in the pathogenesis of frequently recurrent genital and labial HSV infection. A decrease in both IFN-γ production and NK has been reported during disease prodrome.[66,208,260] No reproducible data confirm these observations. The relevance of lymphokine expression in vaccine development can be assessed only in prospective field trials.

Host response of the newborn to HSV must be defined separately from that of older individuals. Immaturity of host defense mechanisms is a cause of the increased severity of some infectious agents in the fetus and the newborn. Factors that must be considered in defining host response of the newborn include the mode of transmission of the agent (viremia vs. mucocutaneous infection without blood-borne spread) and time of acquisition of infection. Transplacentally acquired neutralizing antibodies either prevent or ameliorate infection in exposed newborns as does ADCC.[148,226,343] Preexisting antibodies, indicative of prior infection, significantly decrease the transmission of infection from pregnant women to their offspring,[32] contributing to the rationale for the development of an HSV vaccine.

Infected newborns produce IgM antibodies specific for HSV within the first 3 weeks of infection. These antibodies increase rapidly in titer during the first 2 to 3 months and may be detectable for as long as 1 year after infection. The most reactive antigens are the surface viral glycoproteins, particularly gD. Humoral antibody responses have been studied using immunoblot technology, resulting in patterns of response similar to those of adults with primary infection.[127,279] The quantity of neutralizing antibodies is lower in babies with disseminated infection.[279,343]

Cellular immunity has been considered to be important in the host response of the newborn. The T-lymphocyte proliferative responses to HSV infections are delayed in newborns compared to older individuals.[279] Most infants have no detectable T-lymphocyte responses to HSV 2 to 4 weeks after the onset of clinical symptoms.[214,230,279] The correlation between these delayed responses may be of significance in evaluating outcome to neonatal HSV infection. Specifically, if the response to T-lymphocyte antigens in children who have disease localized to the skin, eye, or mouth (SEM) at the onset of disease is significantly delayed, disease progression may occur at a much higher frequency than babies with a more appropriate response.[54,279]

Infected newborns have decreased production of IFN-α in response to HSV when compared to adults with primary HSV infection.[279] Lymphocytes from infected babies have decreased responses to IFN-γ during the first month of life.[37,279] In general, the newborn has poorer immune responses than older children and adults. Antibodies plus complement and antibodies mixed with NK, monocytes, macrophages, or polymorphonuclear leukocytes will lyse HSV-infected cells *in vitro*. ADCC is an important component of the development of host immunity to infection.[146] However, the total population of NK of the newborn seems to be lower than that found in older individuals and monocytes and macrophages of newborns are not as active as those of adults.[106,147,167,294] These findings are supported by animal model data.

Host Susceptibility

Clinically, elegant studies have identified several inborn errors involving single genes among children with HSV-1 encephalitis (HSE) and some adults. Single gene errors in the Toll-like receptor 3 (TLR3) signaling pathway have been associated with forebrain HSV-1 encephalitis (HSE), including *TLR3, TRIF, UNC93B1, TyK2, TRAF3, IRF3, and TBK1*.[194,244,349,350] Studies in two children, one with a loss of a functional mutation in nuclear factor-kB essential modulator (*NEMO*) and the other with an autosomal recessive mutation in signal transducer and activator of transcription 1 (*STAT-1*) genes, both encoding proteins essential for IFN production, developed HSE and *in vitro* studies showed that their cells had impaired interferon production upon exposure to HSV-1.[10,78] These seminal observations demonstrate the importance of the TLR3 and interferon pathways to contain HSV replication in the CNS.

Other studies of genetic susceptibility have been reported. Autosomal recessive DRB1 (an RNA lariat debranching enzyme) deficiency has been associated with brainstem HSV-1 infection.[348] Exome analysis of a cohort of patients with forebrain HSE has also revealed rare autosomal dominant variants in the small nucleolar RNA (*snoRNA*)-encoding gene, *snoRA31*, that are associated with increased HSV-1 replication in *in vitro* studies of cortical CNS neurons. The function of *snoRA31* is unknown *in vivo*, but in cortical neurons, it is a cell-intrinsic antiviral factor and is not dependent on the TLR3 pathway, suggesting a novel susceptibility mechanism for HSE.[154] In addition to identifying genetic susceptibility to HSE, these studies of rare genetic variants associated with HSE have greatly enhanced our understanding of HSV-1 pathogenesis in the CNS.[45,244,349] Such severe infections have been identified in severe combined immunodeficiency syndrome in the presence of a DOCK8 mutation.[347] Extensive studies of individuals with recurrent herpes labialis found an association with C21orf91 genotypes correlating with increased susceptibility.[152] Likely, further genetic associations will be identified.

EPIDEMIOLOGY

The development of serologic assays in the mid-1970s that reliably differentiated between HSV-1 and HSV-2 infection revolutionized the ability to understand the epidemiology of HSV infections.[200]

Orolabial HSV Infections: Primary and Recurrent

Humans are the sole reservoir for transmission of HSV to other humans. Virus is transmitted from infected to susceptible individuals during close personal contact. There is no seasonal variation in the incidence of infection. Because infection is both rarely fatal and is chronic, people have the potential to transmit HSV throughout their life span. As a result, HSV is one of the most prevalent infections worldwide. In 2012, 3.7 billion people aged 0 to 49 years were estimated to be infected with HSV-1, for a prevalence of 67% across all ages.[165] In addition, the annual incidence of HSV-1 infection is high, with an estimated 118 million new infections in 2012. Geographic location and age are primary factors that influence HSV-1 seroprevalence. For example, the worldwide prevalence of HSV-1 is estimated to increase from 27% among those aged 0 to 4, to 71% at age 15 to 19, and 79% at age 45 to 49. These estimates indicate that HSV-1 is most commonly acquired in childhood, likely through oral exposure, but acquisition can

continue as people age. The prevalence of HSV-1 infection is similar among men and women. The highest HSV-1 seroprevalence rates are found in Africa (87% for both men and women), the Eastern Mediterranean (75% among men and women), and the Western Pacific (73%), with the lowest rates in the Americas (49% among women, 39% among men). Estimates are limited by small sample sizes and lack of data in some regions.

In the United States, periodic seroprevalence studies among those aged 14 to 49 have been performed in the National Health and Nutrition Examination Surveys (NHANES) since 1977,[84,200] using the same serologic assay. Between 1999–2000 and 2015–2016, the HSV-1 seroprevalence declined by over 11% to 48.1% in 2015–2016 (Fig. 10.2).[183] Between 1999 and 2010, the most substantial decline was found among those aged 14 to 19 (39% to 30%, a 23% decrease). In the United States, higher rates of HSV-1 seroprevalence are found among racial and ethnic minority groups compared to white populations. These associations are likely due to social factors such as lower household income and education and increased crowding,[31,71] rather than biologic factors. The declining HSV-1 seroprevalence is thought to be secondary to improvements in hygiene and decreased crowding, resulting in less oral HSV-1 transmission during childhood. Paradoxically, decreased HSV-1 acquisition during childhood may place adolescents at increased risk for genital HSV-1 infection when they become sexually active (see below). Similar findings have recently been observed in several European countries.[176,334]

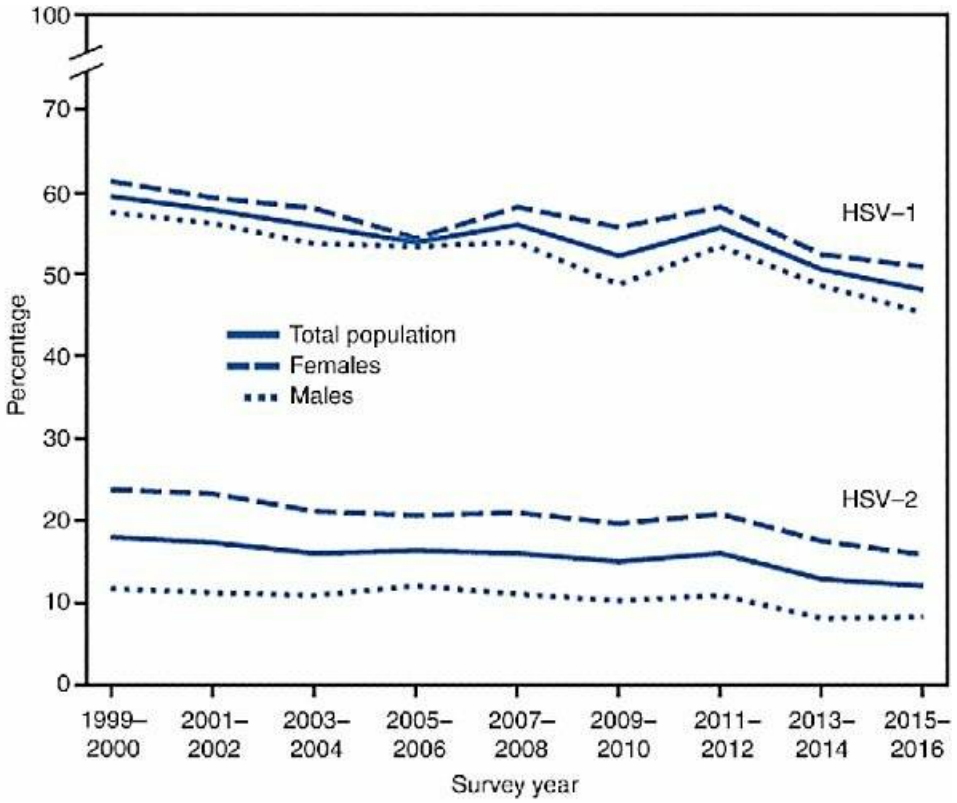

FIGURE 10.2 QuickStats: Age-Adjusted Trends in the Prevalence of Herpes Simplex Virus Type 1 (HSV-1) and Herpes Simplex Virus Type 2 (HSV-2). From QuickStats: Age-adjusted trends in the prevalence of Herpes Simplex Virus Type 1 (HSV-1) and Herpes Simplex Virus Type 2 (HSV-2) among adolescents and adults

aged 14-49 Years - United States, 1999-2000 through 2015-2016. *MMWR Morb Mortal Wkly Rep* 2018;67(6):203. doi: http://dx.doi.org/10.15585/mmwr.mm6706a7.

Following the association of HSV and gingivostomatitis,[39] virologic screening was used to study the epidemiology and natural history of infection. Primary infection led to the shedding of virus in mouth and stool and from the former site for as long as 23 days (average, 7 to 10 days).[2] Neutralizing antibodies appeared between 4 and 7 days after the onset of disease and peaked in approximately 3 weeks. Virus was isolated from the saliva of asymptomatic children in approximately 20% of children 7 months to 2 years of age.[36] Virus shedding in children less than 6 months of age was uncommon. In older children, 3 to 14 years of age, asymptomatic shedding was documented in 18%. Retrieval of infectious virus decreased with advancing age, being only 2.7% in individuals over 15 years of age. These frequencies of shedding are similar to contemporary cross-sectional surveys, ranging from 2% to 5%. Application of PCR demonstrates higher frequencies of shedding and for intermittent periods.

In prospective studies of HSV-1 acquisition, evidence of oral herpetic infection was found in approximately 13% of children over a 10-year period. Children 1 to 2 years of age were most commonly infected, accounting for over half of all cases.[70,236] Most children experienced asymptomatic infection, accounting for over 65% of the seroconversions.[3,49]

In summary, these studies demonstrate that HSV-1 is acquired during childhood and adolescence, particularly in settings with greater crowding and lower socioeconomic status, and that in higher income settings there has been a significant decrease in seroprevalence over time. The frequency of direct person-to-person contact, indicative of crowding encountered with lower socioeconomic status, appears to be the major mediator of infection.

The largest human reservoir of HSV-1 is latent infection in the trigeminal ganglia, which reactivates leading to recurrent herpes labialis. Studies performed to assess the frequency and severity of recurrent infection in the immunocompetent host are limited. A positive history of recurrent herpes labialis was noted in 38% of 1,800 graduate students.[263,264] Lesions occurred at a frequency of one per month in 5% of students and at intervals of 2 to 11 months in 34% of the infected students. Recurrences of one per year or less often were found in 61%.[87,262]

Recurrent viral shedding occurs in the absence of clinical symptoms. Asymptomatic excretion of HSV in healthy children occurs in about 1% to 5%[92.318] Nearly 1% of pregnant women and nursery personnel excrete HSV at any time, providing a source of virus for transmission to the newborn. Asymptomatic shedding also occurs in nearly one-third of seropositive transplant recipients.[49,215,216]

Genital HSV Infections: Primary and Recurrent

Genital herpes can be caused by either HSV-1 or 2. Because infections with HSV-2 are usually acquired through sexual contact, antibodies to this virus are rarely found before the onset of sexual activity.[337] An increasing proportion of genital herpes is attributable to HSV-1.[79,128,335] Worldwide, there are estimated to be 140 million genital HSV-1 infections in persons aged 15 to 49.[165] Over 50% of first-episode genital herpes at some sexually transmitted disease (STD) clinics are caused by HSV-1.[67,79,337] In a recent prophylactic vaccine study enrolling sexually

active HSV-1/HSV-2 seronegative women, the rate of infection for HSV-1 was more than twice that of HSV-2.[22] Modeling studies suggest that genital acquisition of HSV-1 will continue to increase over time, as oral acquisition declines.[12] The contribution of HSV-1 to overall genital infection cannot be defined by seroprevalence. Antibodies to HSV-1 do not distinguish between oral and genital infection. The distinction in virus type is not insignificant; genital HSV-1 infections are usually both less severe clinically and less prone to recur.[233]

In 2012, worldwide estimates of HSV-2 seroprevalence revealed that 11.3% of people aged 15 to 49 years were HSV-2 seropositive (an estimated 417 million people),[165] with an additional 19.2 million people with incident infection that year. In contrast to HSV-1, HSV-2 seroprevalence is about twofold higher in women compared to men.[165] Similar to HSV-1 infection, HSV-2 seroprevalence increases with age, with an estimated 4.6% seroprevalence at age 15 to 19, increasing to 17% prevalence at age 45 to 49. The burden of HSV-2 infection is widely variable throughout the world, with an estimated 134.9 million people infected in the WHO African Region and 81.2 million in the WHO Western Pacific Region, as compared to only 24.9 and 31.4 in the WHO Eastern Mediterranean Region and WHO European Region, respectively. In the United States, the most recent NHANES survey in 2015–2016 showed an age-adjusted HSV-2 seroprevalence of 12.1% among those aged 14 to 49, a significant decrease from a high of 21.9% in 1988–1994 and from 18.0% in 1999–2000 (Tables 10.1 and 10.2 and Fig. 10.3).[183] In parallel, one study in Seattle, WA, found a significant decline in HSV-2 seroprevalence rates among pregnant women between 1989–1999 and 2000–2010, decreasing 46%, from 30.1% to 16.3%.[72] However, a NHANES study among women between 1999 and 2014 found stable HSV-2 seroprevalence among pregnant women and nonpregnant sexually active women.[84,183,219,338] Paralleling global estimates, United States seroprevalence increases with age, being 2-fold higher in women compared to men[81]. Antibodies to HSV-2 are virtually nonexistent in nuns, and HSV-2 seroprevalence increases with increasing numbers of lifetime sexual partners (Fig. 10.4),[338] indicating that sexual exposure is a significant risk factor for acquisition of HSV-2 infection. Although HSV-2 seroprevalence rates are decreasing for all racial/ethnic groups in the United States, racial disparities persist, with a 3.3-fold higher seroprevalence rate in black compared to white U.S. women in 2007–2010,[81] and worsening disparities seen in 2015–2016. Importantly, in 2007–2010, 87.4% of HSV-2 seropositive persons reported no history of an HSV-2 diagnosis.[81] NHANES last explored the association of HSV-2 seroprevalence with sexual behavior in 2001–2006. Among women who have sex exclusively with women, HSV-2 seroprevalence rates are relatively low (8.2%).[340] Men who have sex with men have a similar HSV-2 seroprevalence to men who have sex exclusively with women.[339] In 2003–2006, HSV-2 seroprevalence was significantly higher among person with HIV infection compared to the general population (59.7% vs. 19.2%).[218] HSV-2 serologic trends in the United States have been reported but require updating.[53]

TABLE 10.1 Herpes simplex virus type 2 seroprevalence[a] among persons aged 14 to 49 years, by selected characteristics—National Health and Nutrition Examination Survey, United States, 2005–2008

Characteristic	Overall			Female			Male		
	Sample Size	Sero-prevalence (%)	(95% CI[b])	Sample Size	Sero-prevalence (%)	(95% CI)	Sample Size	Sero-prevalence (%)	(95% CI)

Vaccine and antiviral studies have defined the risk of transmission.[64,158] First, women remain more susceptible to HSV infection than men. Second, transmission usually occurs from an asymptomatic individual and does so in over 70% of cases. Third, overall, the annual rate of transmission is approximately 4% to 5% per annum. The rate of acquisition by women is about 8% annually, whereas it is lower for men, namely 2%.

As with HSV-1 infections of the mouth, HSV-2 can be shed from the genital tract in the absence of symptoms after primary, initial, or recurrent infection.[295,312] Viral transmission most commonly occurs during episodes of asymptomatic shedding.[187] Initial studies used viral culture to detect HSV-2 from patient-collected swabs to determine rates of asymptomatic shedding.[141,312] Using HSV PCR to study HSV-2 shedding rates,[306] persons with symptomatic HSV-2 infection shed virus from the genital tract on 20% of days, while persons with asymptomatic HSV-2 shed on 10% of days.[295] Shedding rates are similar in men and women, and among those with and without HSV-1 coinfection.[295] Shedding episodes are short, lasting a median of 13 hours.[177] Viral shedding associated with symptomatic genital ulcer disease has higher shedding rates.[1] As a result, the viral shedding rate has been used as a marker of viral suppression in studies of novel HSV therapeutics.[1] Shedding of virus occurs more frequently in the first year following genital infection than in subsequent years,[311] but shedding persists for years or even decades after acquiring the virus.[221] Detailed anatomic surveys of genital tract shedding have also shown that shedding occurs throughout the genital tract on days with shedding, rather than being localized to a specific anatomic area.[124] These studies have helped redefine latency by demonstrating viral reactivation at the neuronal level is more permissive than realized.[121] Mathematical modeling studies suggest that HSV is frequently introduced into the genital tract in small quantities from neurons and that the immune response to infected epithelial cells is a key determinant of shedding and lesion frequency.[248,249]

The sacral ganglia contain the largest reservoir of HSV-2, and reactivation leads to recurrent HSV-2 infection. A recurrence is associated with a shorter duration of viral shedding and fewer lesions. The frequency of recurrences varies somewhat between males and females, with calculations of 2.7 and 1.9 per 100 patient-days, respectively. Detecting HSV by both culture and PCR, viral excretion was documented at 6% annually, but PCR detection of viral DNA occurred on 18% to 25% of days—a three- to fourfold increase over viral culture. Notably, there was an association between detection of virus by PCR (but not by culture) and person-to-person transmission.[295,312]

Several studies have reported a frequency of recurrence as high as 60%. Broadly, nearly 90% of HSV-2–infected patients will have one or more recurrences per year, 38% greater than 6 recurrences and 20% greater than 10 recurrences[20] HSV-1 infection recurs less frequently than

does HSV-2 infection.[20,155]

HSV and HIV Interactions

HSV-2 infection, by nature of being an ulcerative disease, is associated with increased risk of acquisition of both human immunodeficiency virus type 1 (HIV-1) and human T-cell lymphotropic virus type 1 (HTLV-1) by two- to threefold,[86,309] in particular in regions where HIV and HSV-2 are both epidemic (Fig. 10.5). For example, in a prospective cohort study in Kenyan women between 1993 and 2012, prevalent HSV-2 infection was associated with 2.5-fold increased risk of acquiring HIV infection. When comparing the population attributable risk percentage (PAR%), the PAR% for prevalent HSV-2 infection was 48.3% and was stable over time, demonstrating the sustained impact of HSV-2 infection on the HIV epidemic. A systematic review and meta-analysis estimated a threefold increased risk of HIV acquisition among HSV-2 seropositive persons aged 15 to 49 in 2016, for an overall PAR% of 29.6%.[166] Not surprisingly, the PAR% was highest in settings with the highest HSV-2 seroprevalence, such as the WHO Africa region, and in women, who have a higher HSV-2 seroprevalence than men. HSV-2 infection is associated with an increased number of HIV target CCR5+CD4+ T cells in the female genital tract.[258,259] Similarly, when examining foreskin samples obtained after male medical circumcision, increased numbers of CD4+ T cells were found in the foreskin of HSV-2 seropositive men[118,119] compared to HSV-2 seronegative men, and foreskin inflammation was greatest among men with HIV and HSV-2 coinfection. At the site of a recurrent genital HSV-2 ulcer, increased numbers of CCR5+CD4+ target cells permissive for HIV infection persist[353] for weeks after the ulceration has healed. In addition, genital ulcer disease is associated with increased risk of HIV transmission to HIV seronegative partners. Unfortunately, studies of suppressive acyclovir among HSV-2 seropositive persons to prevent acquisition[47] or transmission of HIV infection did not provide evidence of effectiveness.[48] Furthermore, this study showed that acyclovir blood levels are lower in African subjects than in non-African subjects.[168]

Molecular Epidemiology

HSV molecular epidemiology has blossomed with the advent of high throughput (next-generation) sequencing. While HSV is a large (152 kB) and challenging virus to sequence given its high GC content and large repeat regions,[217] optimization of HSV sequencing has led to important insights into molecular epidemiology. Initial efforts utilized viral cultures of both laboratory strains and clinical isolates of HSV-1 for sequencing.[58,285] These studies revealed both heterogeneity between laboratory and clinical strains as well as overall stability of a single strain in culture over time.[57] Twenty HSV-1 strains were sequenced from around the world, revealing both geographic clustering and a high degree of HSV-1 × HSV-1 recombination.[284] After revealing significant differences in the pathogenicity and sequence of the canonical HSV-2 laboratory strain, HG52, and a low-passage clinical isolate from South Africa, SD90e HSV-2 clinical isolates from around the world were sequenced, revealing little overall sequence variation (maximum nucleotide divergence: 0.4%) and no geographic clustering patterns.[57,203] Frequent HSV-1 × HSV-2 recombination was identified in another cohort of clinical HSV-2 samples.[143] HSV-1 sequencing in unique patient cohorts has provided insight into the exceptional stability of viral genomes over time. For instance, a father–son pair, each with 4 to 5 recurrences of oral HSV-1 infection per year had a reported transmission event nearly 20 years prior. Viral isolates collected from an oral HSV-1 recurrence were sequenced (father 43 years postinfection, son 17 years postinfection). The genomes were 98.9% identical at the consensus level, with only 2 differences that affected coding sequences.[210] These viruses had similar pathogenicity in a mouse ocular model of infection. Similarly, a woman with recurrent symptomatic genital HSV-1 infection had several samples sequenced over a 4-month period, and these were 98.5% identical overall.[265] Two participants in a prophylactic HSV-2 vaccine study

had HSV-2 genomes sequenced from primary infection and with a 5th or 6th recurrence, revealing virtual identity, with fewer than 10 nonsynonymous changes between the two samples from each.[189] These studies suggest very slow evolution in the host, despite frequent recurrences. Sequencing studies have also suggested that infection with more than one strain of HSV-2 is quite rare. Only 18 (3.9%) of 459 people had dual-strain infection; HIV seropositivity was found to be a significant risk factor.[122]

Maternal Genital HSV Infections

Genital HSV infection in the pregnant woman poses a risk to fetus and newborn.[97] An uncommon problem encountered with HSV infections during pregnancy is that of widely disseminated maternal disease.[318] In a limited number of cases, dissemination after primary oropharyngeal or genital infection has led to life-threatening disease, such as necrotizing hepatitis with or without thrombocytopenia, leukopenia, disseminated intravascular coagulopathy, and encephalitis. The mortality rate among these pregnant women is reported to be greater than 50%. Fetal deaths also have occurred in more than 50% of cases, although mortality did not necessarily correlate with the death of the mother. Surviving fetuses were delivered by cesarean section and none had evidence of neonatal HSV infection. Fortunately, with the advent of safe antiviral therapy, symptomatic HSV infection can be treated in pregnant women.

From several prospective trials, the major risk to the fetus is maternal primary or initial genital HSV infection.[34,153] Thus, identification of the woman at risk for primary infection (seronegative for HSV-2 or both types) is important. Studies of the discordant serologic status of sexual partners and rates of acquisition of genital HSV-2 infection define this problem.[34] Primary or initial genital infection occurs at rates from 5.0% to 10% per year.[35] If a pregnant woman experiences initial or primary genital infection in the last trimester of gestation, the likelihood of transmission to the fetus is between 30% and 50%. On the other hand, recurrent maternal infection is associated with a rate of transmission of 3% or less.[33] These different rates of transmission have direct implications on strategies to prevent neonatal disease or at least ameliorate it if the child is inadvertently delivered through an infected birth canal. In the United States, approximately 1 in 2,000 live births (~2,000 per year) are infected with HSV.[175]

Maternal primary infection before 20 weeks of gestation in some women has been associated with spontaneous abortion. The contribution of primary maternal genital infection to spontaneous abortion must be weighed above that of a routine rate of fetal loss of approximately 20%. Infection that develops later in gestation has not been associated with the termination of pregnancy.[97,99]

Recurrent infection is the most common form of infection during gestation. Transmission of infection to the fetus is usually related to shedding of virus at the time of delivery. The actual prevalence of viral excretion at delivery is about approximately 0.5% for all women, irrespective of past history.[304]

Several prospective studies have evaluated the frequency and nature of viral shedding in pregnant women with a known history of genital herpes. In a predominantly white, middle-class population, documented recurrent infection occurred in 84% of pregnant women with a history of herpes.[304] Asymptomatic viral shedding occurred in at least 12% of the recurrent episodes.

Viral shedding from the cervix occurred in 0.56% of symptomatic infections versus 0.66% of asymptomatic infections and higher in some populations (3%).[7] The frequency of recurrences has not been shown to be different from one pregnancy to the next for a given woman. The frequency of shedding does not appear to vary by trimester during gestation.[304] Most infants who develop neonatal disease are born to women who are completely asymptomatic for genital HSV infection and have neither a past history of genital herpes nor a sexual partner reporting a genital vesicular rash.[324,329,333] These women account for 60% to 80% of all women whose infected children become clinically ill.

CLINICAL MANIFESTATIONS OF DISEASE

HSV disease ranges from the usual case of mild illness or asymptomatic in the majority of individuals, to sporadic, severe, and life-threatening disease in a few infants, children, and adults. Although HSV-1 and HSV-2 are usually transmitted by different routes and can involve different areas of the body, there is a great deal of overlap between the epidemiology and clinical manifestations of these two viruses. Historically, primary HSV-1 oropharyngeal infections occurred in the young child, less than 5 years of age, and were most often asymptomatic. More recently, HSV-1 infections have become a significant cause of genital herpes as the first manifestation of disease, as is discussed below.[338] When the oropharynx is involved, the mouth and lips are the most common sites of HSV-1 infections, causing gingivostomatitis; however, any organ can become infected with this virus.

Primary/Recurrent Oropharyngeal Disease

The clinical symptoms of primary HSV-1 infections vary greatly. Infection can be totally asymptomatic or result in combinations of fever, sore throat, ulcerative and vesicular lesions, gingivostomatitis, edema, localized lymphadenopathy, anorexia, and/or malaise. Asymptomatic infection is the rule rather than the exception. The incubation period ranges from 2 to 12 days, with a mean of approximately 4 days.

Symptomatic disease in children is characterized by involvement of the buccal and gingival mucosa (Fig. 10.6).[270] The duration of clinical illness may be from 2 to 3 weeks with fever of 101°F to 104°F. Children with symptomatic primary infection often are unable to swallow liquids because of the significant edema and ulcerative lesions of the mucosal membranes and the associated pain. Intraoral lesions do not scab. Submandibular lymphadenopathy is common with primary HSV gingivostomatitis but rare with recurrent infections. A clinical distinction should be drawn between intraoral gingival lesions and lip lesions indicative of presumed primary and recurrent infections, respectively. Utilizing PCR detection of viral DNA, evidence of viremia can be documented in approximately one-third of symptomatic patients with primary infection.[98]

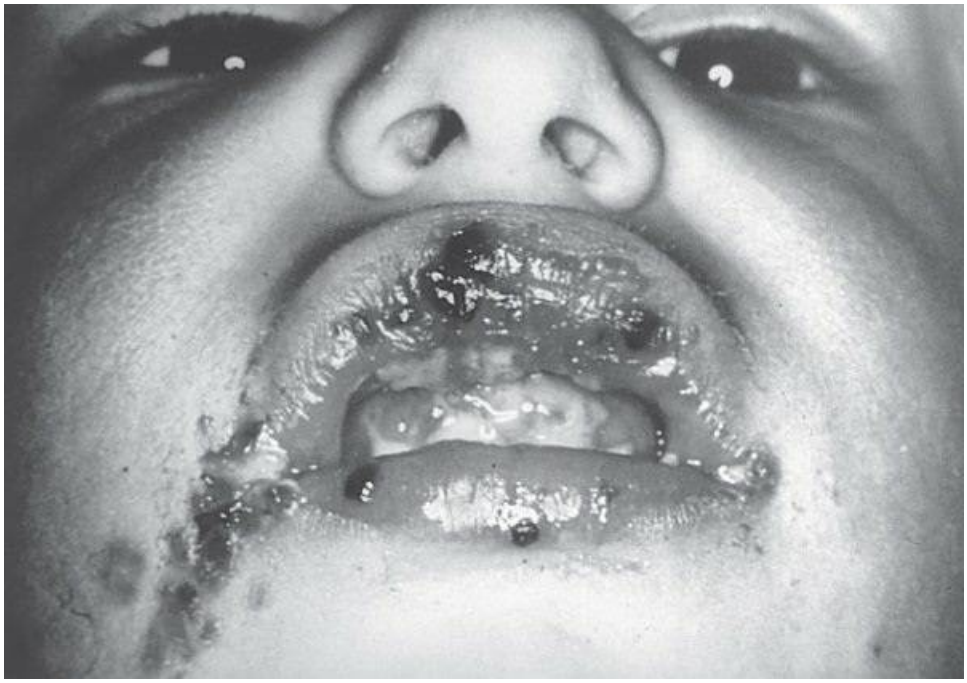

FIGURE 10.6 Herpes simplex gingivostomatitis.

With primary HSV infections during adulthood, HSV pharyngitis in association with a mononucleosis syndrome is common. Ulcerative tonsillar lesions on an erythematous base with associated submandibular lymphadenopathy are characteristic.[92] The differential diagnosis of both primary HSV gingivostomatitis and pharyngitis includes herpangina (caused by coxsackieviruses), *Candida albicans*, group A streptococcal infections, Epstein-Barr or cytomegalovirus-induced mononucleosis, lesions induced by chemotherapy or radiation therapy, and Stevens-Johnson syndrome.

The onset of recurrent orolabial lesions is heralded by a prodrome of pain, burning, tingling, or itching, which generally lasts for less than 6 hours followed by vesicle formation.[271] The natural history of recurrent herpes labialis is illustrated in Figure 10.7.[270] Vesicles appear most commonly at the vermillion border of the lip and persist in most patients 48 hours or less (Fig. 10.8).[318] Vesicles generally number 3 to 5. The total area of involvement usually is less than 100 mm^2 and lesions progress to the pustular or ulcerative and crusting stage within 72 to 96 hours. Pain is most severe at the outset and resolves quickly over 96 to 120 hours. Similarly, the loss of virus from lesions decreases with progressive healing over 2 to 3 days.[13,271] Healing is rapid, generally being complete in 8 to 10 days. The frequency of recurrences varies among individuals.[271] Factors responsible for recurrences are highly variable but include fever, stress, immunosuppression, and exposure to UV light.[262]

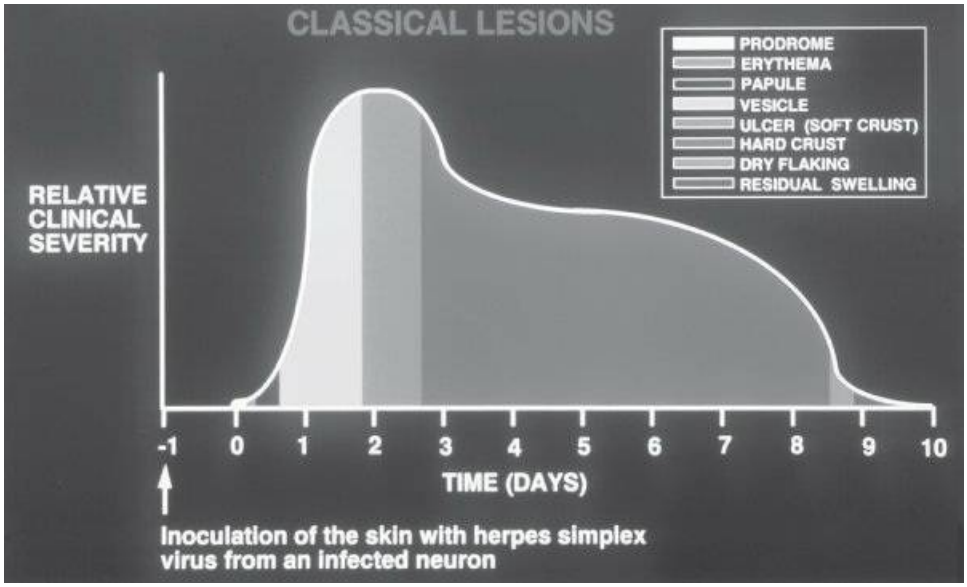

FIGURE 10.7 Herpes simplex labialis natural history.

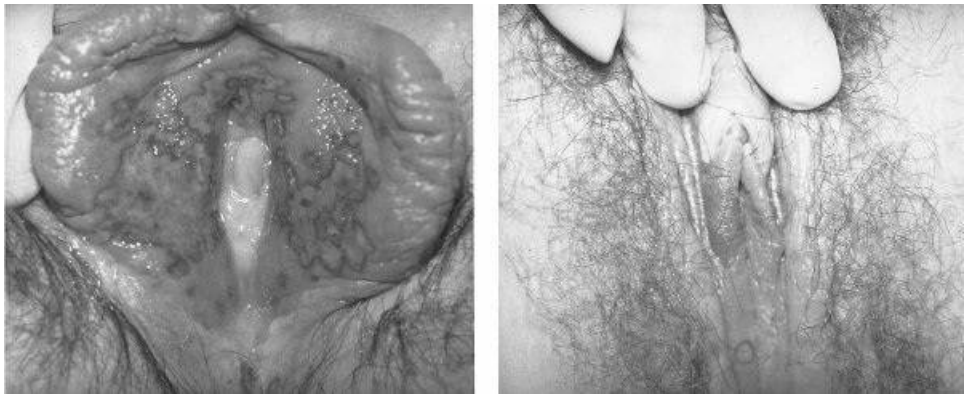

FIGURE 10.8 Recurrent herpes simplex labialis.

Primary/Initial/Recurrent Genital Disease

Symptomatic primary genital infection is usually the most severe. After acquisition of HSV infection at a mucocutaneous site, macules and papules, followed by vesicles, pustules, and ulcers, appear. The duration of lesions averages 3 weeks. There are both similarities and differences in the clinical symptomatology between men and women with infection.[59] Furthermore, there appears to be no difference in clinical symptoms associated with primary genital HSV infection attributed to either virus type.

Primary infection is associated with (a) larger quantities of virus replicating in the genital tract (more than 10^6 viral particles per 0.2 mL of inoculum) and (b) a period of viral excretion that may persist for 3 weeks in the absence of antiviral treatment. Systemic complications in men are relatively uncommon; however, aseptic meningitis can develop. Paresthesias and dysesthesias that involve the lower extremities and perineum can result from genital herpetic infection. Primary infections can be associated with fever, dysuria, localized inguinal

adenopathy, and malaise in both men and women. The severity of primary infection and its association with complications are statistically higher in women than in men, for unknown reasons. Systemic complaints are common in both sexes, approaching 70% of all cases. Extragenital lesions are common.

In women with primary infection, lesions appear on the vulva and are usually bilateral, as shown in Figure 10.9,[236] with the cervix often involved. The actual frequency of primary cervical infection in the absence of vulvar infection is unknown. Lesions usually are excruciatingly painful, associated with inguinal adenopathy and dysuria, and may involve the vulva, perineum, buttocks, cervix, and/or vagina. A urinary retention syndrome occurs in 10% to 15% of females, and as many as 25% will develop aseptic meningitis.

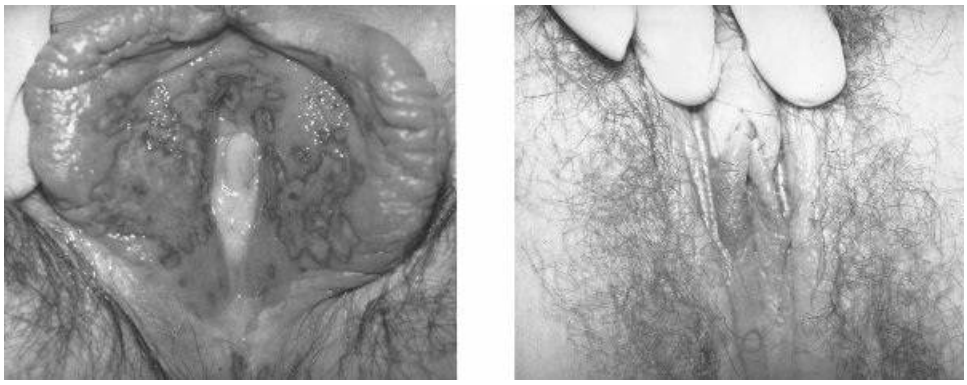

FIGURE 10.9 Genital herpes simplex infection (female).

In men, primary genital HSV infections are most often associated with vesicular lesions superimposed on an erythematous base, usually appearing on the glans penis or the penile shaft, as shown in Figure 10.10.[236] The total number of lesions can vary significantly. Extragenital lesions of the thigh, buttocks, and perineum can occur.

FIGURE 10.10 Genital herpes simplex infection (male).

Complications of primary genital herpetic infection have included sacral radiculomyelitis, which can lead to urinary retention, neuralgias, and meningoencephalitis.[103,105,288] Primary perianal and anal HSV-2 infections, as well as associated proctitis, are common in men who have sex with men.[95] HSV-2 can be isolated from the rectum of heterosexual males and females. Many primary HSV-2 illnesses are subclinical, often involving the uterine cervix.[344]

Nonprimary but initial genital infection (i.e., occurring in an individual with preexisting antibody to the other virus type) is less severe symptomatically and heals more quickly than does primary infection. The duration of disease approximates 2 weeks. The number of lesions, severity of pain, and likelihood of complications are significantly decreased compared to primary infection. Preexisting antibodies to HSV-1 appear to have an ameliorative effect on disease severity of HSV-2[252,312] but do not prevent infection.

Recurrent genital herpes is usually a much milder form of disease. With recurrent genital herpetic infection, a limited number of vesicles, usually 3 to 5, appear on the shaft of the penis of the male or as simply a vulvar irritation in the female. The duration of disease is approximately 7 to 10 days and parallels that encountered with recurrent HSV labialis. Neurologic or systemic complications are uncommon with recurrent disease; however, paresthesias and dysesthesias can occur.

Some individuals experience their “first-episode” genital infection years after an asymptomatic or atypical primary infection. Therefore, when antibody to the virus has already developed, it is difficult to determine when acquisition of the virus occurred.

The extent of viral replication is different for recurrent infection as compared with primary infection. Virus is shed for an average of only 2 to 5 days and at lower concentrations (~10^2 to 10^3 per 0.2 mL of inoculum in tissue culture systems). Recurrent genital infection in both men

and women is characterized by prodrome consisting of tingling/itching or burning, which is thought to be caused by virus traveling down the nerves[169] and localized irritation.

A major problem with genital HSV infection is the frequency of recurrences, which varies substantially from one individual to the next. Anecdotally, the severity of primary infection correlates directly with the frequency of recurrences; that is, the more severe the primary infection, the more likely and frequent the recurrences. Notably, virtually all patients will suffer from recurrences, whether symptomatic or asymptomatic. For those individuals with genital HSV-1 infection, the probability of recurrences is significantly less and, in some patients, virtually not at all.[21] HSV-2 genital infections are prone to recur. One-third of patients are estimated to have recurrences in excess of six times per year, one-third will have two to three per year, and the remaining third will have four to six. With recurrences, either symptomatic or asymptomatic, transmission of infection to sexual partners can occur with intimate contact.

Neonatal HSV Infection

Incidence and Transmission of Newborn Infection

The estimated incidence of neonatal HSV infection is approximately 1 in 2,000 deliveries per year in the United States.[125,175] Globally, there are estimated to be 10.3 cases of neonatal herpes per 100,000 livebirths.[164] At least four factors influence transmission of infection from mother to fetus. First, maternal primary or first-episode genital infection during the third trimester results in a transmission rate of 30% to 50% as compared with 3% or less with recurrent infection.[32,34] Second, transplacental maternal neutralizing and ADCC antibodies appear to have an ameliorative effect on acquisition of infection and disease presentation.[9,226,342,343] Third, rupture of membranes more than 6 hours increases the risk of transmission. Fourth, the use of fetal scalp monitors is associated with increased risk.[130,213]

Acquisition and Presentation of Infection

Infection of the newborn can be acquired *in utero (congenital)*, intrapartum, or postnatally. The mother is the source of infection for the first two of these routes of transmission.[97,317]

Congenital Infection

In utero infection can occur as a consequence of either transplacental or ascending infection.[14,114] The incidence has been estimated to be 1 in 200,000 deliveries.[14] Intrauterine infection is characterized by the triad of skin vesicles or skin scarring, eye disease (chorioretinitis or microphthalmia), and the far more severe manifestations of microcephaly or hydranencephaly.

Intrapartum Infection

The most common route of infection is that of intrapartum contact of the fetus with infected maternal genital secretions. Likely, 80% to 90% of infected babies acquire HSV infection by this route. Babies who are infected intrapartum or postnatally with HSV infection are classified as having: (a) disease localized to the skin, eye, and mouth (SEM); (b) encephalitis with or without skin involvement; and (c) disseminated infection that involves multiple organs, including the

CNS, lung, liver, adrenals, skin, eye, and/or mouth.[136,331]

Disseminated infection has the highest mortality and morbidity,[324] typically presenting for therapy at 9 to 11 days of age. The principal afflicted organs are the liver, lungs, and adrenals, but virtually all organs can be involved. Constitutional signs and symptoms include irritability, seizures, respiratory distress, jaundice, bleeding diatheses, shock, and, frequently, the characteristic vesicular exanthem, which is often considered pathognomonic for infection. Encephalitis is a common component of this form of infection, occurring in about 60% to 75%. Over 20% of these children do not develop skin vesicles during the course of their illness.[324] Mortality in the absence of therapy exceeds 80%; all but a few survivors are impaired. Death in these babies is caused either by HSV pneumonitis or by disseminated intravascular coagulopathy.

Babies with infection of the CNS alone or in combination with disseminated disease (75%) present with the findings of encephalitis. Clinical manifestations of encephalitis include seizures (both focal and generalized), lethargy, irritability, tremors, poor feeding, temperature instability, bulging fontanelle, and pyramidal tract signs. Whereas babies with disseminated infection often have skin vesicles in association with brain infection, the same is not true for the baby with encephalitis alone. This latter group of children may only have skin vesicles in approximately 60% of cases at any time during the disease.[97,280,324] Death occurs in 50% of babies with localized CNS disease who are not treated. Survivors are left with severe neurologic impairment.[319,325]

The long-term prognosis, after either disseminated infection or encephalitis, is poor in the absence of antiviral therapy. As many as 50% of surviving children have some degree of psychomotor retardation, often in association with microcephaly, hydranencephaly, porencephalic cysts, spasticity, blindness, chorioretinitis, or learning disabilities. Recent data suggest that CNS damage can be progressive after initial therapy, as predicated upon long-term antiviral suppressive data administered to babies with encephalitis. Indeed, this may represent low-grade replication of HSV in the brain.

Subclinical infection of the CNS has been detected in babies with disease apparently localized to the SEM. These children had normal cerebrospinal fluid (CSF) assessments but PCR-detectable HSV DNA at the onset of disease.[135] Subsequently, a subset of these children developed neurologic impairment.

Importantly, in as many as 40% of children with disease localized to the CNS (e.g., the 2- to 3-week-old baby with cells and protein in the CSF), skin vesicles (the classic sign of disease) are not present. For the neonate with CSF findings indicative of infection, HSV must be considered along with bacterial pathogens (e.g., group B *streptococcus*, *Escherichia coli*).

Infection localized to the SEM is associated with lower mortality, but morbidity can occur. When infection is localized to the skin, the presence of discrete vesicles remains the hallmark of disease. With time, the rash can progress to involve other areas of the body as well, particularly if viremia occurs. Vesicles occur in 90% of children with SEM infection, presenting at about 10 to 11 days of life. Skin lesions invariably will recur, regardless of whether therapy was administered. Although death is not associated with disease localized to the SEM, approximately 30% of these children eventually develop neurologic impairment.[319,325,329] The skin vesicles usually erupt from an erythematous base and are 1 to 2 mm in diameter. Other manifestations of skin lesions have included a zosteriform eruption.[198]

Infections involving the eye may manifest as keratoconjunctivitis or, later, as chorioretinitis. The eye can be the only site of HSV involvement.[325] These children present with keratoconjunctivitis or evidence of microphthalmia and retinal dysplasia.

Postnatal Acquisition

Postnatal acquisition of HSV-1 accounts for about 10% of cases.[159,160,199,281] The presentation is similar to that described above and usually is the consequence of family contact with the newborn.

Herpes Simplex Keratoconjunctivitis

Viral infections of the eye are usually caused by HSV-1 beyond the newborn age.[27,207] Approximately 300,000 cases of HSV infections of the eye are diagnosed yearly in the United States. These infections are second only to trauma as the cause of corneal blindness in the United States. Primary herpetic keratoconjunctivitis is associated with either unilateral or bilateral conjunctivitis, which can be follicular in nature, followed soon thereafter by preauricular adenopathy. HSV infection of the eye is also associated with photophobia, tearing, eyelid edema, and chemosis, accompanied by the pathognomonic findings of branching dendritic lesions (Fig. 10.11).[236] Less commonly, with progressive disease, the infection is associated with a geographic ulcer of the cornea (Fig. 10.12).[236] Healing of the cornea can take as long as 1 month, even with appropriate antiviral therapy.

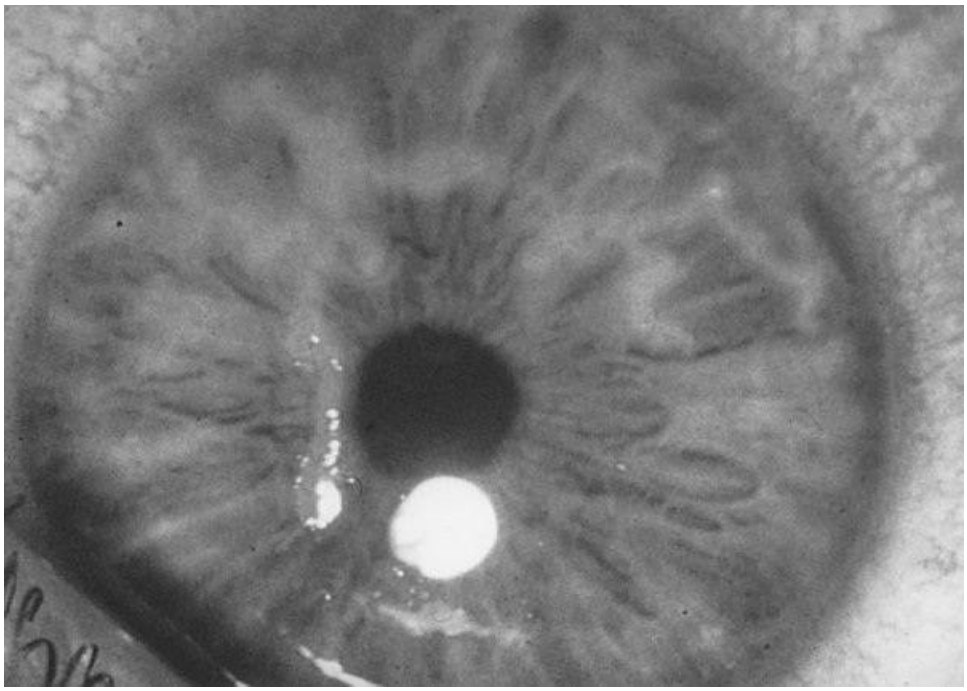

FIGURE 10.11 Dendritic lesions of herpes simplex keratoconjunctivitis.

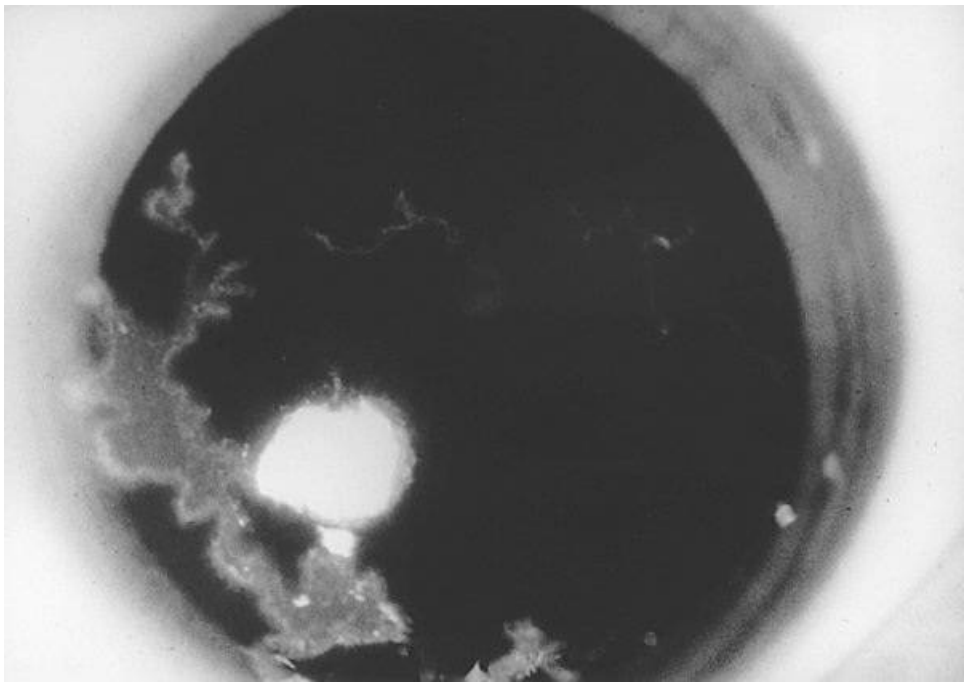

FIGURE 10.12 Geographic corneal ulcer caused by herpes simplex virus infection.

Recurrent HSV infections of the eye are common. Most frequently, recurrences are unilateral in involvement, but a small percentage of cases involve both eyes. Characteristically, either dendritic ulceration or stromal involvement occurs. Visual acuity is decreased in the presence of the ulcers; with progressive stromal involvement, opacification of the cornea may occur. The route and pathogenesis of infection remain unknown. Progressive disease results in visual loss and even rupture of the globe.

Skin Infections

Skin infections caused by HSV generally manifest as eczema herpeticum in patients with underlying atopic dermatitis, occurring in 1% to 2%.[228,287,315] The lesions can either be localized, resembling herpes zoster with a dermatomal distribution, or disseminated. The latter occurs commonly in Kaposi's varicella-like eruption. HSV infections of the digits, known as herpetic whitlow, have been reported and are particularly common among medical and dental personnel.[239] The estimated incidence is 2.4 cases per 100,000 individuals per year, and the cause may be HSV-1 or HSV-2.[91] With the uniform use of disposable gloves by medical personnel, the incidence has decreased.

In addition to individuals with atopic disease, patients with skin abrasions or burns appear particularly susceptible to HSV-1 or HSV-2 infections and some may develop disseminated infection. Disseminated HSV infections have been also reported among wrestlers (herpes gladiatorum).[316] Other skin disorders associated with extensive cutaneous lesions include Darier disease and Sézary syndrome.[101,107] Localized recurrences followed by an episode of dissemination have been reported. HSV infections of either type can trigger erythema

multiforme.[314] The presence of HSV DNA in skin lesions of erythema multiforme is as high as 80%.

Infections of the Immunocompromised Host

Patients compromised by immunosuppressive therapy, underlying disease, or malnutrition are at increased risk for severe HSV infections. Renal, hepatic, stem cell, and cardiac recipients are all at risk for increased severity of HSV infection.[197,215,328] An example of cutaneous dissemination after shaving, in a renal transplant recipient, is shown in Figure 10.13.[236] Acquisition of HSV infection from a transplanted organ (kidney) has been reported.[77] These patients may develop progressive disease involving the respiratory tract, esophagus, or even the gastrointestinal tract.[150,193] The severe nature of progressive disease in these patients appears to be directly related to the type of immunosuppressive therapy. Esophagitis is a common occurrence in the immunocompromised host and can be caused by HSV, cytomegalovirus, or *Candida albicans*. Notably, acyclovir-resistant HSV disease can occur in the immunocompromised host and can be progressive. Reactivation of latent HSV infections in these patients can occur at multiple sites, and healing in these patients with severe progressive disease occurs over an average of 6 weeks.[332]

FIGURE 10.13 Cutaneous dissemination of herpes simplex virus infection in an immunocompromised host.

Since the first reports of acquired immunodeficiency syndrome (AIDS), the severity of HSV clinical disease in the absence of antiretroviral therapy was noted.[313] Disease severity correlates with CD4 count and the probability of developing resistance to antiviral therapy. Atypical, hypertrophic or “pseudotumor” lesions that mimic squamous cell carcinoma may occur in patients with HIV infection.[246] Furthermore, after starting antiretroviral therapy in persons with a low CD4 count and HSV-2 infection, genital HSV recurrences and genital ulcer disease increase, possibly as a manifestation of the immune reconstitution inflammatory syndrome.[83,225,290] Asymptomatic excretion of HSV can occur even in the immunocompromised host, as is best exemplified in HIV-infected individuals.[247,312]

Infections of the Central Nervous System

Herpes simplex encephalitis (HSE) is one of the most devastating of all HSV infections (Fig. 10.14),[236] being the most common cause of sporadic, fatal encephalitis in this country,[206,323] having an incidence of approximately 1 in 250,000 individuals per year (1,250 cases in the United States).

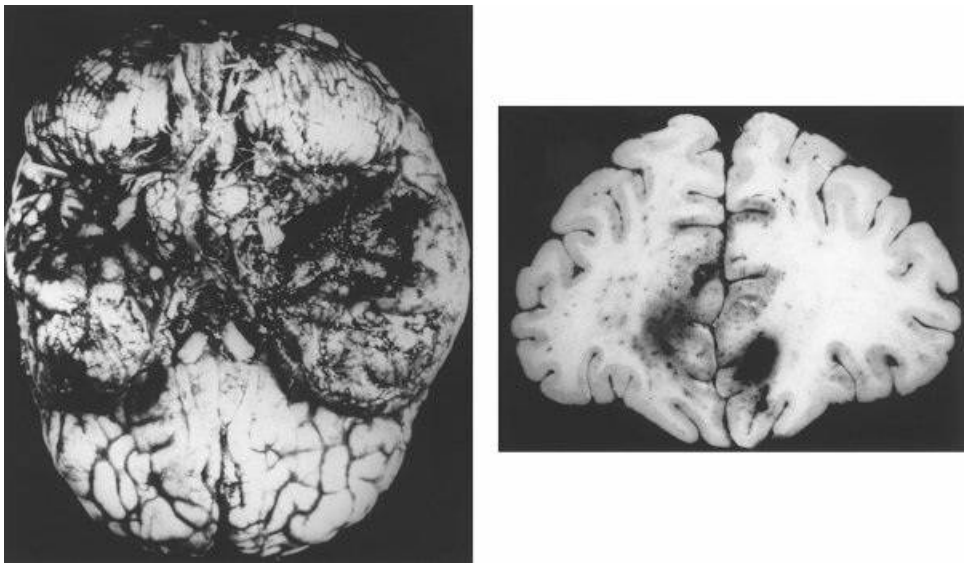

FIGURE 10.14 Coronal section of brain from a patient with herpes simplex encephalitis.

HSV encephalitis is primarily a focal encephalitis associated with fever, altered consciousness, bizarre behavior, disordered mentation, and localized neurologic findings.[317] These clinical signs and symptoms generally are associated with evidence of localized temporal lobe disease.[330,331] There are no pathognomonic findings of HSE; however, a progressively deteriorating level of consciousness, fever, an abnormal CSF formula with a lymphocytic predominance and/or blood, and focal neurologic findings in the absence of other causes should make this disease highly suspect. In the absence of antiviral therapy, mortality exceeds 70%, and only 2.5% of all patients return to normal neurologic function.

Neurodiagnostic procedures used in the evaluation of patients with suspected HSV encephalitis include CSF examination, electroencephalogram, and, preferably, a magnetic resonance image scan. Characteristic abnormalities of the CSF include elevated levels of cells (usually mononuclear) and protein. Red blood cells are found in most (but not all) CSF obtained from patients with HSV encephalitis. The electroencephalogram generally demonstrates localized spike and slow-wave activity in the temporal lobe. A burst suppression pattern is considered characteristic of HSV encephalitis. Imaging indicates localization of disease to the temporal lobe with evidence of edema that is followed by evidence of hemorrhage and a midline shift in the cortical structures.

PCR detection of HSV DNA in the CSF is the diagnostic modality of choice.[157] Serologic assessments of serum or CSF for HSV antibodies are not helpful early in the disease course when therapeutic decisions are mandatory.[201]

Other Neurologic Syndromes

In addition to encephalitis, HSV can involve nearly all anatomic areas of the nervous system including meningitis, myelitis, and radiculitis, among others.[65] Aseptic meningitis is a common occurrence in individuals with primary genital HSV infections. Recurrent aseptic meningitis (Mollaret syndrome) will occur in patients with genital herpes.[296] Notably, HSV DNA has been detected in the brain from all lobes at autopsy in individuals dying from other causes.[15]

DIAGNOSIS

The appropriate use of laboratory tools is essential if a diagnosis of HSV infection is to be achieved.[60] Virus isolation is one definitive diagnostic method; however, PCR detection of viral DNA has replaced culture in many laboratories. If a culture is obtained, skin vesicles/lesions should be swabbed/scraped and transferred promptly in appropriate virus transport media to a diagnostic virology laboratory. In addition to skin vesicles, other sites from which virus may be isolated include the CSF (rarely), stool, urine, throat, nasopharynx, and conjunctivae. Clinical specimens should be shipped on ice for inoculation into cell culture systems (e.g., foreskin fibroblasts, Vero cells) that are appropriate for the demonstration of the cytopathic effects characteristic of HSV replication.[255] Cytopathic effect tends to develop within 24 to 48 hours after inoculation of specimens containing infectious virus. HSV is labile, and therefore the shipping and processing of specimens for viral culture should be expedited to avoid false-negative results.

The advantage of cell culture is the ability to obtain a virus isolate for further testing (e.g., resistance). Typing of an HSV isolate may be accomplished both in culture and by PCR. Differentiating between HSV-1 and HSV-2 infection in the genital tract is important for patient counseling.

Serologic diagnosis of HSV infection is clinically valuable in the counseling of patients regarding genital herpes provided that the assays are type specific (differentiate between HSV-1 and HSV-2), namely HSV-1 and HSV-2 gG-specific antibodies.[309] If a clinically apparent HSV infection is suspected, empiric therapy should be started without awaiting the commercial and FDA-approved assays that are available. IgM antibody responses do not correlate with disease activity or infection and are not recommended for diagnosis.[209,336] Screening for HSV infection by serology among persons without symptoms is not recommended by the CDC.[82]

The development of PCR has revolutionized the diagnosis of HSV infections and also allowed for detailed studies of disease pathogenesis. PCR assessment of CSF is the standard for diagnosis of HSV encephalitis[227,240,293] as well as skin lesions—either orolabial or genital. HSV DNA can be detected in the CSF of patients undergoing brain biopsies for HSV encephalitis with a sensitivity of more than 95% and a specificity that approaches 100%.[157] PCR evaluation of CSF can be used to follow therapeutic outcome in patients with HSV encephalitis. Persistence of HSV DNA in the CSF of newborns with HSV encephalitis at the completion of antiviral therapy predicts poor neurologic outcome.[138]

PREVENTION AND CONTROL OF HSV INFECTIONS

Genital HSV Infections

Because of the increased awareness of genital herpes and neonatal herpes and its association with increased risk of acquisition of HIV, every effort should be made to prevent HSV-2 infections. The use of condoms should be promoted as use moderately decreases the probability of acquiring genital HSV infection, with a 30% decreased risk of HSV-2 acquisition among people who always use condoms (compared to never users).[181] Some studies have shown that condoms are more effective in the prevention of infection of females than males.[44,174,308] Among HSV-2 heterosexual serodiscordant couples without HIV infection, use of daily suppressive valacyclovir for the HSV-2–seropositive partner is associated with a 48% decreased risk HSV-2 transmission to the seronegative partner.[64] Conflicting results have been found in studies of medical male circumcision (MMC) conducted in Africa for prevention of HIV infection.[184] Some studies have showed a significant 30% decrease in the risk of HSV-2 acquisition among men undergoing MMC,[290] and female partners of those undergoing MMC have a decreased risk of HSV-2 acquisition.[96] Disclosure of HSV serostatus to sexual partners is also associated with decreased risk of transmission.[307]

Prevention of Neonatal HSV Infection

The risk of neonatal infection is increased in the presence of genital ulcers, but HSV transmission can also occur in the absence of lesions. Surgical abdominal delivery is associated with the decreased transmission of infection when membranes are ruptured less than 4 hours, but cesarean section has not been proven efficacious when membranes are ruptured for longer periods of time.[34]

For women with a past history of genital HSV infection, some obstetricians prescribe an antiviral medication during the last 4 weeks of gestation, recognizing a decreased probability of virus excretion.[5] However, recent data indicate, that in spite of maternal compliance, maternal transmission can still occur, resulting in severe neonatal HSV disease.[222]

For babies born to mothers with known primary infection during the third trimester of gestation, the American Academy of Pediatrics Redbook Committee recommends 10 days of high-dose intravenous acyclovir therapy followed by careful serial medical assessment.[134] If a child is born through a known infected birth canal, particularly in the presence of an established genital infection, skin surface cultures and careful follow-up are in order. Should the cultures become positive or the child ill, further evaluation (i.e., CSF and blood assessment by PCR) is indicated with therapy initiated until a diagnosis is either confirmed or excluded.

At the time of presentation to the labor and delivery suite, a careful vaginal examination is of paramount importance. Although visualization of the cervix is often difficult, speculum examination for documentation of recurrent lesions is extremely important and should be attempted in all women because it will guide management of the newborn (see below).

Hospital Staff

Temporary removal of personnel who have cold sores is advocated for some clinical services. Education regarding the risk of transmission of virus and the importance of hand washing when lesions are present should be repeatedly emphasized to healthcare workers. Some infection control physicians recommend that hospital personnel should wear masks when active lesions are present.

Prevention of Other HSV Infections

At the present time, the only mechanism for prevention of mucocutaneous HSV infection is to avoid contact with infected secretions. Gloving of hospital personnel will decrease risk of hand exposure. There are no proven effective postexposure antiviral therapies or vaccines.

VACCINE DEVELOPMENT

Human HSV Vaccine Development

An important consideration for human HSV vaccines is the definition of expectations, warranting a distinction between infection and disease. From animal data, disease can be ameliorated if not prevented; however, infection still occurs and with it the potential for reactivating and transmitting infection. Similarly, the potential of altering the immune response to change the pattern of recurrences in previously infected individuals is unlikely. HSV vaccine research has focused on prevention of HSV-2 infection. Clinical trials have explored both prophylactic vaccines, which aim to prevent acquisition of HSV-2, and therapeutic vaccines, which are given to HSV-2–seropositive persons to prevent recurrences and shedding. Despite extensive research, no vaccines have elicited sufficient efficacy to gain licensure for use. Early investigations provide important insights into these expectations according to candidate vaccine: (a) wild-type virus, (b) inactivated or killed virus, (c) subunit vaccines, and (d) live vaccines.

Wild-Type Virus Vaccines

Numerous investigators have studied (a) autologous virus, (b) virus from another infected individual, or (c) virus recovered from an experimentally infected rabbit. In some cases, inoculation led to recurrences of latent infection.[29] These live viruses were subsequently abandoned because many patients failed to develop lesions at the site of inoculation; therefore, it was concluded that the virus did not produce an “adequate take,” as compared to smallpox immunization.

Inactivated (or Killed) Virus Vaccines

Killed viruses were used as vaccines in a variety of animal models. The initial inactivated vaccines were made from phenol-treated tissues obtained from infected animals. Because of the potential for demyelination after the administration of animal proteins, these vaccines attracted

little biomedical attention. UV light inactivation of purified virus derived from tissue culture experiments provided greater impetus for the vaccine field. Viral antigens obtained from a variety of cell cultures were inactivated by formalin, UV light, or heat and administered to thousands of patients.[320] While decreased recurrences were reported in as many as 60% to 80% of patients,[202] no controls were used.

Several important observations were made from these studies. First, despite repeated inoculations, antibody titers (as measured by neutralization or complement fixation) remained unchanged in the majority of patients or demonstrated only slight increases.[269,303] Second, although few side effects were reported, some authors noted concern that, in patients with keratitis, autoimmune phenomena might make the herpetic disease worse.[254] Lastly, placebo-controlled trial designs were not routinely employed.

Subunit Vaccines

Subunit vaccines evolved from attempts to remove viral and cellular DNA, to enhance antigenic concentration and induce stronger immune responses, and, finally, to exclude any possibility of contamination with residual live virus. The immunogenicity of envelope glycoproteins was demonstrated in animals.[42,43,188,267] The subunit vaccines elicited some protection, as evidenced by reduction of morbidity and mortality in the immunized animals. However, the predictability of these models for human studies is disappointing. Furthermore, several injections with an adjuvant were required to induce protection. Protection in a rodent model is significantly easier than that in nonhuman primates. Vaccination of primates, specifically rhesus monkeys,[41] chimpanzees,[41,42] and *Cebus* monkeys,[104] induces neutralizing antibodies, which can lead to an amnestic response after subsequent injection months later.

Subunit vaccines have failed in human experiments despite initial promising results. Both HSV-1 and HSV-2 antigens have been prepared in human diploid cells and chicken embryo fibroblasts. The first envelope subunit vaccine[8,104,345] was administered to uninfected sexual partners of patients known to have genital herpes and demonstrated that HSV infection was nearly equal for both placebo and vaccine recipients, indicating that the vaccine was not effective.

Further extensive studies have been completed with two gB and/or gD recombinant vaccines in humans, including adjuvants. Some studies demonstrated an increase in the geometric mean neutralizing antibody titer to gD-2; however, lymphocyte blastogenic responses were inconsistent.[277] Other studies afforded a high level of protection from HSV disease in animal models[243]; but with unacceptable reactogenicity. Notably, in these studies, the quantity of neutralizing antibodies elicited by immunization and the total HSV antibody titer (as measured by ELISA) were higher after vaccination than after natural infection.[274] A controlled clinical trial using gD2 and gB2 in an adjuvant of squalene oil and water emulsion failed to demonstrate efficacy for prevention of either infection or disease.[62]

A second candidate vaccine consisting of gD-2 with an alum and monophosphoryl lipid A adjuvant induced titers of HSV gD-specific antibody that were higher than those observed in patients who had sexually acquired genital HSV-2 infection. In these studies, women who were seronegative for both HSV-1 and 2 were significantly protected from disease (72% efficacy; p = 0.01 and 0.02, respectively) and there was a trend toward protection against infection (43%

efficacy; $p = 0.06$ and 0.07). However, in individuals seropositive for HSV-1, irrespective of sex, and seronegative men, no significant clinical benefit could be demonstrated. Thus, this genital herpes vaccine (gD-Alum/MPL) was only effective in preventing HSV-1 or 2 genital herpes disease in a subset of volunteers, that is, women who were HSV-1 and 2 seronegative (HSV-1/2) prior to vaccination. However, these studies were neither designed nor powered to assess efficacy exclusively in HSV-1/2 women and therefore did not meet their primary endpoints of overall efficacy. The vaccine had no effect in women who had preexisting antibodies to HSV-1 or men regardless of their serologic status. A large placebo-controlled study to verify these results showed only 20% efficacy in preventing genital herpes disease overall (the primary endpoint) but did show 58% efficacy for preventing HSV-1 genital disease.[18] By including HSV seroconversion in the definition of genital infection, the vaccine showed only 22% protection from HSV infection overall, but 35% efficacy for preventing HSV-1 infection. A trivalent subunit vaccine appears promising in preclinical studies for prevention of genital herpes. The vaccine attempts to build on the partial successes of the prior subunit vaccine studies. The vaccine consists of HSV-2 glycoproteins C, D, and E intended to block virus entry mediated by glycoprotein D and prevent immune evasion from antibody and complement mediated by glycoproteins C and E.[11]

More recently, other approaches have either entered or are being considered for clinical trials. A therapeutic vaccine consisting of immunogenic T-cell antigens has been assessed in persons with HSV-2 infection in Phase I and II clinical studies. The vaccine decreased the frequency of shedding and recurrences by approximately 40%, demonstrating a proof of principle that stimulating T-cell responses by vaccination can alter the natural history of HSV-2 infection.[25,300] However, to date, this impact was not significant enough to pursue Phase III licensure trials.

Live Virus Vaccines

For decades, live virus vaccines have been considered most likely to provide a high level of protection as occurs with measles, mumps, and rubella. Moreover, these vaccines usually require smaller quantities of antigen and, therefore, should be more economical. Several approaches to live virus vaccines have been attempted, including HSV mutants, heterologous herpesviruses, antigens expressed in non-HSV viral vectors, and genetically engineered viruses.

Genetically Engineered HSV Vaccines

Current technology allows the construction of recombinant HSV as prototype vaccines.[185,235] These vaccines were engineered with the objectives that they should be attenuated so as not to cause primary disease or to reactivate; be able to protect against HSV-1 or HSV-2 disease; provide biomarkers that distinguish vaccine from wild-type infection; and, potentially, serve as vectors to express immunogens of other human pathogens. Notably, there is overlap between engineered vaccine candidates and HSV constructs that are used for gene therapy; see below.

The initial construction of candidate vaccines was based on the use of HSV-1. An engineered HSV was constructed that deleted the viral thymidine kinase gene and the junction region of the U_L and U_S segments in order to excise some of the genetic loci responsible for neurovirulence. An HSV-2 DNA fragment encoding the HSV-2 glycoproteins D, G, and I was inserted in place of the internal inverted repeat. The resulting recombinant, designated as R7017, was further

altered by insertion of the thymidine kinase gene next to the HSV-2 DNA fragment (R7020). Because this virus expresses thymidine kinase, it is amenable to antiviral chemotherapy with acyclovir.

When evaluated in rodent models, the two constructs were considerably attenuated in pathogenicity and ability to establish latency and were capable of inducing protective immune responses. These results were corroborated by studies in owl monkeys (*Aotus trivirgatus*). Although 100 plaque-forming units of wild-type virus administered by peripheral routes were fatal to the monkeys, recombinants given by various routes in amounts at least 10^5-fold greater were innocuous or produced only mild infections, even in the presence of immunosuppression by total lymphoid irradiation.[186] When R7020 was administered to humans to determine reactogenicity, immune responses were elicited[40]; however, R7020 was not effective at the relatively low doses tested at that time.

The application of these principles to HSV-2 constructs was undertaken and assessed in animal models. The *$\gamma_1$34.5* gene of HSV-1 was proven to be a mediator of CNS replication, providing a potential vaccine construct upon deletion.[55] Furthermore, deletions of $\gamma_1$34.5 significantly decrease the ability of this construct to establish latency.

One promising approach to an HSV vaccine is using replication-defective viruses.[75] A current construct deletes *U_L5* and *U_L29* in HSV-2 to generate the dl5-29 vaccine candidate.[195,204] This vaccine candidate was compared to a gD-2 subunit vaccine in Freund adjuvant. Significant protection was induced along with high titers of neutralizing antibodies and $CD8^+$ T cells.[76,109,110] This vaccine candidate has been evaluated in Phase I human trials and generated only modest immune responses.[74]

A vaccine deleted in gH was studied in a Phase II trial in the United Kingdom. This vaccine, known as the HSV-DISC vaccine, undergoes a single cycle of replication. Because gH is deleted, no further replication is possible. The results of this Phase II study failed to demonstrate effectiveness in reducing reactivation and disease in persons with recurrent HSV-2.[69] A similar approach by deleting another essential entry molecule, glycoprotein D, is under evaluation as a prophylactic vaccine for genital herpes in preclinical studies.[38]

Vectored Gene Expression and Other Approaches

Vectored approaches have utilized vaccinia virus[268] and adenoviruses[182] for expression of foreign genes, namely the gD and/or gB genes that showed varying effectiveness in animal models but have not been advanced to human trials.[352]

Other approaches being tested as therapeutic vaccines include DNA plasmid vaccines of gD2 that are optimized to generate both humoral and cell-mediated immunity (COR-1). In Phase I/II studies, this approach generated gD2-specific immune responses.[51] In addition, a “prime and pull” strategy, which uses traditional parenteral vaccination followed by application of a topical chemokine on the genital mucosa, is being studied in animal models as a therapeutic vaccine approach and generates better viral control than vaccination alone.[24,261,272]

Future vaccines must be directed against both HSV types. As noted above, one advanced at this time is a construct that deletes *U_L5* and *U_L29* in HSV-2 to generate the *dl5-29* vaccine candidate. One such construct will consider the utilization of immunologically dominant T-cell

epitopes as a means to improve immune responses.

ONCOLYTIC HSV THERAPY

Genetically engineered HSVs have been assessed for the treatment of human glioblastoma multiforme and melanoma. These constructs have included mutations in the viral genes for thymidine kinase, DNA polymerase, ribonucleotide reductase, and $\gamma_1$34.5[30,50,117,129,179,190] and have been identified as HF10, HSV1716, NV1020, G207, G47Δ, OncoVEX$^{GM\text{-}CSF}$, rRp450, M032, and C134.[46,80,94,161,173,185,191,205] While virtually any alteration of HSV reduces neurovirulence, only the deletions in the *$\gamma_1$34.5* gene consistently demonstrate safety and efficacy in animal models. Tumoricidal effects *in vitro* and *in vivo* in multiple glioma models (mouse, rat, and human glioma cell lines, human glioma explants) are demonstrable. Imlygic has been licensed for the treatment of melanoma.[115]

Animal Model Studies

Studies in animal models of gliomas of various constructs of HSV (engineered viruses deleted in $\gamma_1$34.5) demonstrate the following principles: (a) the time course of infection (quantitative virology and PCR) represents impaired replication with limited spread of virus across the brain using marker genes (*lacZ* under an ICP6 promoter) with HSV antibody staining,[117,129] (b) two selected mutations appear to avoid mutations with reversion to wild-type phenotype ($\gamma_1$34.5 and ribonucleotide reductase deletions),[341] (c) the retention of the native HSV TK allows for acyclovir susceptibility,[50] (d) the safety of these constructs was established in susceptible primates (*Aotus*),[341] and (e) HSV could be used as a vehicle to express foreign genes,[4,212.56,89]

The status of these viruses can be summarized as follows.

HF10

HF10 is derived following serial passage of the wild-type HSV-1 strain HF.[205] This virus is not neuroinvasive and was determined to have stable duplications in the *U_L53*, *U_L54*, and *U_L55* genes, as well as deletion of the *U_L56* gene. Notably, HF10 contains both native copies of the *$\gamma_1$34.5* neurovirulence gene, but its lack of neuroinvasiveness is presumably due to the absence of *U_L56* or to *syn* alterations that may also have an effect.[299] HF10 has been evaluated in murine models of peritoneal tumor distribution as well as breast and bladder cancer.[149,286,289] Preliminary clinical studies of HF10 demonstrated the safety of HF10 following intratumoral injection into metastatic squamous cell carcinoma of the head and neck, as well as metastatic breast cancer.[88,133] A Phase I clinical trial investigating the safety of HF10 in patients with refractory head and neck cancer has been conducted.

HSV1716

HSV1716 is one of two conditionally replication-competent, engineered HSV directly injected into malignant glioma with demonstrated safety and the absence of neurovirulence. HSV1716 has been clinically studied for the treatment of malignant glioma in the United Kingdom. A series of Phase I studies of direct intratumoral and surrounding normal parenchyma administration of HSV1716 at doses ranging from 1×10^3 to 1×10^5 pfu proved safety and viral replication in the tumor.[100,211,229] HSV1716 has also been assessed as a therapy of oral squamous cell carcinoma (1×10^5 pfu of virus intratumorally) and melanoma with evidence of safety but no documentation of viral replication.[171,172]

NV1020

Engineered as a vaccine to prevent HSV-1 and -2 infections, NV1020 is deleted in only one of the two $\gamma_1 34.5$ genes.[185] NV1020 has been studied as an oncolytic HSV for hepatic colorectal adenocarcinoma metastases at doses ranging from 3×10^6 to 1×10^8 pfu followed by chemotherapy 2 to 3 days later.[131] Serious adverse events were minimal. Concomitant sampling of the hepatic vein for viral DNA by PCR detected little evidence of systemic exposure, a perceived risk of administering virus intra-arterially. Efficacy cannot be determined from these studies but the investigators concluded that NV1020 may render infected malignant cells moderately susceptible to chemotherapy regimens against which they are resistant.[85,90]

G207

G207, derived from the HSV-1 (F) strain, is deleted for both $\gamma_1 34.5$ genes and is further attenuated by insertion of the *lacZ* gene into the $U_L 39$ locus, preventing expression of ribonucleotide reductase. G207 was demonstrated to be safe following direct intracranial injection in both mice and in highly susceptible *Aotus nancymae* primates.[113,282]

The first Phase I safety trial with G207 evaluated direct intratumoral injection of virus in escalating doses ranging from 1×10^6 to 3×10^9 pfu. Several Phase I studies have been performed that demonstrate safety and a modicum of clinical response.[180.178]

G47Δ

G47Δ, directly derived from G207 and thus lacking both $\gamma_1 34.5$ gene copies as well as containing a *lac*Z gene insertion within $U_L 39$, is additionally deleted for the *α47* gene. This latter modification prevents G47Δ from downmodulating MHC-I presentation and additionally alters the kinetics of $U_S 11$ gene expression from late to early in infection.[292] These modifications increase the immunogenicity and replicative ability of G47Δ without affecting neurovirulence.[292] G47Δ reduces tumor mass in multiple models.[291] The *in vivo* efficacy of G207 and G47Δ has been directly compared, with G47Δ providing an equal or improved survival advantage over G207.[162,292,301] A Phase I-II clinical trial investigating the safety and efficacy of G47Δ in recurrent glioblastoma multiforme is currently recruiting patients in Japan.

OncoVEX$^{GM\text{-}CSF}$

OncoVEX$^{GM\text{-}CSF}$ is derived from the pathogenic clinical isolate JS-1.[161] Attenuations in this vector include replacement of both *$\gamma_1$34.5* genes with the gene encoding human granulocyte–macrophage stimulating factor (GM-CSF), and deletion of the *α47* coding sequence such that the *U_S11* gene is expressed from the immediate-early *α47* promoter. OncoVEX$^{GM\text{-}CSF}$ expresses a transgene hypothesized to enhance antitumor effects by complementing the lytic mechanism of tumor clearance. In the case of OncoVEX$^{GM\text{-}CSF}$, this additional mechanism is immune stimulation through the cytokine GM-CSF, a hematopoietic growth factor that promotes the maturation and development of dendritic cells as well as elicits the formation of Th1 skewed immune responses. OncoVEX$^{GM\text{-}CSF}$ is the first armed oncolytic HSV vector to be evaluated in clinical trials.

OncoVEX$^{GM\text{-}CSF}$ has been evaluated in several Phase I clinical trials enrolling patients with refractory cutaneous or subcutaneous metastases of breast, gastrointestinal adenocarcinoma, malignant melanoma, or epithelial cancer of the head and neck.[112] Direct intratumoral injection of 1 or 3 doses (1×10^6 to 1×10^8 pfu) established safety. OncoVEX$^{GM\text{-}CSF}$ is currently being evaluated in malignant melanoma.[256] No severe events were attributable to virus administration.

rRp450

rRp450 is derived from the first-generation vector hrR3. hrR3 was engineered by replacing the *U_L39* gene encoding RR of the wild-type strain KOS with *lacZ*. rRp450 followed with the replacement of the *lacZ* genes with the *CYP2B1*, the gene encoding the rat cytochrome p450 enzyme responsible for prodrug metabolism.[52] Cytochrome p450 2B1 expression is hypothesized to serve as a method of concentrating active metabolites of chemotherapeutics in malignant cells. Notably, rRp450 retains both native copies of *$\gamma_1$34.5*. Preclinical studies with rRp450 demonstrated its selective replication in tumor cells with increased expression of mammalian ribonucleotide reductase, demonstrating a level of targeting afforded by the ICP6 deletion, as well as increased cytotoxicity of these cells when infection was combined with nitrogen mustard alkylating agents *in vitro*.[52] *In vivo* studies demonstrated synergistic efficacy of rRp450 and cyclophosphamide against a model of hepatitic metastases of colon adenocarcinoma in mice.[220]

M032, C134

The engineered HSV recombinants M032 and C134 are similar in that both were originally derived from the wild-type HSV-1 (F) strain. They share identical deletions of the *$\gamma_1$34.5* gene but differ with regard to the inserted genes replacing $\gamma_1$34.5. M032 expresses the human immunostimulatory cytokine interleukin-12 (IL-12). IL-12 promotes the activation of IFN-γ secretion and Th1 polarization of $CD8^+$ T lymphocytes and also has antiangiogenic effects. Preliminary studies of a murine IL-12–expressing virus M002 demonstrate increased survival in intracranial tumor–bearing mice treated with M002, and increased infiltration of innate and adaptive immune cells into tumors.[212]

Currently, the safety of M032, expressing human IL-12, in patients with recurrent glioblastoma is being evaluated in a Phase Ib study (NCT02062827).

C134 expresses the cytomegalovirus (CMV) PKR evasion and IFN-γ resistance molecule

IRS1.[257] IRS1 has equivalent functions as the $\gamma_1 34.5$ gene product ICP34.5 in terms of PKR evasion, but unlike ICP34.5, it does not contribute to neurovirulence. Cells infected with C134 do not undergo PKR-mediated host protein shutoff. This resistance to PKR-mediated host protein shutoff has been found to occur in neuroblastoma cell lines, prompting the submission of an IND application for a Phase I clinical trial of C134 in pediatric patients with recurrent glioblastoma.[46]

Summary

Engineered HSV constructs have been proven consistently safe when administered intracranially to humans at high doses. With some constructs, suggestions of efficacy are apparent. Likely, no one construct or approach will cure all tumors. Future work will need to focus on improving replication competence without sacrificing safety, improving delivery, and gaining a better understanding of host gene expression to optimize the oncolytic approach.

ANTIVIRAL THERAPY

Advances in the treatment of HSV infections have led the way in the development of antiviral therapeutics. The details of antiviral therapy appear elsewhere in this textbook. In the 1970s, vidarabine (adenine arabinoside) was the first licensed antiviral therapeutic for the treatment for HSE and neonatal HSV infections, as well as varicella zoster virus infections in the immunocompromised host. Vidarabine was replaced by acyclovir for the treatment of all HSV infections. Today, acyclovir and its prodrug valacyclovir as well as the prodrug of penciclovir, famciclovir, are the most useful and widely prescribed therapeutics for the treatment of HSV infections. Both valacyclovir and famciclovir have a distinct advantage over acyclovir. Specifically, the oral bioavailability of acyclovir following valacyclovir administration allows for improved pharmacokinetics. The same case is also made of plasma levels of penciclovir following famciclovir administration. The mechanism of action of acyclovir and penciclovir, as well as the details of antiherpetic therapy, is summarized elsewhere. Brief reference will be made to the use of these medications, as well as foscarnet and cidofovir, in the management of HSV infections.

Table 10.3 summarizes the use of the antiviral therapeutics in the treatment of HSV infections. A brief summary of the status of therapy is provided.

TABLE 10.3 Drugs For Herpes Simplex Virus

Infection	Drugs	Adult Dosage[a]
Orolabial	*Topical*	
	Acyclovir: ointment	5% cream 5 times/d x 4 d
	Docosanol	10% cream 5 times/d until healing
	Penciclovir	1% cream applied q2h while awake x 4
	Oral	
	Acyclovir	400 mg PO 5 times/d while awake x 4
	Famciclovir	400 mg PO bid x 7 d
	Valacyclovir	2 g PO q12h x 1 d
Genital		
First episode	Acyclovir	400 mg PO tid or 200 mg PO 5 times/d x 7–10 d[b]
	Famciclovir	250 mg PO tid x 7–10 d
	Valacyclovir	1 g PO bid x 7–10 d
Episodic treatment of recurrences	Acyclovir	800 mg tid or 400 mg PO tid x 3–5 d
	Famciclovir	125 mg PO bid x 5 d
	Valacyclovir	500 mg PO bid x 3 d
Suppression of recurrences	Acyclovir	400 mg PO bid
	Famciclovir	250 mg PO bid
	Valacyclovir	500 mg or 1 g PO 1 time/d
Mucocutaneous (immunocompromised)	Acyclovir	5 mg/kg IV q8h x 7–14 d or 400 mg PO 5 times/d x7–10d
	Famciclovir	500 mg bid x 7–10 d
	Valacyclovir	500 mg or 1 g bid x 7–10 d
Encephalitis	Acyclovir	10–15 mg/kg IV q8h x 14–21 d
Neonatal	Acyclovir	20 mg/kg IV q8h x 14–21 d
Keratoconjunctivitis	Trifluridine	1% solution 1 drop q2h (max 9 drops/d)
Acyclovir resistant (severe infection, immunocompromised)	Foscarnet	40 mg/kg IV q8h x 14–21 d

[a]Dosage adjustment may be required for renal insufficiency.

[b]For severe initial genital herpes, IV acyclovir (5–10 mg/kg q8h for 5–7 d) can be used.

Note: Generic and trade names of drugs are as follows: acyclovir (Zovirax), docosanol (Abreva), penciclovir topical (Denavir), famciclovir (Famvir), valacyclovir (Valtrex), trifluridine (Viroptic), and foscarnet (Foscavir).

Life-threatening HSV infections, including HSE, neonatal HSV infection, and progressive or visceral disease in the immunocompromised host, are routinely treated with intravenous acyclovir. For infections involving the CNS, most notably HSE, mortality is decreased from 70% in placebo recipients to 25% in those who receive intravenous acyclovir therapy. Of the survivors, only 1 out of 3 returns to normal function. For neonatal HSV infection, multiorgan disseminated involvement, as defined above, can be treated with acyclovir with a resultant overall mortality of 25%. Neonatal HSV encephalitis is associated with a mortality of 5% following therapy. For both of these entities, survivors are left with significant neurologic impairment in the majority of cases, namely 60%. Factors that predict a poor outcome include disseminated intravascular coagulopathy and prematurity for those babies with disseminated neonatal herpes, while for those with encephalitis, seizures and prematurity predict a poor neurologic outcome.[136,321,322,326] These data indicate the requirement for improved therapies of HSV infections of the CNS.

Six months of suppressive acyclovir therapy, following 3 weeks of intravenous therapy, has been shown to improve neurologic outcome for newborns with HSV brain disease.[137] In a placebo-controlled clinical trial, the treated babies had Bailey Developmental scores that were 30 points higher on average than those for the controls. These data suggest that low grade continuing viral replication in the brain can be suppressed. Currently, this is the recommended standard of care.[134] Unfortunately, similar benefit was not achieved with valacyclovir suppressive therapy following HSV-1 encephalitis in adults.[93]

Ocular HSV infections are routinely treated with topical trifluorothymidine with or without concomitant oral acyclovir, valacyclovir, or famciclovir therapy. Topical idoxuridine has also been used for ocular infections. Acyclovir, and likely valacyclovir and famciclovir, can be used to suppress recurrences of HSV keratoconjunctivitis. However, it should be noted that no clinical trials of valacyclovir or famciclovir have been performed for this entity.

The most significant advances in antiviral therapy have been achieved in the management of mucocutaneous HSV infections. The prototypic treatment and suppressive regimens have been developed for the management of genital HSV infections. Acyclovir, valacyclovir, and famciclovir all are efficacious in the treatment of both primary and recurrent genital HSV infections. Valacyclovir and famciclovir[242] can be administered to patients on a suppressive basis to prevent reactivation of infection, as occurs more commonly with HSV-2 infections. While these medications significantly reduce the frequency of recurrences and, therefore, the probability of reactivation, periodic excretion of virus still occurs during suppressive therapy and can result in person-to-person transmission of infection. Indeed, even valacyclovir at approved doses does not prevent intermittent shedding of HSV.[64] In a seminal clinical trial, valacyclovir has been shown to decrease person-to-person transmission by approximately 48% when drug is administered once daily at 500 mg.[64] Suppressive therapy can be successfully achieved with valacyclovir administered once daily, whereas famciclovir requires twice daily dosing for suppression. Both valacyclovir and famciclovir[6,242] can be administered for short periods of therapy (3 days and 1 day, respectively) to treat recurrences of genital herpes with efficacy compared to longer treatment regimens.[123]

Acyclovir, valacyclovir, and famciclovir are all approved for the treatment of herpes labialis. As with genital HSV infection, short-course therapy provides excellent therapeutic results. At the present time, while acyclovir has been studied for the management of HSV gingivostomatitis, registrational trials have not been submitted to the US Food and Drug Administration.

HSV infections in the immunocompromised host pose unique challenges. Intravenous acyclovir is used routinely for progressive and/or life-threatening disease. Valacyclovir and famciclovir are useful in the management of HSV infections in individuals with HIV/AIDS. However, in some patient populations, progressive disease occurs in the presence of intravenous acyclovir therapy, implying the development of resistance. The propensity to develop resistance to these medications is greatest in patients with profound immunocompromise, such as hematopoietic stem cell transplant recipients and individuals who have advanced HIV/AIDS with low CD4 counts. When HSV isolates are mapped for resistance, the most common mutations are found in thymidine kinase.[253] Alternatively, mutations have been detected in HSV DNA polymerase rendering acyclovir triphosphate and penciclovir triphosphate ineffective. Under such circumstances, foscarnet or, rarely, cidofovir, drugs with alternative mechanisms of action have been employed.

Future Needs

The development of new antiviral agents for the management of HSV infection has been stymied by the overwhelming success of drugs like acyclovir, valacyclovir, and famciclovir. In large part, the pharmaceutical industry does not identify a niche for the development of future antiviral drugs in this area. Regardless, the persistent mortality and elevated morbidity in patients with HSV infections of the CNS define a medical need for which improved therapy should be

developed. Recently, novel helicase/primase inhibitors have been effective for treatment or suppression in Phase II clinical trials, but clinical development has been stalled because of toxicity in nonhuman primates.[297,305,310]

PERSPECTIVE

HSV infections of humans are ubiquitous, being identified since ancient Greek times. Their unique biologic properties of neurovirulence and the ability to establish latency and recur create unique problems for those biomedical scientists attempting to develop either the ape tics or vaccines. Their ability to persist and cause recurrent disease despite potent host immune responses has stymied efforts to develop effective vaccines. Nevertheless, the application of genetically engineering the virus can turn a potentially lethal virus into a useful therapeutic.

CHAPTER 11

Epstein-Barr Virus

Benjamin E. Gewurz • Richard M. Longnecker • Jeffrey I. Cohen

History
Classification
Virus structure
Genome structure
Steps in replication
- Attachment and entry
- B lymphocytes
- Epithelial cells
- EBV latency programs
- Epigenetic regulation of EBV programs
- Latency gene functions
- EBV lytic replication

Entry into host—portal of entry, site of primary replication, cell types infected
Immune response
- Innate immune response
- Antibody response
- T-cell immune response
- EBV evasion of the immune response

Epidemiology
Primary infection
- Healthy carriers
- Infectious mononucleosis

EBV-associated diseases
- X-linked lymphoproliferative disease
- Chronic active EBV and related disorders
- EBV lymphoproliferative disease: congenital, iatrogenic, and posttransplant
- Burkitt lymphoma
- Hodgkin lymphoma
- Nasopharyngeal carcinoma
- Gastric carcinoma
- Non-Hodgkin lymphomas and other malignancies in nonimmunocompromised persons
- EBV and HIV
- Model for EBV oncogenesis
- Other diseases associated with EBV

Diagnosis

Inhibitors of replication
Treatment
Infectious mononucleosis
EBV posttransplant lymphoproliferative disease
Hodgkin lymphoma
Nasopharyngeal carcinoma
Other therapies
Prevention and vaccines
Perspective
Acknowledgments

HISTORY

In 1958, Denis Burkitt described a tumor in young African children in areas where malaria was holoendemic. This tumor is now referred to as Burkitt lymphoma.[67] In 1964, Epstein, Achong, and Barr discovered a member of the herpes family in cultured Burkitt lymphoma cells using electron microscopy to detect viral particles.[172] The virus was named Epstein-Barr virus (EBV). Gertrude and Werner Henle described an immunofluorescent antibody test for EBV in 1966 finding that patients with Burkitt lymphoma as well as most American adults had antibody to EBV.[243] In 1969, a chance discovery by the Henles in serological studies investigating the prevalence of EBV found that EBV was a causative agent for mononucleosis when a control subject seroconverted and was found to have infectious mononucleosis.[245] Descriptions of patients with symptoms resembling infectious mononucleosis were first reported in the medical literature in the late 19th century and infectious mononucleosis was first named in 1920.[666] Heterophile antibodies were first used in the diagnosis of infectious mononucleosis in 1932.[530] In 1967, EBV was found to immortalize human B lymphocytes in cell culture.[242,550] In 1984, the virus was shown to replicate in human epithelial cells.[641] These discoveries allowed laboratory experimental model systems that provided a means to study the newly identified virus. Sero-epidemiologic evidence that EBV was a cause for Burkitt lymphoma came from pioneering studies of de-The and colleagues.[687] Subsequently, EBV genome positivity was discovered in nasopharyngeal carcinoma (NPC) in 1970,[766] in lymphoma/lymphoproliferative disease in posttransplant patients in late 1970, and in the analogous non-Hodgkin lymphoma in patients with AIDS in 1982,[762] in T-cell lymphoma in 1988,[301] and in some cases of Hodgkin lymphoma in 1989.[728] Since then, the virus has been detected in other malignancies, notably NK cell lymphoma and in a subset of gastric carcinoma. Its potential relationship to nonmalignant diseases such as multiple sclerosis and systemic lupus erythematosus continues to be studied and will be discussed later in this chapter.

CLASSIFICATION

EBV is a member of the gamma herpesvirus subfamily consisting of the gamma 1 or lymphocryptovirus (LCV) genus, which includes EBV and LCVs in nonhuman primates, and the gamma 2 or rhadinovirus (RDV) genus, which includes herpesvirus saimiri (HVS) and Kaposi's sarcoma herpes virus (KSHV, also called HHV8). Many Old World and some New World primate species naturally carry their own LCVs, which are collinearly homologous to EBV. In contrast, RDVs are found not only in most primate species but also in many subprimate mammalian species. Overall, the nucleotide sequences of gamma herpesvirus genomes have substantial collinear homology and much less collinearity and homology with alpha and beta herpesvirus genomes.[145]

Among the gamma herpesvirus genomes, LCVs are likely to have evolved from RDVs. RDVs have more diverse genomes than LCVs, are naturally found in more diverse mammalian species, and characteristically have homologs of multiple cellular cDNAs in their genomes. Old World LCVs have collinear homologous genomes with a unique group of recently evolved nuclear protein-encoding genes, which lack homology to RDV or cell genes and are only partially present in New World LCV genomes. New World LCVs may therefore be intermediates in the evolution of Old World primate LCVs.

LCV genomes are very similar to each other in structure, gene organization, and have collinear homology, albeit with some exceptions in the case of New World LCVs, which as shown by the common marmoset LCV lack two EBNA3 genes, the viral interleukin-10, and EBV-encoded small RNAs (EBERs) when compared to EBV.[583] Shared features include 0.5 kbp tandem terminal direct repeats (TR), 3 kbp tandem internal direct repeats (IR1), and short tandem internal direct repeats (IR2, IR4). RDVs have longer and more highly reiterated TRs and lack long internal direct repeats. Old World primate LCV genes encode latency-associated nuclear antigen proteins EBNA1, EBNA2, EBNA3A, EBNA3B, and EBNA3C, which are expressed when EBV growth transforms primary B lymphocytes to lymphoblastoid cell lines (LCLs). LCVs also include genes that encode latent membrane proteins (LMPs) important for efficient latent infection–associated B-lymphocyte growth transformation and survival,[182] genes that encode two small nonpolyadenylated EBER RNAs,[259,372] genes that encode differentially spliced Bam A rightward transcripts (BARTs), genes that encode an IL-10 and a bcl-2 homolog,[471,531] genes that encode distinctive microRNAs (miRNAs),[542] and a large number of genes that are important for replicating and packaging the genome and infecting target cells (Table 11.1).

TABLE 11.1 EBV-encoded proteins

EBV Gene	HSV	KSHV	EBV Name	Known or Proposed Function
BNRF1		ORF75		Major tegument protein, disrupts DAXX and ATRX complex
BNLF2b				
BNLF2a				Interacts with Tap, immune evasion
EBER1,2				Small RNAs, cell survival factor, PAX5 recruitment to genome
BCRF1				IL-10 homolog—host immune modulator
BCRF2				
BCLT1				Nuclear noncoding RNA—lytic replication
BCRT2				Nuclear noncoding RNA—lytic replication
BWRF1			**EBNALP**	**Regulator of gene transcription (EBNA5)—EBV nuclear antigen**
BYRF1			**EBNA2**	**Regulator of viral gene transcription—EBV nuclear antigen**
BHRF1		ORF16		Bcl-2 homolog
BHLF1				Transcript required for OriLyt function
BFLF2	UL31	ORF69		Required for nuclear egress—binds BFRF1
BFLF1	UL32	ORF68		Virion protein—DNA cleavage/packaging
BFRF1	UL34	ORF67		Nuclear egress—binds BFLF2—ESCRT recruitment
BFRF2		ORF66		Part of vPIC with BDLF3.5, BDLF4, BGLF3, BGLF4, BVLF1
BFRF3	UL35	ORF65		Capsid protein
BPLF1	UL36	ORF64		Tegument protein—deubiquitinase
BOLF1	UL37	ORF63		Tegument protein
BORF1	UL38	ORF62		Capsid assembly
BORF2	UL39	ORF61		Ribonucleotide reductase (large subunit)—inhibits cellular APOBEC3B
BaRF1	UL40	ORF60		Ribonucleotide reductase (small subunit)
BMRF1	UL42	ORF59		Polymerase-associated processivity factor
BMRF2	UL43	ORF58		Transmembrane glycoprotein—binds integrins and BDLF2

EBV Gene	HSV	KSHV	EBV Name	Known or Proposed Function
BSLF2/BMLF1	UL54	ORF57		SM, posttranscriptional regulator of viral gene expression
BSLF1	UL52	ORF56		DNA replication—helicase/primase complex

RPMS1				Interacts with the CBF1-associated corepressor and negatively regulates EBNA2 and Notch
Raji LF1				Part of BILF1
BARTS				microRNAs

Genes in “EBV” column bolded are expressed in latent infection.
In the “HSV” and “KSV” columns, the homology with the proteins underlined with EBV is not significant; however, they may be positional homologs. EBV proteins and RNAs that inhibit the immune system are shown in Table 11.3. EBV, Epstein-Barr virus; HSV, herpes simplex virus; KSHV, Kaposi’s sarcoma herpes virus; IL, interleukin; HLA, human leukocyte antigen; CSF-1, colony-stimulating factor-1; vPic, virus preinitiation complex; GPCR, G protein-coupled receptor; MHC, major histocompatibility complex class I.

The EBV genome and gene organization is shown in Figures 11.1 and 11.2. EBV was the first herpesvirus genome to be completely cloned in sets of overlapping fragments based in part on previously derived restriction endonuclease maps generated by Elliott Kieff’s laboratory.[141,142] The EBV genome was subsequently sequenced from BamHI digested cloned DNA fragments[27] and open reading frames (ORFs) were designated by their order in a rightward or leftward direction within each BamHI fragment, which were given letters based on the size of the fragment[27] (Fig. 11.2 and Table 11.1). The majority of KSHV-predicted ORFs are collinearly homologous to ORFs of EBV[594] (Table 11.1), emphasizing the common evolutionary origin of the gamma 1 and gamma 2 herpesviruses. LCVs and RDVs also have analogous but nonhomologous DNA sequences encoding nuclear proteins that are necessary and sufficient for persistence of the genomes as episomes in dividing cells.[744]

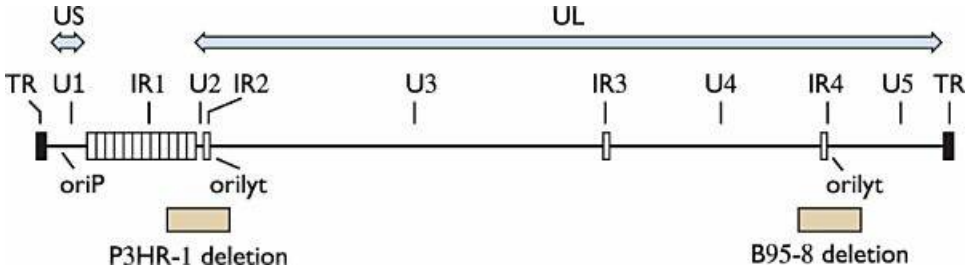

FIGURE 11.1 Schematic depiction of the linear Epstein-Barr virus (EBV) genome. Linear representation of the overall genome arrangement with the unique short (US) and unique long (UL) regions shown. Within the genome the terminal repeats (TR), internal repeats (IR1-4), and unique sequence domains (U1-U5) of the EBV genome are depicted in proportion to their overall size. The position of the cis-acting element for episome maintenance and replication in latent infection, oriP, is indicated. The origins for EBV DNA replication in lytic infection (oriLyt) are in U3 and U5 just to the right of IR2 and IR4, respectively. The deletions in B95-8 and P3HR-1 genomes are shown.[235,286,300]

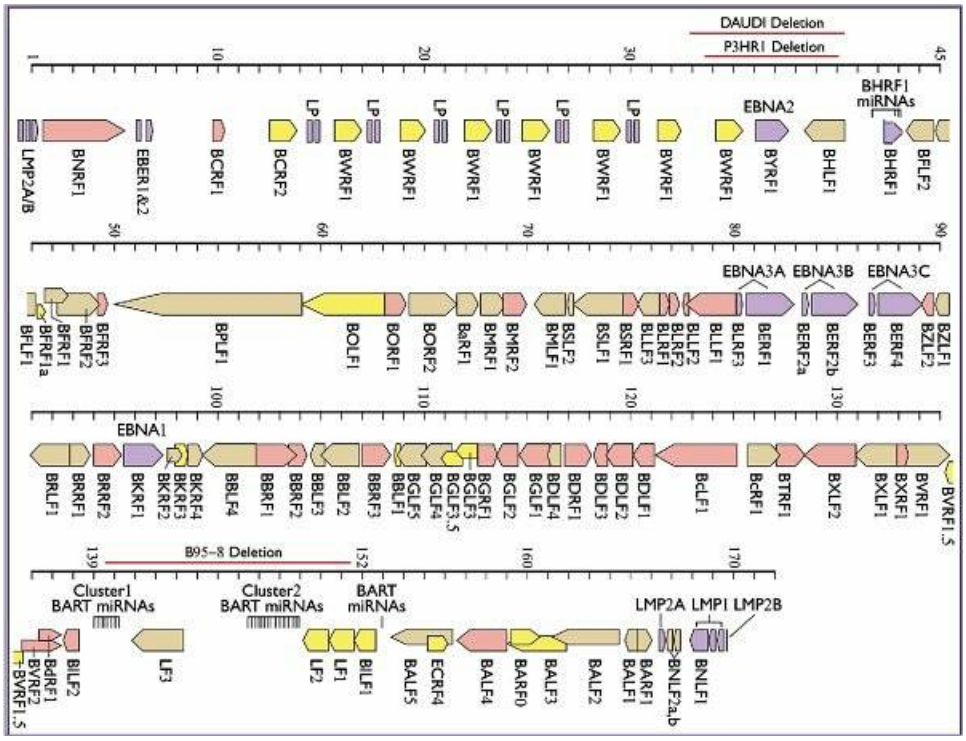

FIGURE 11.2 Schematic depiction of the linear Epstein-Barr virus (EBV) genome with encoded open reading frames (ORFs). EBV ORFs are named based on their location (first ORF, second ORF, etc.) and direction (rightward or leftward) within the Bam H1 fragment (A, B, C, and so on, in decreasing size).[27] The prototypic EBV type 1 genome DNA sequence (171,820 bp) found in the National Center for Biotechnology Information (NCBI) is actually a composite of two viral genomes (B95-8 and Raji) due to deletions within the viral genomes during passage in tissue culture.[27,526] Size and direction of the ORFs are indicated, as are the noncoding RNAs EBER1 and EBER2.

The latency-associated ORFs or exons that make up these ORFs are colored purple. The early lytic ORFs are beige and late lytic ORFs are shaded with red. *Yellow arrows* depict ORFs of unknown gene class or are hypothetical. LMP2A and LMP2B are encoded across the circularized genome. The locations of microRNA (miRNAs) encoded by the genome are shown. Numbers refer to kilobase pairs. More broadly, all alpha, beta, and gamma herpesvirus DNAs have conserved distantly homologous gene blocks with conserved gene order and collinear homology at the predicted protein level (see Chapter 8).[145] These are primarily genes that encode proteins involved in nucleotide metabolism, proteins that replicate and process viral DNA, and proteins that comprise the structural components of the virion capsid, tegument, and envelope. In addition, genes that are at least partially shared among the gamma herpesviruses and have more limited representation in the genomes of other herpesviruses include BZLF1 and BRLF1, which encode the immediate-early regulators of viral gene expression, BALF1, which encodes a bcl-2 homolog and LMP1 and LMP2A, which encode integral membrane proteins with 6 and 12 membrane spanning domains, respectively.

The gamma herpesvirus subfamily classification was initially established on the basis of biologic properties including oncogenic associations and restricted host range for infection in cell culture. Gamma herpesviruses also establish latent infection in lymphocytes but are not unique in this regard. Beta herpesviruses such as HHV-6, HHV-7, and CMV can also latently infect lymphocytes and other hematopoietic cells. Segregation into the gamma herpesvirus subfamily based on nucleotide and protein sequence homology and genome collinearity provides a more enduring basis for phylogenic classification.[145] Taxonomists have named EBV as human herpes virus 4 (HHV4), although EBV is typically used.

Two EBV types circulate in most populations. EBV type 1 and 2 (also named types A and B, respectively) differ largely in EBV nuclear antigen (EBNA) genes that encode leader protein (EBNA-LP), EBNA2, EBNA3A, EBNA3B, and EBNA3C, which are expressed in latency III growth transformation of B cells to LCLs.[606] The type 1 and 2 alleles for EBNA2, EBNA3A, EBNA3B, and EBNA3C differ in predicted primary amino acid sequence by 47%, 16%, 20%, and 28%, respectively. Both types are present worldwide but type 1 EBV is the more common type in most populations, particularly so in the developed world, whereas type 2 EBV reaches its highest prevalence among people in equatorial Africa and New Guinea.[159] Type 1 and 2 EBV may also be found in throat washings from immunocompromised patients, particularly HIV-infected people, who may be colonized with both EBV types and even with multiple strains of those types. Intertypic recombinants and EBNA2 deletions have been identified in the oropharynx and lymphocytes of immunocompromised people and less commonly from otherwise healthy people.[642] Aside from the EBNA differences, the genomes of EBV type 1 and 2 differ little more than that found among individual strains of either type, which mostly differ in inter- and intragenic small and large repeats. Similarities in the numbers of DNA repeats at various sites in the EBV genome among EBV isolates from a given geographic area have been used to group isolates into strains and to epidemiologically track EBV infection.

VIRUS STRUCTURE

Like other herpesviruses, EBV has a toroid-shaped DNA core in a nucleocapsid with 162 capsomeres, an outer envelope with external glycoprotein spikes, and a protein tegument between the nucleocapsid and envelope[160,297] (Fig. 11.3). EBV capsids from purified enveloped virus are composed of the 155 kD major capsid protein BcLF1, 30 kD minor capsid protein, 18 kD small capsid protein, 40 kD minor capsid protein binding protein, and 68 kD portal protein BBRF1. The EBV tegument is composed of the 350 kD large tegument protein BPLF1, 140 kD large tegument protein binding protein BOLF1, 15 kD myristoylated protein BBLF1, 32 kD Myristoylated protein binding protein BGLF2, 58 kD capsid associated protein BVRF1, 58 kD packaging protein BGLF1, 27 kD palmitylated protein BSRF1, and 47 kD serine–threonine protein kinase BGLF4, which are common components of herpesvirus teguments.[297] In addition, EBV has a 140 kD major tegument protein BNRF1, 19 kD BLRF2, 72 kD BRRF2, 54 kD BDLF2, and 42kD BKRF4, which are gamma herpesvirus specific.[297] Cellular proteins including actin, HSP70, cofilin, β-tubulin, enolase, and Hsp90 are also significant components of the EBV tegument, potentially related to cytoplasmic re-envelopment. The major glycoprotein components of the envelope are gp350 (BLLF1), gH (BXLF2), gB (BALF4), gp42 (BZLF2), gM (BBRF3), gp78 (BILF2), gN (BLRF1), gp150 (BDLF3), and gL (BKRF2) and were also observed in virions.[297] Some EBV-encoded proteins, notably the EBNAs, LMP1, LMP2, gp64 (BILF1), BMRF2, and the homologs of HSV UL7 (BBRF2), UL14 (BGLF3), UL31, (BFLF2), and UL34 (BFRF1) were not detected in EBV virions.[297]

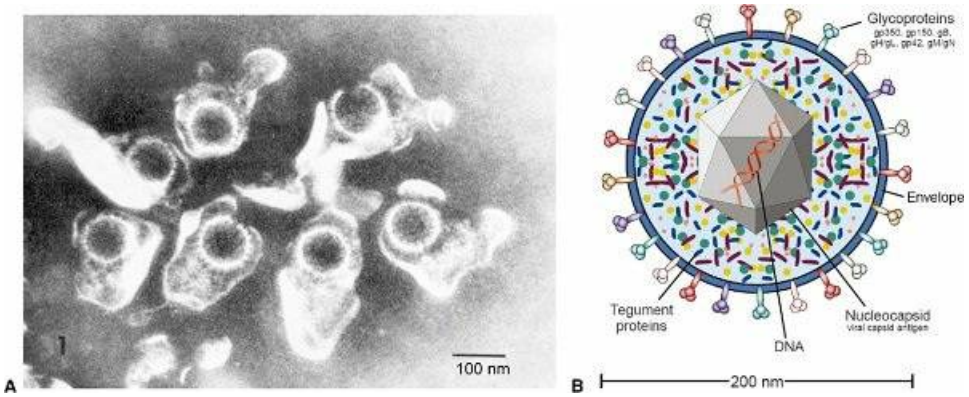

FIGURE 11.3 Electron micrograph and schematic diagram of EBV virions. A: EBV particles purified from the supernatant of B95-8 marmoset cells. Bar represents 100 nm. (Republished with permission of Rockefeller University Press from Miller G, Lipman M. Comparison of the yield of infectious virus from clones of human and simian lymphoblastoid lines transformed by Epstein-Barr virus. *J Exp Med* 1973;138(6):1398–1412; permission conveyed through Copyright Clearance Center, Inc.) **B:** Diagram of EBV virion. The major structural components of the virion are shown including the virion envelope, which is studded with glycoproteins important for binding and subsequent fusion of the virion envelope with cellular membranes, the tegument, which contains both virus-encoded proteins as well as cellular proteins, the

capsid, and viral genome.

GENOME STRUCTURE

The EBV genome is a linear, double-stranded DNA composed of 60 mole percent guanine and cytosine as elegantly shown by Elliott Kieff prior to sequencing of the EBV genome.[27,325] As a historic first, the EBV genome was the first genome fully sequenced by a conventional subcloning and Sanger sequencing strategy.[27] The prototypic EBV type 1 genome DNA sequence (171,823 bp) found in NCBI (GI:82503188) is actually a composite of two viral genomes B95-8 and Raji, both of which carry deletions within the viral genome that may have occurred during passage in tissue culture (Fig. 11.1).[27,526] B95-8 was selected for virus production in culture and was found to be deleted for the BARTs, which is discussed in the EBV miRNAs section of this chapter.[566,648] B95-8 remains the most extensively studied EBV strain. P3HR1, another deletion virus, was important for the discovery of the essential role of EBNA2 before genetic manipulation with the EBV genome was possible (see EBNA2 section in this chapter) and the role of the Z protein in initiation of lytic replication (see lytic replication in this chapter).[135,235,286,300] Type 2 strains have been sequenced and the prototypic type 2 stain deposited in NCB1 (AG876) is 172,760 bp and as described above is highly homologous to type 1 EBV.[159] An isolate of an EBV type 1 strain (M81) has an increased ability to infect epithelial cells, reduced ability to infect B cells, and increased lytic replication, and has been proposed as a new EBV subtype.[698] The characteristic features of EBV and most other LCV genomes include (a) a single overall format and gene arrangement; (b) 2 to 5 tandem, 0.5 kbp, direct repeats of the same sequence at both termini (TR)[209]; (c) 6 to 12 tandem reiterations of a 3 kbp, internal direct repeat (IR1); (d) short and long largely unique sequence domains (US and UL) that have almost all of the genome coding capacity; (e) perfect and imperfect tandem DNA repeats, most of which are within ORFs; and (f) a duplicated region, IR2, near the left end of UL, which consists of multiple, highly conserved, G-C rich, tandem 125 bp repeats and 2 kbp of adjacent unique DNA, all of which have extensive homology to a region, IR4, near the right end of UL. IR4 is comprised of G-C rich, tandem 102 bp repeats and 1 kbp of nearby unique DNA. The IR3 and IR4 repeats are within ORFs. Because the IR3 repeat is 125 kbp and not divisible by three, sequential iterations are translated in different reading frames, resulting in an unusual protein. IR3 and IR4 also include the origins for initiation of viral DNA replication.[227]

The reiteration frequency of the EBV tandem perfect repeats becomes variable during viral DNA replication, with the average number of repeats being identical to the parent genome and most of the progeny having similar numbers of repeats as the parental genome. When EBV infects a cell, the genome becomes an episome with a characteristic number of TRs, dependent on the number of TRs in the parental genome, and the unique cleavage and joining events of the single infecting viral genome. If infection is nonpermissive for viral replication and permissive for latent infection and continued cell growth, each EBV episome in progeny infected cells will usually have the same number of TRs as the parent cell. Homogeneity or heterogeneity in the number of TRs is therefore useful in determining whether a group of latently infected cells arose from a single common progenitor infected cell or from multiple progenitors.[568] The number of 3

kbp IR1 repeats also varies among EBVs and among progeny of EBV replication but is more difficult to assess as a marker of heterogeneity because of the 18 to 30 kbp total size. Other, smaller, imperfect, or less highly reiterated repeats within ORFs are more stable during replication but differ sufficiently among different virus isolates so that the size of the encoded proteins can be used to uniquely identify each isolate.

STEPS IN REPLICATION

Attachment and Entry

EBV uses different glycoprotein combinations to infect B cells and epithelial cells (Fig. 11.4), but similar to other human herpesviruses, the core fusion complex consists of gB (originally designated gp110) and gH/gL (originally designated gp85/gp25). Antibodies directed against the core EBV fusion complex can potently neutralize fusion and infection.[613,653] EBV gB is the fusogen for viral entry, and the gB structure is composed of trimers and is similar to the structure of HSV gB.[26,239] The solved gB structure likely represents a postfusion conformation since the structure is very similar to the low-pH or postfusion form of G protein of vesicular stomatitis virus.

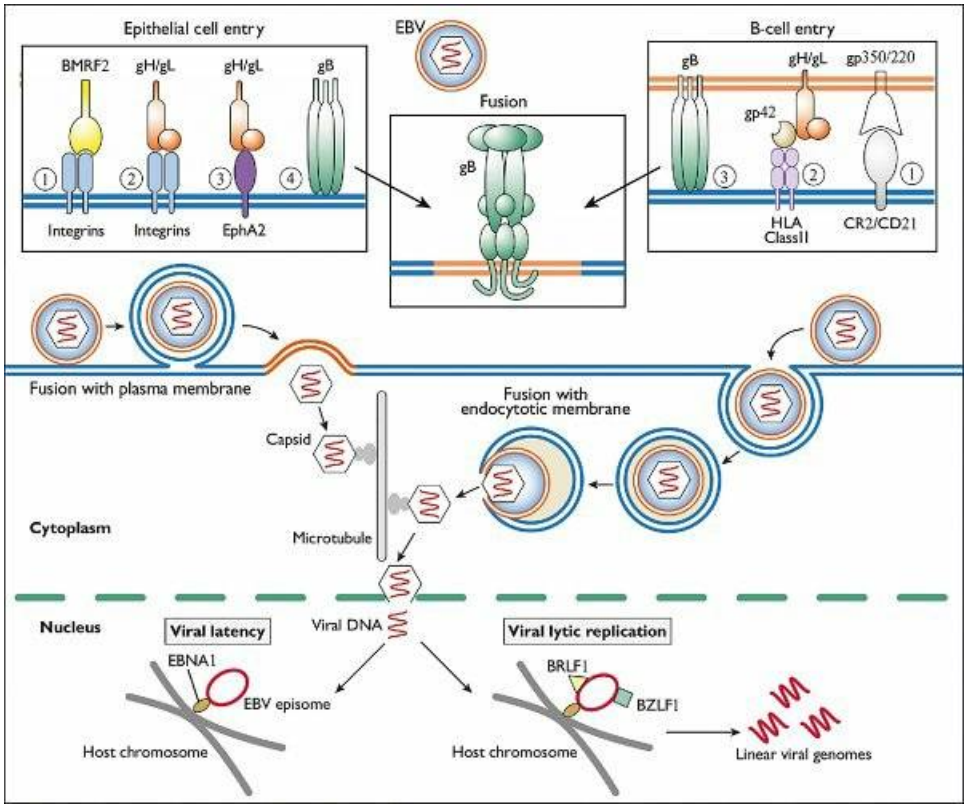

FIGURE 11.4 EBV entry and replication in epithelial and B cells. EBV enters B cells by fusion with an endocytic membrane after endocytosis. EBV enters epithelial

cells by fusion at the plasma membrane. For B-cell entry, EBV virions first bind to CR2/CD21 via gp350/220 (*1*). Following this interaction, gp42 binds to HLA class II (*2*) triggering fusion mediated by gH/gL and gB (*3*). For epithelial cell entry, EBV virions may first bind via an interaction of integrins with BMRF2 (*1*). Following this binding, gH/gL binds to ephrin A2 (*2*) and triggers fusion mediated by gB (*3*). For both B and epithelial cells, following fusion, the capsid is released into the cytoplasm and is transported to the nuclear membrane by microtubule-mediated transport. The EBV genome is released into the nucleus through a nuclear pore. Latency can result, in which the genome is tethered to host chromosomes via an interaction with EBNA1. Lytic replication resulting in the production of viral genomes may also result, induced by the BRLF1 and BZLF1 EBV gene products.

B Lymphocytes

B lymphocytes and epithelial cells are the major sites for EBV infection in the human host. CD21, also known as complement receptor 2 (CR2), is critical for EBV B-cell entry. Reflecting the importance of CD21 for B-cell infection, CD21 is abundantly expressed on B cells and binds the virus-encoded gp350/220.[184] gp350/220 has homologs in primate gamma herpesviruses, but there are no sequence-related proteins in the other human herpesviruses. CD21 is expressed on mature peripheral CD3+ T cells, with a higher level of expression on the naive CD4+ and CD8+ T-cell subsets and has recently been shown to be an entry receptor for the virus into T cells.[650] gp350 and gp220 are encoded by the same mRNA, but a single splice generates the gp220 reading frame.[269] No known distinct function of either gp350 or gp220 has been determined since they both contain the domain that binds CD21.[681] CD35 also binds gp350/220 and functions to allow EBV attachment to B cells.[514]

CD21 is the receptor for the C3d component of complement and is part of a large family of complement regulatory proteins. Family members have one or more extracellular structural motifs known as short consensus repeats (SCRs). As well as being expressed on B cells, CD21 is expressed on other cell types including tonsillar epithelial cells.[288] The extracellular domain of CD21 contains multiple SCRs, but only SCR-1 and SCR-2 are required for EBV and C3d binding.[86,404] Soluble CD21 binds to the EBV virion and can block B-cell infection.[499] The structure of the key gp350 binding domain on CD21 was solved[562] and the region of gp350 required for binding to CD21 is contained within a portion of gp350 that is not glycosylated.[675] Compatible with this finding, deglycosylated gp350 binds to CD21 as does the fully glycosylated gp350.[675]

Binding of EBV virions or a soluble form of gp350 to CD21 results in capping of CD21 followed by endocytosis[498,681] indicating a putative role of signal transduction in EBV B-lymphocyte entry. The binding of gp350/220 to CD21 parallels the interaction of HSV gC with cell surface proteoglycans in tethering virions to target cells. This initial step is not absolutely required for infection since EBV deleted for gp350/220 or HSV-1 deleted for gC have only modest defects in virus entry *in vitro* when infections are performed with high virus titers. After binding to B cells, EBV virions are endocytosed[460] and fusion of the viral membrane is thought to occur via the interaction of gp42 with HLA class II followed by fusion mediated by gH/gL and gB.

HLA-DR was found to bind gp42 in an expression library screen for proteins that bound a soluble form of gp42.[665] Both structural and functional studies have shown that gp42 exhibits features of the C-type lectin family[480,665] and has no known sequence homologs in other human herpesviruses but is found in the EBV-related primate viruses. The gp42/HLA-DR interaction is essential for EBV infection of B cells since antibodies to gp42 and HLA-DR block infection.[380,459] In addition, virus deleted for gp42 does not infect B cells unless soluble gp42 is provided in trans or polyethylene glycol is added to promote fusion.[713] Also indicative of the important role of gp42 in B-cell infection, virosomes lacking gp42 bind B cells but are unable to fuse.[225] The binding site of gp42 on HLA class II has been extensively studied by mutagenesis[224] and by protein crystallography.[480] Specific HLA-DR alleles correlate with EBV infection and binding to gp42.[106,376] Because of the key role of antigen presentation, studies have suggested that gp42 may block HLA class II antigen presentation preventing CD4 T-cell activation.[579,665]

gp42 stably interacts with gH/gL and links receptor binding with fusion mediated by gH/gL and gB. The structure of gp42 not bound to receptor indicates that a conformational change occurs upon binding of gp42 to HLA class II, widening a hydrophobic pocket on the surface of gp42, which suggests a conformational change is important in triggering fusion by engaging other components of the EBV fusion complex.[336] The EBV gH/gL structure has also been solved,[437] revealing an elongated rod-like shape, with the middle being the widest and gL forming intimate contacts with the N-terminal residues of gH. These features are compatible with the known chaperone function of gL for gH expression, processing, and transport.[742] Of particular interest, a KGD sequence found on the gH/gL surface is implicated in integrin binding and epithelial cell entry.[437] Validating the central role of gH/gL in EBV entry, gH mutants within a gH glycosylation site, the cytoplasmic tail, or a large groove that separates domain 1 and domain 2 of gH/gL all have defects in fusion.[100,101,467]

The structure of gH/gL/gp42 complex bound to an anti-gH/gL antibody (E1D1) has been solved.[611] In these studies, it was shown that gp42 interacts with gH/gL via two domains in the gp42 amino terminus located outside the gp42 C-type lectin domain.[335,380,396] gp42 domains cross three domains on the gH surface. Both the binding of the gp42 N-terminal domain and E1D1 to gH/gL selectively inhibit epithelial cell fusion; however, they engage distinct surfaces of gH/gL. The extensive structural and mutational studies of EBV entry proteins has led to a model for the assembly of the putative B-cell entry complex comprised of gH/gL, gp42, and HLA class II (Fig. 11.5).[612] These studies provide a snapshot of an intermediate state in EBV entry and highlight the potential for the triggering complex to bring the two membrane bilayers into proximity by interactions of the constituents of the complex based on an “open” and “closed” form of the complex observed in CryoEM. These open and closed forms resemble those previous seen in Cryo-ET studies done with HSV-1.[438] Interestingly, in this assembled complex, gH/gL interacts with the gp42 hydrophobic pocket. This result suggests that following receptor engagement, binding of gp42 may drive fusion mediated by gH/gL and gB by bringing the viral and cellular membranes together. Previous studies indicated that a domain containing gL amino acids Q54 and K94[546] is important for triggering gB and may specifically interact with EBV gB to trigger fusion (Fig. 11.5).

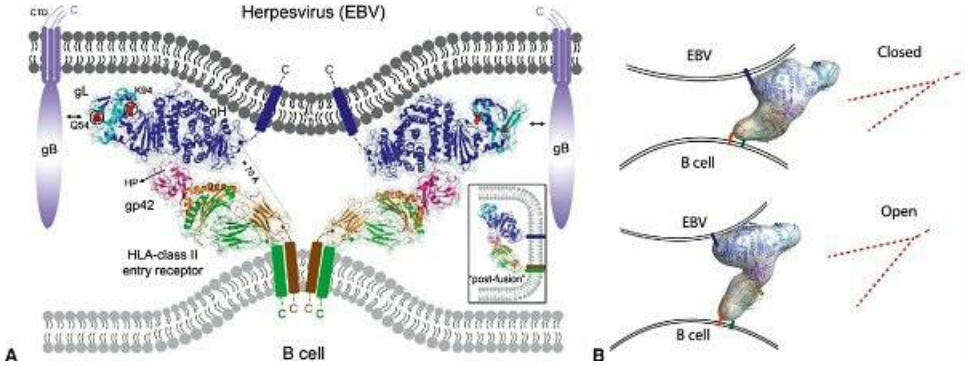

FIGURE 11.5 Proposed EBV B-cell entry complex required for B-cell fusion.[612] **A:** *Top* represents the viral membrane bilayer with prefusion gB (*purple*), gH/gL (*blue/cyan*), and gp42 (*hot pink*). The structure of gB in a prefusion form is not known. HLA class II (*green/brown*) is at the *bottom*. Locations of the transmembrane (TM) domains of gH and HLA are indicated schematically with rectangles since no structural data are available (*blue*—HLA and *green/brown*—class II). The C-termini of gH and HLA class II are also indicated. gp42 is a type II transmembrane protein and the N-terminal TM domain must be cleaved for it to be active in fusion. The location of the gp42 N-terminus is not known. The approximately 170 Å long complex shown suggests a conformation that could bridge viral–cellular membranes potentially distorting and thereby facilitating fusion between the viral and cellular membranes. This model places gL residues (Q54 and K94) involved in gB activation[546] on the opposite side of the gH and HLA membrane anchors. The external location of gB implied by this model may indicate an initial peripheral activation of gB followed by its movement to a more central position to mediate membrane fusion. The gp42 hydrophobic pocket (HP), which is critical for fusion activation and located at the gH D-II/D-III junction, is highlighted to show its location with respect to the triggering complex. A potential postfusion arrangement is shown in the **inset. B:** Representation of the V/Y shape of the respective open and closed triggering complexes highlighting their similarity to the structures observed in cryo-ET studies of HSV-1 entry described in.[612] (Reprinted from Sathiyamoorthy K, Jiang J, Hu YX, et al. Assembly and architecture of the EBV B cell entry triggering complex. *PLoS Pathog* 2014;10(8):e1004309. https://creativecommons.org/licenses/by/4.0/.)

EBV virions produced by B cells have reduced gp42 as a consequence of gp42 binding to HLA class II, which is present in infected B cells, during lytic replication.[57] EBV deficient in gp42 is defective in B-cell infectivity but is enhanced in epithelial cell infectivity.[57] The absence of gp42 enables the gH/gL complex to engage an epithelial cell receptor, which is otherwise occluded by gp42. During virus egress from epithelial cells, the absence of HLA class II results in virions containing gp42 bound to gH/gL that efficiently infect B lymphocytes.

Epithelial Cells

In contrast to B-cell entry, EBV entry into epithelial cells occurs at the cell surface in the absence of endocytosis.[460] CD21 is expressed in tonsil epithelium, but not in epithelium from buccal

mucosa, uvula, soft palate, or tongue by RT-PCR suggesting that the gp350/222 interaction with CD21 may be important for epithelial cell infection.[288] BMRF2 may also have a role in epithelial cell entry. BMRF2 is a multispan membrane protein that contains an extracellular RGD motif that is a ligand for α1, α5, α3, and αv integrins.[737] This interaction is important for infection of polarized epithelial cells,[701] and antibodies to BMRF2 or to α5β1 integrin block EBV infection of polarized epithelial cells through the basolateral cell surface. Interestingly, BMRF2 is not abundant in the EBV virion[297] and appears not to have a role in fusion, so BMRF2 may function similar to gp350/220 to tether virions to target cells and to induce signal transduction pathways. Integrin signaling has been shown to be important in Kaposi's sarcoma herpesvirus (KSHV) infection.[631] Integrins αVβ5, αVβ6, and αVβ8 bind to gH,[106] but this interaction is not required for the triggering of fusion. Earlier studies had shown that a soluble form of gH/gL bound specifically to epithelial cells, but not B cells.[58] In addition, gH-null virus does not bind to epithelial cells[468,513] and a monoclonal antibody to gH/gL can reduce both gH/gL and virus binding.[58,468] In more recent studies, integrin αV knock-out HEK293 cells were generated using the CRISPR-Cas9 system. No difference between WT HEK293 and integrin αV knock-out HEK293 cells were found for viral infection or fusion activity, indicating that integrins are not essential for entry in HEK293 cells and may function as entry mediators.[104] In these same studies, a novel and more rapid approach using readily available RNA-seq databases was used to identify potential epithelial cell receptors and Ephrin A2 (EphA2) was identified as an EBV receptor for epithelial cells.[104] Another group independently identified EphA2 also as an EBV receptor in epithelial cells using microarray and RNA interference screen and CRISPR analyses.[749] EphA2 belongs to the largest receptor tyrosine kinase (RTK) family, with 14 known human members that play roles in boundary formation, cell migration, axon guidance, synapse formation, angiogenesis, proliferation, and cell differentiation. EphA2 is also a receptor for KSHV, another human gammaherpesvirus.[226]

Other modes of EBV infection may also exist for virus entry. Virus coated with IgA can bind to the polymeric IgA receptor.[643] This form of infection may be relevant in NPC, where high levels of EBV-specific IgA antibodies are found in the blood.[244] However, EBV is transcytosed in polarized epithelial cells without evidence of replication.[204] Interestingly, antibodies directed against gp350/220 can enhance EBV epithelial infection independent of Fc receptor interactions, and cell contact also enhances epithelial infection.[628,702] Cell-associated virus is very efficient in infecting epithelial cells or B cells.[278,630] Recently, a novel mechanism for EBV infection was reported for nonsusceptible epithelial cells through the formation of cell-in-cell structures.[500] Epithelial CNE-2 cells that are resistant to infection were invaded by EBV-infected Akata B cells to form cell-in-cell structures *in vitro*. Interestingly, similar unique cellular structures were observed in biopsies of NPC. How these different routes of infection impact EBV infection in humans requires further investigation.

EBV Latency Programs

An intriguing aspect of EBV is its ability to establish different types of latent B-cell infection. EBV switches between latency programs to navigate the B-cell compartment and to colonize memory B cells, the reservoir for lifelong EBV infection. Up to 9 EBV proteins are expressed in EBV latency programs (Table 11.1).[556,600] These include 6 EBNAs, 2 LMPs, and the viral BCL2 homolog BHRF1. Their key functions are shown in Table 11.1. EBV latency genes are

conserved with closely related primate LCVs but not with other herpesviruses. In addition to protein products, 2 highly abundant Epstein-Barr encoded RNAs (EBERs) and up to 44 viral miRNAs are expressed.

Following primary B-cell infection, the EBV W promoter (*Wp*) drives transcription of a message that encodes EBNA-LP and EBNA2 (Fig. 11.6).[478] While this message potentially encodes all six EBNAs, at very early time points EBNA2 and EBNA-LP are preferentially expressed. BHRF1 is also expressed at low levels, and T cells can recognize BHRF1 epitopes in newly infected cells.[63,317] A *Wp* upstream element recruits YY1, Pax5, and additional transcription factors that together provide B-cell tropic expression.

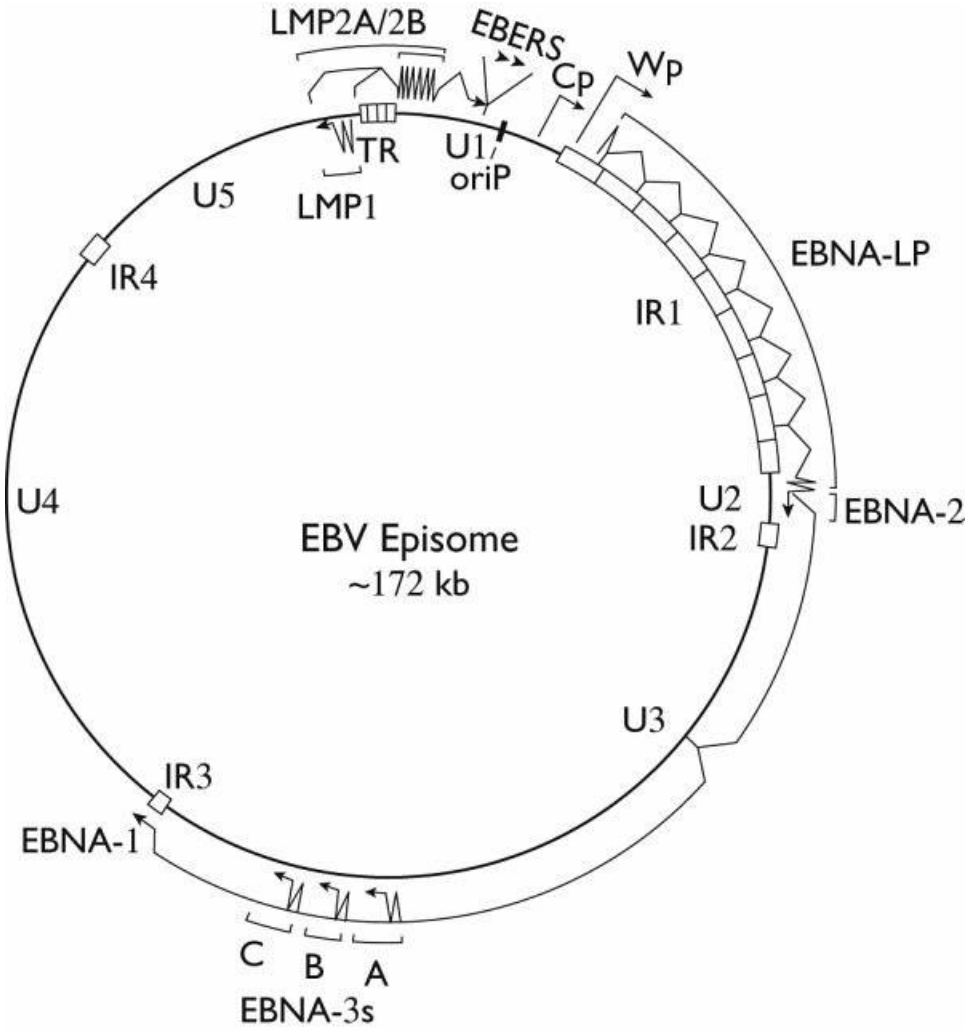

FIGURE 11.6 Schematic depiction of the EBV episome. The EBV episome is circularized through terminal repeats (TR). Shown are the transcripts, mRNAs, and major proteins in type III latent B-lymphocyte infection. Largely unique (U1-U5) and internal (IR1-4) or terminal (TR) repeat DNA segments are indicated. The origin for latent infection EBV episome replication, oriP, is also indicated. Exons encoding EBV nuclear proteins (EBNA1, EBNA2, EBNA3A, EBNA3B, EBNA3C, and EBNA-LP) or EBV integral latent membrane proteins (LMP1, LMP2A, or LMP2B) are indicated by

vertical lines radiating from the circular episome map. EBNA transcription is shown as it is first initiated from the IR1 or Wp. In many infected lymphocytes, after expression of EBNA-LP and EBNA2, *Cp* in U1 dominates EBNA transcription. Alternative polyadenylation and splicing result in expression of the various EBNA mRNAs. EBNA-LP is encoded by repeating exons from IR1 and two short unique exons from U2. The EBERs are two small, nonpolyadenylated, RNAs. LMP1 is transcribed in direction opposite to the EBNAs, LMP2A, and LMP2B, and EBERs. LMP2A has an upstream EBNA2 response element, whereas LMP1 and LMP2B share the same EBNA2 response element.

EBNA-LP and EBNA2 reach levels significantly higher than those observed in LCLs by 48 hours postinfection,[478,721] contributing to major host transcriptome and proteome remodeling. At 72 hours postinfection, some infected cells rapidly proliferate.[505,543,723] Together with host factors, EBNA2 activates the EBV C promoter (*Cp*). The *Cp* CBF1 region associates with RBP-Jκ, which recruits EBNA2. The CBF2 region recruits Pax5.[693] Interestingly, *Cp* and *Wp* are mutually exclusive, and posttranscriptional mechanisms repress *Wp* upon *Cp* activation.[263,563]

Cp and *Wp* regulation is complex. RBP-Jκ/CBF1 is a host sequence specific transcription factor that associates with *Cp* and recruits EBNA2 to this and other key DNA sites. EBNA2, EBNA-LP, and EBNA1 promote *Cp*/*Wp* activity, whereas EBNA3 proteins compete with EBNA2 for binding to CBF1 to down-modulate their activity.[298,429,585,586]

Cp initially drives the viral latency IIb program, where an approximately 125 kilobase EBV transcript is alternatively spliced for expression of six EBNAs.[8,35,38,219,232,386,393,537,604,663,664] BHRF1 is also expressed, at low levels.[478] EBNA3A, EBNA3B, EBNA3C, and EBNA1 reach levels seen in LCLs at approximately 72 hours postinfection.[478,721] Pol II stalling at *Cp* promotes EBNA expression by regulating nucleosome assembly, recruiting pTEFb and maintaining Pol II C-terminal domain phosphorylation.[519] EBNA1 levels increase to assure EBV episome transmission to progeny cells and to enhance transcription from promoters around *oriP* (the origin for latent viral replication), which includes an EBNA1-dependent enhancer and an EBNA1-dependent replication origin.[28,203,576,577]

Wp and *Cp* are each important for EBV-driven B-cell transformation *in vitro*. Deletion of the control region of the upstream *Wp* copy, which also effects *Cp* activity, decreases *in vitro* B-cell transformation efficiency. Compensatory use of downstream *Wp* copies allows for a reduced level of B-cell outgrowth. *Cp* deletion reduces EBV B-cell transformation efficiency by greater than 100-fold.[672] LCLs derived from wild-type and *Cp* deletion mutant EBV have similar EBNA levels, suggesting that *Wp* can support EBV oncoprotein expression in the absence of *Cp*.[693,746]

Latency III, also called the EBV growth program, is defined by the viral transcripts observed in LCLs with expression of six nuclear antigens (EBNAs 1, 2, LP, 3A, 3B, 3C), three membrane antigens (LMP1, LMP2A, and LMP2B), BHRF1, and noncoding RNAs.[689] BNRF1 is expressed at low levels.[4,6] EBNA2 activates the promoters that drive LMP1 and LMP2, whose levels increase over the first 2 weeks postinfection.[478,558] NF-κB, AP-2, and early B-cell factor also up-regulate LMP promoters.[150,489]

Latency III likely serves to expand the pool of EBV-infected B cells *in vivo* and drives continuous LCL proliferation in tissue culture. Latency III also up-regulates adhesion molecules

and plasma membrane receptors that are thought to drive EBV-infected B cells into lymph node germinal centers, possibly for memory cell differentiation. Within the germinal center, EBV-infected cells are thought to switch to the latency II program, with EBNA1, LMP1, LMP2, and noncoding RNA expression. The viral Q promoter (*Qp*) drives EBNA1 expression, whereas LMP promoters (*LMPp*) drive LMP1/2.

Latency I is expressed in memory B cells, where EBNA1 is the only viral protein expressed (Table 11.2). Latency I is also observed in most EBV-positive Burkitt lymphomas. In latency I, EBNA1 transcription is driven by *Qp*, located more than 50 kb downstream from *Cp*.[402,483,512,615,616] However, EBNA1 negatively regulates *Qp*, allowing low EBNA1 levels for immunoevasion.[483,603] EBNA1 is not translated in resting memory cells, resulting in the latency 0 state, in which EBV evades T-cell detection in this important reservoir cell by silencing all viral encoded proteins. In up to 15% of endemic BLs, EBNA2 deleted virus is present and is associated with *Wp* activation, broadening the expression pattern seen in latency I.[317] In addition to expressing EBNAs 1 and 3, *Wp*-restricted Burkitt lymphomas express BHRF1. BHRF1 interacts with proapoptotic BH3-only family members BIM, BID, PUMA, and BAK, confers resistance to multiple apoptotic stimuli, and accelerates MYC-driven lymphomas in a mouse transgenic model.[187]

TABLE 11.2 EBV latency gene expression patterns

Latency	EBERs	EBNA1	EBNA2	EBNA3	EBNA-LP	LMP1	LMP2	BART miRNAs	BHRF1	Disease
0	+	–[a]	–	–	–	–	–	?	–	Blood in healthy carriers
I	+	+[b]	–	–	–	–	–	+	–	BL, gastric carcinoma
IIa[c]	+	+[b]	–	–	–	+	+	+	–	NPC, HL,TCL
IIb	+	+	+	+	+	–	–	+	+	DLBCL
III[d]	+	+[e]	+	+	+	+	+	+	+	PTLD

[a]EBNA1 is expressed only when cells divide.

[b]EBNA1 is driven by the *Q* promoter.

[c]A form of latency termed I/II has been proposed in which some cells do not express LMP1.

[d]BHRF1 miRNAs are also expressed along with low level expression of BHRF1.

[e]EBNA1 is driven by the C or W promoter.

BL, Burkitt lymphoma; NPC, nasopharyngeal carcinoma; HL, Hodgkin lymphoma; TCL, T-cell lymphoma; DLBCL, diffuse large B-cell lymphoma; PTLD, posttransplant lymphoproliferative disease; NPC and gastric carcinoma show variable expression of LMP1.

Epigenetic Regulation of EBV Programs

The viral epigenetic state resets with each lytic cycle, which produces unmethylated and unchromatinized DNA.[111,303] Linear EBV genomes are chromatinized and circularize early after infection.[110,384,402] Multiple layers of epigenetic control enable establishment of latency, control latency program selection, and ultimately support lytic reactivation.

BZLF1 preferentially activates promoters with methylated 5′-cytosine (5mC), termed meZREs,[45,303,304] limiting leaky lytic gene expression in newly infected B cells. DNA methylation levels progressively increase following EBV B-cell infection, with higher levels achieved over the first 50 to 100 cell cycles.[304] The extent of methylation is limited by EBNA2,

which induces the cytosine demethylase TET2. EBNA2 colocalizes with TET2, RBP-Jκ, and EBF1. TET2 depletion triggers lytic gene expression.[407,732] EBV also results in hypermethylation in an oral epithelial cell infection model.[49] By contrast, as detailed below, the BRLF1 immediate-early EBV transcription factor activates unmethylated sites, which facilitates induction of the lytic cycle in newly infected epithelial cells.[733]

Chromatinization has a key role in silencing EBV lytic genes in newly infected cells, and viral genomes are chromatinized by 48 hours postinfection.[69] However, over the first days postinfection, the (virion-associated) major EBV tegument protein BNRF1 supports latency gene expression by disrupting host histone chaperone ATRX/DAXX complexes, which would otherwise deposit repressive histone 3.3 complexes onto EBV genomes.[699] BNRF1 disrupts DAXX/ATRX complexes at PML bodies and is essential for EBNA2 induction.[699] Polycomb repressive complex 2 (PRC2) deposits repressive histone 3 lysine 27 trimethyl (H3K27me3) on the EBV genome, and histone 3 lysine 9 trimethyl (H3K9me3) is also deposited.[20,383,686] While BZLF1 and BRLF1 promoters are nucleosomal, open chromatin at these sites is not sufficient for lytic reactivation.[134]

DNA methylation exerts control over latency program selection and further suppress lytic gene expression. EBV also utilizes hypermethylation to silence host tumor suppressor genes.[597] As EBV-infected B cells enter lymphoid tissue germinal centers, *Cp* DNA methylation may contribute to the transition from latency III to latency II (Fig. 11.7). Initiator DNA methyltransferase DNMT3B is induced in germinal center B cells. The epigenetic enzymes UHRF1 and DNMT1, which copy methylation marks from parental to newly synthesized DNA strands, are induced in germinal center B cells and by primary B-cell infection. It is likely that UHRF1 and DNMT1 maintain methylation marks as cells differentiate into memory B cells with latency I expression. Latency III and lytic gene expression are de-repressed in latency I Burkitt B cells treated with DNA hypomethylating agents or by depletion of UHRF1.[223,435,584] Polycomb repressive complex I (PRC1) further controls LMP promoter activity in B cells and may add a layer of control over latency program switching. Depletion of PRC1 subunits de-represses LMP1 and LMP2A expression in latency I Burkitt lymphoma cells, and PRC1-mediated histone 2 lysine 119 monoubiquitination (H2Ub119Ub1) repressive marks are more abundant in Burkitt cells with latency I than latency III programs[223] (Fig. 11.7).

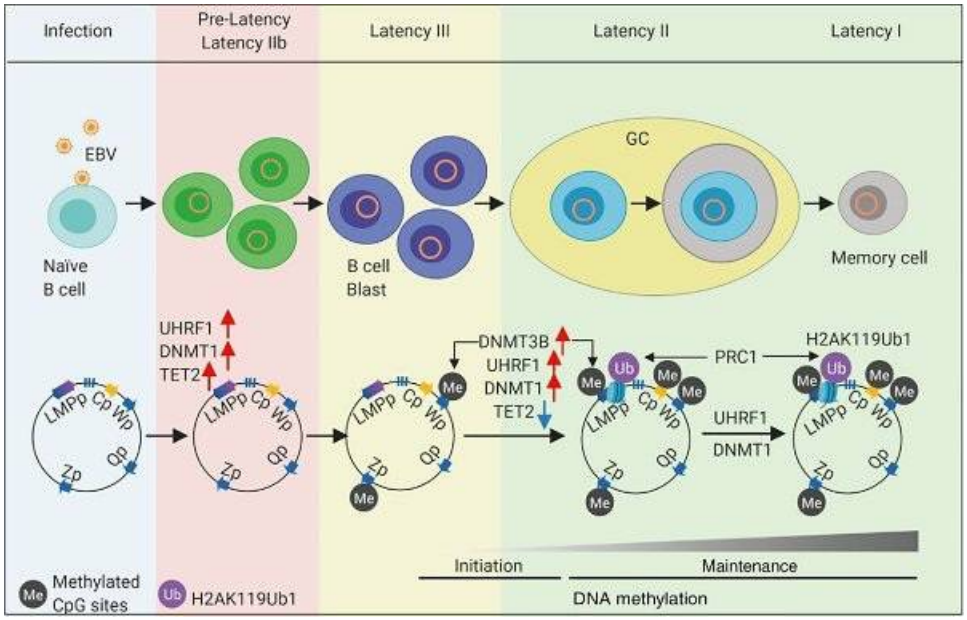

FIGURE 11.7 Schematic model of EBV/host epigenetic regulation in B-cell differentiation. In newly infected naïve B cells, the EBV genome circularizes and is chromatinized. EBNA2 expression in the prelatency and latency IIb phases induces the host DNA demethylase TET2, as well as the maintenance of methylation enzymes UHRF1 and DNMT1. EBNA2 induces the LMP promoter, driving LMP1 and LMP2A expression and causing methylation of *Wp*. The initiator DNA methyltransferase DNMT3B is induced in germinal centers (GC), where *Cp* is methylated and inactivated. Loss of EBNA2 expression diminishes TET2 abundance, potentiating EBV genome methylation. As B cells further differentiate, polycomb repressive complex 1 (PRC1) marks the LMP promoter with histone 2 lysine 199 monoubiquitin (H2AK119Ub1), which together with LMP promoter methylation silences LMP1 and LMP2A expression and allowing *Qp* activation. UHRF1 and DNMT1 propagate DNA methylation marks across cell cycles to maintain latency I.

Higher order DNA structure also regulates EBV gene expression. The CCCTC-binding factor (CTCF) binds to multiple EBV genome sites to mediate long-range chromatin interactions or to insulate genome regions. CTCF binding to the EBV genome may anchor it to the nuclear matrix and direct specific chromatin architectures that can mediate alternative promoter targeting by the *oriP* enhancer. The *oriP* enhancer facultatively associates with either *Cp* in latency III or *Qp* in latency I.[685] Mechanistically, CTCF participates in each of these loops, and disruption of CTCF recruitment perturbs formation of either loop, highlighting how the viral genome coopts a host three-dimensional genome organizing factor for maintenance of epigenetically stable states. Furthermore, CTCF functions as a chromatin insulator at EBV genomic sites including *Qp* to block epigenetic silencing and to prevent promiscuous transcription of surrounding genes. Likewise, mutagenesis studies suggest that the CTCF site upstream of *Cp* also has roles in B-cell latency I epigenetic reprogramming.[264] CTCF activity is posttranslationally regulated by the host enzyme poly(ADP-ribose) polymerase (PARP1) and by DNA methylation. CTCF and PARP1 colocalize at specific EBV genomic sites, where PARP1 stabilizes CTCF occupancy.[410] PARP1

and CTCF suppress the *BZLF1* promoter.

EBV-induced host transcription factor MYC occupies the EBV genome origin of lytic replication (*oriLyt*) sites and prevents looping of these enhancer sites to the immediate-early BZLF1 promoter.[222] MYC depletion triggers EBV three-dimensional genome reorganization that juxtaposes *oriLyt* with the *BZLF1* promoter region. Since Blimp1 suppresses MYC expression, EBV may have evolved this mechanism to sense MYC abundance and link lytic reactivation to plasma cell differentiation. Elevated MYC levels present in newly infected B cells suppress LMP1 expression,[557] further highlighting the intimate relationship between MYC and EBV epigenetic regulation. Latent EBV genomes preferentially associate with human genome heterochromatin regions characterized by lower densities of coding genes and the repressive H3K9me3 mark. Upon lytic reactivation or EBNA1 depletion, EBV genomes move toward active chromatin.[328,473]

Latency Gene Functions

EBNA1

EBNA1 (Fig. 11.8A) is the only EBNA that directly binds DNA. To ensure replication and stable maintenance of EBV genomes, EBNA1 binds both to the viral episome and serves to tether the viral genome to host chromosomes in mitosis. EBNA1 binds to *oriP*, which is the viral genome origin of DNA replication in latency.[577,743] Remarkably, it was subsequently discovered that *oriP* and EBNA1 are sufficient for partitioning of EBV genomes, or plasmids containing *oriP*, to progeny cells.[455,496] EBNA1 and *oriP* maintain the EBV genome as a replicon that is copied by host machinery once per cell cycle in S-phase. Catenation of newly replicated viral genomes appears to lead to their pairing on sister chromatids, which serves to mediate equal partitioning of episomes to daughter cells.[228]

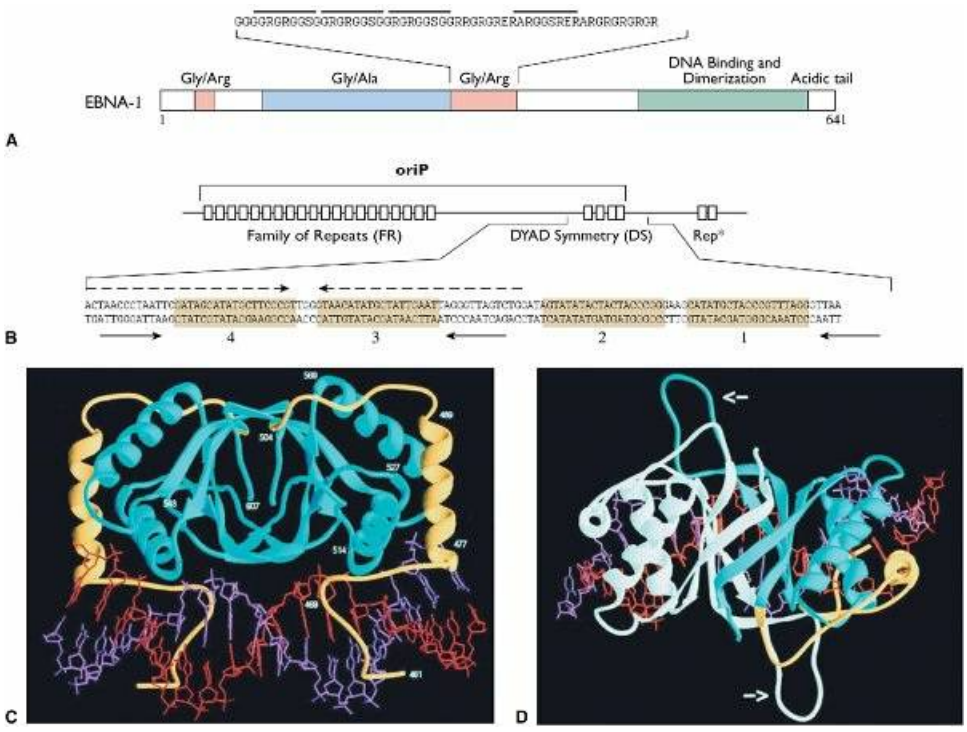

FIGURE 11.8 EBNA1 functional domains, schematic of the *oriP* DNA arrangement, and structure of EBNA1 bound to DNA. A: Important EBNA1 functional domains. The amino terminal Gly/Arg domain is important for replication, segregation, and transcription and has been shown to bind P32/TAP. The central Gly/Arg sequence is also important for replication, segregation, and transcription. This domain has been shown to bind a variety of cell proteins including EBP2, Nap1, p32/TAP, MDF1, PRMT1, and PRMT5. The DNA binding and dimerization domain at the C-terminus of EBNA1 is essential for all known functions of EBNA1 including replication, segregation, and transcription. Regions outside these domains of EBNA1 are generally thought to be nonessential but have been shown to bind cellular proteins including tankyrase and USP7. **B:** The *oriP* family of repeats (FRs) and dyad symmetry (DS) elements are shown with an expanded view of the nucleotide sequence of DS with the EBNA1 binding sites 1 to 4. The nonamer repeats (*solid arrows*) and the 65 base-pair dyad symmetry (*broken arrows*) are also shown. EBNA1-binding sites are shown as *open boxes* with the dyad present in DS denoted by the *head-to-head arrows*. The Rep* element is located 240 bp downstream of DS. **C:** EBNA1 bound to DNA with a ribbon diagram showing the core domain, which contains residues 504 to 607 from each monomer, in *blue*. The flanking domains from each monomer are shown in *yellow*. The amino acids are numbered according to their position in the full-length EBNA1 protein derived from B95-8. **D:** A view down the noncrystallographic axis that shows one monomer in white and the other monomer in the same color scheme as used in **(C)**. The proline loops are indicated by the *arrows*. (Reprinted from Bochkarev A, Barwell JA, Pfuetzner RA, et al. Crystal structure of the DNA-binding domain of the Epstein-Barr virus origin-binding protein, EBNA1, bound to DNA. *Cell* 1996;84(5):791–800. Copyright © 1996 Elsevier. With permission. Ref.[52])

The *oriP* family of repeats (FR), dyad symmetry (DS) element, and two cis-acting elements are critical for maintenance of EBV episomes. FR serves as a approximately 650 bp maintenance element and an EBNA1-dependent enhancer important for *Cp* activity.[28,203,228,321,402,540,547] FR is located approximately 1 kb upstream of DS and contains multiple 18 bp copies of an EBNA1 recognition sequence[412,573,577] (Fig. 11.8B). The EBNA1 N-terminus binds to perichromatic regions enriched for histone methylation marks that are hallmarks of transcriptionally active regions.[151] In this manner, EBNA1 tethers FR-bound episomes to condensed mitotic chromosomes. DS serves as the latency origin for episome DNA synthesis. It contains 4 EBNA1 recognition sites and a 65 bp region of dyad symmetry.[719] DS is necessary for EBNA1-dependent plasmid replication.[228]

EBNA1 binds DNA as a homodimer (Fig. 11.8B–D). The EBNA1 dimerization domain extends from residues 504 to 604. Amino acids 470 to 503 include a helix that projects into the DNA major groove and an extended chain that moves along the minor groove and makes all the DNA sequence specific contacts. Smooth DNA bending stabilizes interactions between EBNA1 dimers.[422] An extensive hydrogen bonding network connects the dimer–dimer interface, disruption of which compromises *oriP*-dependent plasmid replication and MCM3 complex recruitment to *oriP*. The EBNA1 DNA-binding domain itself forms a hexameric ring, highlighting that EBNA1 dimers assemble into higher-order structures. Point mutations at the oligomeric interface destabilize higher-order complex formation, alter cooperative DNA binding, and can either positively or negatively affect EBNA1-dependent functions.[148] Using a structure and fragment-based approach, small molecule inhibitors of EBNA1 DNA binding activity were identified. Remarkably, EBNA1 inhibitors impair LCL and EBV-infected NPC cell survival *in vitro* and xenograft models *in vivo*.[453] Similarly, a small molecule that blocks the ability of the N-terminal EBNA1 AT-hooks to bind host chromosomes causes EBV genome loss in tissue culture.[94]

The repeat unit of *oriP* acts as an enhancer in the presence of EBNA1, which is important for latent gene transcription from *Cp*.[197,228] Host cell factor 1 (HCF1) and octamer-binding transcription factor 2 (OCT2) cooperatively bind o*riP* with EBNA1 and are each important for *oriP* H3K4 trimethylation, *Cp* and *Qp* activity.[154] HCF1 knockdown causes EBV episome loss from Burkitt lymphoma cells, suggesting a potential HCF1 episome maintenance role. EBP2 is important for interactions between EBNA1 and chromosomes in metaphase and association with metaphase chromosomes. The MCM complex associates with DS and may have roles in initiation and licensing of EBV genome replication. EBNA1 may facilitate ORC recruitment to DS by disrupting nucleosomes to provide ORC with DNA access.[197] Timeless and timeless interacting proteins, which have roles in stabilizing replication forks, are also recruited to *oriP*.[153] Timeless depletion from Burkitt cells causes loss of closed circular EBV episomes, accumulation of linear EBV DNA and double-strand breaks at *oriP*, suggesting an important role in replication fork stabilization in episome maintenance.[153]

USP7, which is a key regulator of p53 and Mdm2, stimulates EBNA1 DNA binding activity. USP7 forms a ternary complex with DNA-bound EBNA1[609] and is part of a histone deubiquitylating complex. USP7 depletion increases monoubiquitylated histone H2B at EBV FR and decreases its transcriptional activation activity.[255] Crystallographic studies reveal that EBNA1 and p53 bind the same USP7 pocket, but that EBNA1 makes more extensive contacts with USP7. Association between EBNA1 and USP7 protects cells from apoptotic challenge by

p53 depletion. EBNA1 partially protects them from p53 overexpression-driven apoptosis.[608] Conversely, depletion of EBNA1 in EBV-positive Burkitt cells induces apoptosis.[320] USP7 and EBNA1 also have joint roles in disruption of PML nuclear bodies.[197]

EBNA1 deletion does not prevent EBV-driven B-cell outgrowth or establishment of LCLs,[268,543] likely since episome integration into host chromosomes enables DNA maintenance in the absence of EBNA1. This is apparently rare, as LCLs emerge nearly 1,000-fold less frequently from EBNA1-deficient virus.[268] LCLs established from wild-type versus EBNA1 deletion mutant virus grow at comparable rates and each can form xenografts in SCID mice. Thus, the contribution of EBNA1 to B-cell immortalization outside of activation of EBV latent genes[12] and maintaining the EBV genomes in infected cells may be limited in comparison with roles of other EBV latency oncoproteins.

A large number of putative EBNA1 host genome targets have been identified. EBNA1 ChIP-seq was used together with RNA-seq analysis following EBNA1 depletion from LCLs, Burkitt, and NPC cells.[684] Interestingly, approximately 1,000 host genome EBNA1 binding sites are mostly conserved across cell types, share a consensus DNA motif, and are frequently located proximal to transcription start sites, particularly at highly expressed genes.[408] EBNA1 binding sites are also enriched for LINE 1 retrotransposons. The antiapoptotic host factor survivin is up-regulated by EBNA1.[42]

EBNA2

Early studies by Elliott Kieff ’s group identified a B-cell transformation incompetent, but lytic replication competent EBV strain derived from Jijoye Burkitt cells called P3HR-1.[126,141,143,144,246,325,334,559,570] The search for the biochemical basis of the nontransforming phenotype led to the discovery and characterization of EBNA2, which is the principal ORF deleted in P3HR-1.[126,141,143,144,246,325,334,559,570] While EBNA-LP is also truncated in P3HR-1, it was found that restoring type 1 EBV EBNA2 expression rescued P3HR-1 B-cell growth transformation.[28,124,126,402] Transfection with cloned EBV DNA fragments deleted for part of the EBNA2 ORF or containing a stop codon one-third of the way into the EBNA2 ORF failed to restore transforming ability. Recombinant EBVs with a nontransforming EBNA2 mutation could also be recovered by infection of EBV negative BL cells.[403] More recently, the role of EBNA2 in EBV-driven primary B-cell transformation was again highlighted, where EBNA2 was the only latency gene found to be essential for newly infected B-cell outgrowth over the first 8 days.[543]

EBNA2 typically functions as an activator of B-cell viral and host gene transcription.[126,319,722] EBNA2 is the major viral transactivator of the C and LMP promoters.[722] Genetic analysis identified three essential EBNA2 domains critical for LMP and C promoter up-regulation (Fig. 11.9). These correspond to EBNA2 residues 1 to 58 or 97 to 210, which mediate homotypic association, amino acids 280 to 337, which mediate interaction with RBP-Jκ, and C-transactivation domain (TAD) residues 420 to 464.[118,124,126,219,229,233,241,313,319,758] In B lymphocytes, the EBNA2 C-terminal transactivation domain (TAD) is nearly as strong in activation of basal reporter constructs as the core herpes simplex VP16 activation domain.[124] The VP16 core 14 amino acids can substitute for the corresponding EBNA2 C-terminal transactivation domain residues in primary B-lymphocyte conversion to LCLs in recombinant EBV.[118] The EBNA2 C-terminal TAD recruits basal and activation associated transcription

factors including TFB1/p62, TFIIB, TAF40, RPA70, TFIIH, and the histone acetyltransferases CBP/P300 and PCAF[319] (Fig. 11.9). An intrinsically unstructured EBNA2 region folds into a 9 amino acid alpha helix upon complex formation.[92]

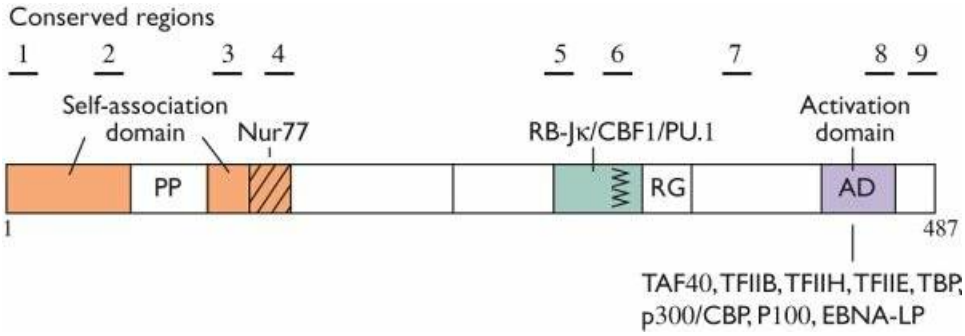

FIGURE 11.9 Schematic depiction of Epstein-Barr virus nuclear antigen (EBNA)-2 domains. EBNA2 contains a domain that interacts with the cellular sequence-specific DNA binding proteins RBP-Jκ and PU.1 to bring it to specific promoters, including the LMP1 promoter. The EBNA2 N-terminus has two domains that can mediate homotypic association with other EBNA2 molecules. Within this region, there is an interactive domain for Nur77. The poly-proline (PP) and poly-arginine-glycine (RG) as well as the activation domain (AD) are shown. The tryptophan-tryptophan-proline (WW) sequence in EBNA2, which is similar to a sequence in the Notch receptor intracellular domain, that normally mediates tight association with RBP-Jκ in up-regulating HES-1 in tissue development is shown. Mutation of this sequence in ablates EBNA2 transactivation.[219] The EBNA2 acidic domain (AD) interacts with TAF40, TFIIB, TFIIH, TFIIE, TBP, P300/CBP, p100, and EBNA-LP in stimulating transcription. The EBNA2 acidic domain is extensively associated with p100, which is a scaffolding protein for c-myb and PIM-1. Nine conserved regions of EBNA2 (bars above the protein) have been identified by comparing type 1 and type 2 EBNA2 with those from related LCVs that infect nonhuman primates.

EBNA2 is recruited to DNA through association with host transcription factors, particularly the Notch pathway sequence-specific DNA binding protein RBP-Jκ/CBF1.[38,219,241,296] Whereas RBP-Jκ assembles corepressor complexes in B cells in the absence of EBNA2, EBNA2 often converts RBP-Jκ into an activator by competing for corepressor binding, through EBNA2 TADs, and through recruitment of coactivators, including EBNA-LP. RBP-Jκ is critical for LCL growth and survival.[416] EBNA2 is at least partially dependent on Jκ DNA sites for transactivation of *Cp*,[293] LMP1, and LMP2.[207,296,362] The *Cp* and *LMPp* sites contain EBNA2 response elements that carry Jκ DNA motifs.

EBNA2 mimics key aspects of activated Notch signalling. The EBNA2 WWP motif (Fig. 11.9) resembles a Notch intracellular domain "WFP" sequence that tightly associates with RBP-Jκ,[679] and EBNA2 and Notch binding to RBP-Jκ are mutually exclusive.[260] EBNA2 residues 318 to 327 mediate RBP-Jκ association.[393] EBNA2 induces formation of new RBP-Jκ occupied sites.[405] Yet, constitutive Notch signaling cannot replace EBNA2 to maintain EBV-transformed

lymphoblastoid B-cell proliferation.[211,253]

Microarray profiling of EBV-uninfected Burkitt cell lines with conditional EBNA2 expression identified 311 significantly EBNA2-induced genes, including CD21, CD23, CCR7, RUNX3, and CD83. Likewise, conditional EBNA2 expression identified key EBNA2 down-regulated targets, including CD79B, TCL-1, and MEF2B.[420,753] ChIP-seq identified a much larger number of host genomic sites occupied by EBNA2[405,420,441,751,755] and suggested that EBNA2 subverts intrinsic B-cell transcriptional programs. Thousands of host genome sites are co-occupied by RBP-Jκ and EBNA2 in LCLs. EBNA2 and RBP-Jκ predominantly co-occupy intergene and intron sites, with only a small proportion proximal to transcription start sites.[221,441,755] Jκ DNA motifs are highly enriched at EBNA2/RBP-Jκ co-occupied sites, whereas EBF1 DNA motifs are enriched at sites occupied by EBNA2 but not RBP-Jκ. EBNA2 reorganizes genomic binding sites of RBP-Jκ and EBF1, and EBNA2-EBF1-RBP-Jκ co-occupancy appears to transcriptionally activate target genes.[210,405]

EBNA2 alleles differ significantly in amino acid sequence between type 1 and 2 EBV strains.[126,143,581] Reconstitution of the type 2 P3HR-1 EBV strain with a type 1, but not a type 2 EBNA2 gene, yields virus that transforms B cells as efficiently as type 1 EBV strains.[126] A single EBNA2 transactivating domain amino acid at residue 442 appears to underlie this phenotype. Substitution of type 2 serine 442 with type 1 aspartic acid confer enhanced LMP1 up-regulation and type 1 transforming activity on a type 2 EBV strain.[705] In contrast, recombination of cloned type 2 EBNA2 DNA in place of the P3HR-1 deletion results in deficient transformation characteristic of type 2 EBV. EBNA2 encoded by type 1 EBV more strongly induces LMP1 and a small number of host cell genes than EBNA2 encodes by type 2 EBV.[409] Similarly, type 2 EBNA2 associates more strongly with the BS69 repressor protein.[549]

Super-enhancers (SEs) are particularly strong enhancers that drive expression of genes critical for cell identity and oncogenic states. EBNA2 occupied 888 SE in LCLs.[221,292,735,759] Often located far from transcriptional start sites, these SE loop to targets, including *RBPJ*, *EBF1*, *BATF*, and *RUNX3*. A subset of EBNA2 SEs, termed EBV SEs, are co-occupied by EBNAs LP, 3A, 3C, and LMP1-activated NF-κB transcription factors.[292,759] EBV SEs often loop to more than one target gene, enabling them to target 1992 sites. EBV SE targets were enriched for host genes essential for LCL growth and survival,[292,416] including *MYC*, *IRF4*, and *CFLAR*. Two EBV SEs loop to the *MYC* promoter from 525 and 428 kbp upstream,[292,735,759] and EBNA2 is important for formation of these loops in newly infected B cells.[292] EBNA2 recruits the SWI/SNF chromatin remodeler complex to *MYC* enhancers to promote interactions with the *MYC* promoter.[735] The pioneer transcription factor MEF2C was also found to be important for MYC-targeting EBV SE activity.[715] Deletion of either *MYC*-targeting EBV SE by CRISPR genome editing diminished MYC expression and LCL proliferation.[292]

EBNA2 also has key roles in host metabolism pathway remodeling in newly infected B cells, both by strongly inducing MYC and also by EBNA2 target gene regulation.[721] EBNA2 has important roles in up-regulation of aerobic glycolysis (the Warburg effect) within the first days of infection.[442,478,721] EBV-mediated NF-κB and PI3K activity are each important for up-regulation of the glucose transporter GLUT1 in transformed cells at later timepoints,[656] though interestingly GLUT1 is up-regulated even before LMP1 and 2A reach significant levels in newly infected cells.[721] EBV infection also markedly remodels mitochondria, most of whose

components are encoded by nuclear genes that can be regulated by EBNA and LMP signaling. Consequently, oxidative phosphorylation is also strongly up-regulated in the first week postinfection and plays similarly important roles in B-cell growth transformation.

Maximal EBNA2 RNA and protein abundance is observed by 48 hours postinfection.[478,717,721] Proteomic analysis highlighted that EBV strongly induces the mitochondrial one-carbon (1C) pathway within the first days of infection, reaching maximal expression levels during the period of hyperproliferation[721] to convert serine into glycine, carbon units, ATP, and NAD(P)H for use in anabolic reactions. Lipid metabolism pathways are also highly induced by EBNA2, which functions with host transcription factors such as SREBP and MYC to remodel mevalonate and fatty acid synthesis pathways. EBV-induced lipid metabolism enables cross-talk between EBNA and LMP oncoproteins.[723]

EBNA-LP

EBNA-LP is a major coactivator of EBNA2 host and viral target genes.[8,200,232,509,636] EBNA-LP targets include the C and LMP1 promoters as well as a large number of host genomic sites. EBNA-LP coactivation with EBNA2 is evident in transient expression assays with artificial LMP1 promoter constructs, and in inducing the latency III program in Burkitt cells when coexpressed by gene transfer together with EBNA2. Yet, EBNA-LP does not globally coactivate EBNA2 targets.[319,402]

EBNA-LP is comprised of 22 and 44 amino acid regions of variable copy number, fused to 11 and 34 residue carboxy-terminal regions. These are encoded by the W1, W2, Y1, and Y2 exons, respectively (Fig. 11.10A and B). The W1 and W2 encoded regions enable homodimerization and association with the EBNA2 acidic activating domain.[232,537] In newly infected B cells, *Wp* drives expression of a 5′ W0 exon, which is alternatively spliced either to the W1 or to a W1’ exon and then to W2. Since W0, W1, and W2 reside within the EBV genome internal repeat 1 (IR1) region, EBNA-LP size varies between viral strains with differing IR1 copy number. Likewise, transcripts can initiate from distinct W0 exons, giving rise to EBNA-LP products of variable length early in B-cell infection. Upon the switch to *Cp* driven transcription, EBNA-LP mRNAs are instead comprised of 5′ C1 and C2 exons that are joined with W and Y exons.[319] At least 5 W repeats are required for optimal B-cell outgrowth, at least two of which are necessary for B-cell transformation in culture.[692] This requirement results from the optimization of *Wp*-driven transcriptional activity. Clinical EBV strains typically have at least 5 to 8 W copies.[692]

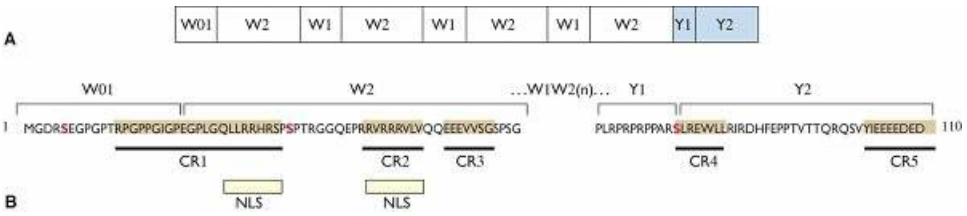

FIGURE 11.10 Schematic diagram of the repeat and unique exon and domain structure of Epstein-Barr virus nuclear antigen leader protein (EBNA-LP). The exons of EBNA-LP are derived from the BamHI W and Y fragments with initiation of

transcription from *Wp* or *Cp*. **A:** The EBNA-LP AUG is generated by a unique alternative 5′ splicing event. The W1 and W2 regions are repeats of 22 and 44 amino acids, respectively. This EBNA-LP repeat domain coactivates transcription mediated by the EBNA2 acidic domain. The unique C-terminus of EBNA-LP consists of Y1 and Y2, which is dispensable for EBNA2 coactivation and modulates EBNA-LP function. **B:** Amino acid sequence of the unique W01 exon and the W2, Y1, and Y2 exons. A single W1/W2 repeat is shown. Also shown are serines that are phosphorylated and conserved regions (CRs) in EBNA-LP proteins encoded in EBV and the nonhuman primate LCVs.

EBNA2 and EBNA-LP interact in yeast two-hybrid assays[77] and as recombinant proteins *in vitro*. However, association between wild-type EBNA-LP and EBNA2 is difficult to detect in LCL extracts. EBNA-LP can bind to and coactivate transcription through the EBNA2 acidic activating domain or through an EBNA2 N-terminal 58 amino acid domain.[537] EBNA-LP potentiates EBNA2-mediated transcription from the C and LMP1 promoters in transient transfection assays with reporter constructs and also coactivates EBNA2 up-regulation of LMP1 expression in type 1 EBV-infected BL cells.

EBNA-LP localizes predominantly to promyelocytic leukemia (PML) nuclear bodies and to a lesser extent in the cytosol.[319] An EBNA-LP region conserved in nonhuman primate LCVs interacts with and displaces Sp100 from PML nuclear bodies.[394] Sp100A mutants deleted for the PML targeting domain, which also interacts with EBNA-LP, can coactivate EBNA2 independently of EBNA-LP, suggesting that displacement of Sp100A from PML nuclear bodies is an important EBNA-LP function.[394] Deletion of a Sp100A domain that interacts with the transcriptional repressor heterochromatin protein 1 (HP1) prevents Sp100A coactivation function, suggesting that EBNA-LP function may in part involve chromatin modification.[394] Together with HA95, EBNA-LP also activates transcription by displacing NCoR and histone deacetylases (HDACs) from matrix-associated deacetylase (MAD) bodies.[551] EBNA-LP can also coactivate host target genes with the host histone acetyltransferase EP300/P300, apparently independently of EBNA2.[725] ChIP-Seq identified nearly 20,000 EBNA-LP occupied host genomic regions.[552] Only 29% were co-occupied by EBNA2, in large part because approximately 50% of EBNA-LP sites were within 2 kb of transcriptional start sites. Long-range DNA interactions may increase contact between EBNA2-bound enhancer and EBNA-LP occupied promoter sites.

Recombinant EBV studies suggest that EBNA-LP is important for B-cell transformation. Complete repair of the P3HR1-1 deletion encoding EBNA2 and the Y1/Y2 EBNA-LP exons restores B-cell immortalization, whereas repair of only EBNA2 reduces immortalization efficiency by approximately 10-fold.[28,425] EBNA-LP knockout (KO) virus exhibited reduced naive B-cell transformation efficiency. Deletion of just the Y1 and Y2 exons also substantially decreased the rate of EBV-driven B-cell outgrowth.[676] EBNA-LP KO EBV likewise slows outgrowth of tonsil B cells.[543] By contrast, EBNA-LP KO virus failed to establish LCLs from umbilical cord B cells, which underwent cell death by 2 weeks postinfection. Absence of EBNA-LP significantly diminished recruitment of EBNA2, EBF1, and RBP-Jκ to the viral genome, but not to the EBNA2 target *IL7* host target gene.[676]

EBNA3A, EBNA3B, and EBNA3C

EBNA3 proteins have important roles in host and viral gene regulation. EBNA3s share an N-terminal homology domain, a proline-rich region and repeat sequences. EBNA3C also has a putative leucine zipper that mediates association with the host transcription factor PU.1/SP1.[754] EBNA3s target DNA sites through interactions with host factors, in particular RBP-Jκ.[585,586] Each EBNA3 has transcription repression activity when tethered to DNA by a heterologous GAL4 DNA binding domain.

EBNA3A, 3B, and *3C* genes are arranged in tandem (Fig. 11.11) and are conserved with primate LCVs, but do not have homology with host proteins. EBNA3 proteins are expressed from a polycistronic transcript that encodes all 6 EBNAs, that is alternatively spliced, and that is present at low abundance in LCLs.[9] *Wp* or *Cp* drive expression of EBNA3 transcripts in the latency IIb and III programs, respectively. EBNA3 messages share a U exon with EBNA1 and have individual splice acceptor sites that compete with EBNA1. EBNA3 transcripts have individual downstream polyA sites. EBNA3s are expressed within 48 hours of primary B-cell infection, reaching maximal levels between 4 and 7 days postinfection cell culture.[478,717,721] EBNA3s inhibit EBNA2 activation of *Cp*, which may account for the significant drop in EBNA2 expression by 96 hours postprimary B-cell infection.

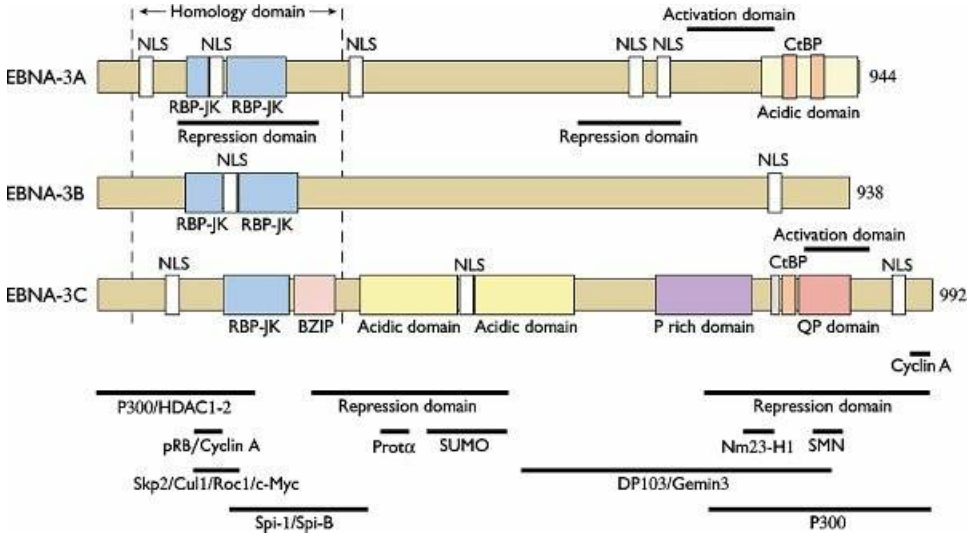

FIGURE 11.11 Schematic diagram of the Epstein-Barr virus nuclear antigen (EBNA)3A, EBNA3B, and EBNA3C and their functional domains. EBNA3A, EBNA3B, and EBNA3C proteins are shown with the number of their amino acids and with a common domain that contains the RBP-Jκ interaction domain. Also indicated are domains that have activating or repressive effects in addition to a variety of domains that associate with cellular proteins including CtBP, p300/HDAC1-2, pRB/cyclin A, prothymosin-α (Protα), Skp2/CulI/RocI/c-Myc, Spi-1/Spi-B, SUMO, Nm23-H1. SMN, DP103/Gemin3, and p300. Nuclear localization signals (NLS), a leucine zipper (BZIP), acidic domains, proline (P)-rich region, and a glutamine (Q) and proline region are shown. (Reprinted with permission from Sims K, Saha A, Robertson ES. Regulation of Cellular Processes by the Epstein-Barr Virus Nuclear Antigen 3 Family of Proteins. In: Robertson ES, ed. *Epstein-Barr Virus—Latency and*

Transformation. Norfolk, UK: Caister Academic Press; 2010:81–100. Ref.[635])

EBNA3s compete with EBNA2 for the same RBP-Jκ binding surface.[585,586,752] However, EBNA3s bind more tightly to RBP-Jκ,[690] reminiscent of the *Drosophila* Notch antagonist Hairless. Deletion of the EBNA3A or EBNA3C RBP-Jκ association region abrogates their EBNA2 antagonism.[431,729] Interaction between EBNA3A or 3C and RBP-Jκ is essential for LCL growth and survival.[116,368,433]

EBNA3s also repress target genes through assembly of corepressor complexes. EBNA3s associate with host corepressors C-terminal binding protein (CtBP), Sin3A, NCoR, and HDACs HDAC-1 and 2.[9,600] The EBNA3A and EBNA3C region that associates with CtBP1 is required for LCL growth.[368,644] CtBP1 is important for LCL, but not Burkitt growth and survival.[416] EBNA3A and EBNA3C recruit CtBP by mimicking "PLDLS" domains that mediate association between CtBP and transcription corepressors. EBNA3s association with CtBP is important for the assembly of polycomb repressive complex 2 (PRC2) at target gene sites, where the histone methyl transferase subunit EZH2 deposits histone 3 lysine 27 trimethyl (H3K27me3) repressive chromatin marks.[9] H3K27me3 have been identified at EBNA3A and EBNA3C occupied sites proximal to transcriptional start sites of major tumor suppressor genes, including *BCL2L11*.[527,735]

ChIP-Seq has identified a wide range of EBNA3 host and viral target gene sites. Greater than 13,000 EBNA3C sites were identified in LCLs, 64% of which were at chromatin sites with activating H3K4me1 and H3K27ac enhancer marks. DNA motifs for RUNX3, BATF, IRF4, and ATF2 are enriched at these sites.[291] EBNA3C ChIP-seq signals were strongest at sites with either composite BATF/IRF4 elements (also known as ATF–interferon composite elements, or AICE) or composite SPI1/IRF4 elements (also known as ETS–interferon composite elements, or EICE). Similarly, ChIP-seq identified 10,000 EBNA3A host genome binding sites in LCLs, 55% of which were active enhancers and 11% of which were at active or weakly active promoters.[617] AICE and EICE motifs were enriched at EBNA3A occupied sites. A total of 25% of host genomic binding sites were shared between EBNA2 and EBNA3 proteins in Burkitt lymphoma cells with latency III expression.[441]

EBNA3s can also serve as transcriptional activators, alone or in concert with EBNA2. EBNA3C associates with PU.1/SPI1[754] and with the histone acetyltransferase p300.[133] The EBNA3C leucine zipper interacts *in vitro* with the PU.1-Ets domain and appears to up-regulate transcription through the LMP1 promoter PU.1 binding site.[754] The EBNA3C effect is independent of the RBP-Jκ binding site in the LMP1 promoter and of the RBP-Jκ interaction domain in EBNA3C.[754] Furthermore, EBNA3C fully coactivates with an EBNA2 mutant that does not interact with RBP-Jκ.[389]

Using EBV-negative Burkitt lymphoma cells infected by wild-type versus EBNA3 knockout EBV, microarray analysis identified greater than 1,000 host genes whose expression significantly changed with EBNA3 deficiency.[730] More than one EBNA3 protein regulated a third of these, with EBNA3C apparently cooperating with EBNA3A, EBNA3B, or both. Expression profiling identified 167 up-regulated and 129 down-regulated host genes in LCLs established from EBNA3A-deficient versus wild-type virus.[247] EBNA3A-regulated genes were enriched for targets previously identified as being regulated by EBNA2. Likewise, 550 host genes were at

least 1.5-fold differentially regulated in LCLs with conditional EBNA3C inactivation, and these significantly overlapped with genes regulated by EBNA2 and EBNA3A.[751]

EBNA3A and EBNA3C, but not EBNA3B, are each important for B-cell transformation into LCLs.[9,600,695] EBNA3A KO virus is attenuated for B-cell transformation and gives rise to LCLs with increased apoptosis and reduced proliferation rates.[247] Conditional EBNA3C inactivation results in the accumulation of cell cycle inhibitors p16(INK4A), p14(ARF), p53, and hypophosphorylation of Rb.[432,751] Similarly, EBNA3A or 3C inactivation results in active chromatin marks at the p14 and p16 encoding *CDKN2A* locus.[291] Knockdown of p14 or p16 partially rescues LCL growth in the absence of either EBNA3A or EBNA3C.[434] B cells obtained from an individual with a homozygous *CDKN2A* locus deletion that causes p16 deficiency are transformed equally well by wild-type and EBNA3C-deficient virus, highlighting an EBNA3C role in overcoming a p16-dependent block to B-cell proliferation 2 to 4 weeks postinfection.[645]

EBNA3A and EBNA3C have key roles in regulation of B-cell differentiation.[670] B cells infected by EBNA3A and EBNA3C conditionally inactivated virus, or virus deficient for EBNA3s altogether, initially proliferate. However, they subsequently undergo plasmablast differentiation at 20 days postinfection. This phenotype may result from EBNA3C suppression of *BCL6*[535] and BLIMP1. Once committed to plasmablast differentiation, re-expression of EBNA3A and EBNA3C does not rescue LCL differentiation.[670] EBNA3A or 3C have key roles in repressing the *BCL2L11* encoded tumor suppressor BIM. EBNA3A and 3C co-occupy assemble a PRC2 repressive complex upstream of the *BCL2L11* promoter.[441,527,735] Inhibition of EZH2 up-regulates BIM expression,[735] as does KO of BATF or IRF4, suggesting that they may play roles in EBNA3 recruitment to this site.[416] The H3K4me3 chromatin mark, which can be found at activated promoters, does not change with H3K27me3 deposition, suggesting that bivalent chromatin is formed.[645] EBNA3A also has key roles in up-regulation of the antiapoptotic *MCL-1* gene to promote infected B-cell survival at early timepoints postinfection.[555]

The onset of EBV-induced hyperproliferation at 3 days postinfection induces DNA replication stress and the DNA damage response (DDR) pathway.[113,505] EBNA3C suppresses the ATM/Chk2-mediated DNA damage responsive signaling pathway in newly EBV-infected cells.[113,505] The DNA damage response has an important tumor suppression role in limiting EBV-induced B-cell transformation *in vitro*, as inhibition of the DNA damage response pathway kinases ATM or CHK2 increased B-cell transformation efficiency.[505]

Functionally important EBNA3C interactions have been defined, many of which regulate cell cycle progression, the G1/S checkpoint, and cell survival. EBNA3C binds p53 and represses its functions by interacting with the inhibitor of growth family proteins ING4 and ING5.[595,599] EBNA3C recruits the ubiquitin ligase Skp1/Cul1/F-box complex resulting in ubiquitination of the cell cycle regulators Rb and p27.[340,341] EBNA3C also interacts with and modulates the activity of cyclins A, D1, and E.[338,339,596] EBNA3C associates with the transcription repressor E2F6 to reduce E2F1 activity.[534] Furthermore, the EBNA3C N- and C-terminal domains associate with E2F1 to block its induction of apoptosis stimulated by the DNA damage response.[598] EBNA3C up-regulates and associates with PIM-1 kinase to down-modulate activity of the cell cycle inhibitor p21/WAF1.[32] EBNA3C also recruits Skp2 ubiquitin ligase complexes to cyclin A to target degradation of the kinase inhibitor p27 and further promote cell

proliferation.[341] The EBNA3C N-terminal domain associates with IRF4 and IRF8 and stabilizes IRF4. IRF4 depletion causes decreased MYC and CDK6 expression and causes LCL death.[33,416] EBNA3C induces and associates with the WTAP N6-methyladenosine transferase, which in turn regulates EBV transcript stability and promotes EBV-transformed cell growth.[360]

In cord blood humanized mouse models, EBNA3C-deficient EBV induced lymphomas at decreased frequency and with delayed onset in comparison to wild-type virus. P16 levels were increased in tumors that arose from EBNA3C knockout virus in comparison to wild-type virus-infected tumors.[589] EBNA3C-deficient tumors had increased T-cell infiltration and up-regulation of the type 1 interferon response, suggesting additional EBNA3C immunomodulation roles *in vivo*. EBV deficient for either EBNA3A or 3C establishes persistent infection but fails to induce tumors in humanized NOD-SCID mouse models.[491] EBNA3B is not critical for EBV-driven primary B-cell conversion to LCLs.[11,141,694] EBNA3B epitopes are frequently recognized by cytotoxic T lymphocytes. Interestingly, humanized mouse infection by EBNA3B-deficient EBV causes aggressive monomorphic lymphomas, which are not infiltrated by EBV-reactive T cells despite their expansion in this model.[731] EBNA3B knockout deficient B cells secreted less CXCL10, a chemokine that attracts T cells, a phenotype that was also observed in EBNA3B-deficient LCLs. Thus, EBNA3B can be considered to have tumor suppressor roles *in vivo*, perhaps safeguarding against malignancy during the establishment of latency.

LMP1

LMP1 was identified by Elliott Kieff's group as the most abundant viral mRNA in lymphoblastoid B cells.[182] LMP1 mimicks CD40 signaling to subvert a major B/T-cell communication pathway[476] and is essential for *in vitro* B-cell conversion into LCLs.[156,314,316,327] LMP1 also promotes differentiation-induced lytic replication.[88] As described in detail below, LMP1 constitutively activates NF-κB, mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase (PI3K), JAK/STAT, interferon regulatory factor (IRF), and SUMOylation pathways in a ligand-independent manner. In single gene transfer experiments using heterologous promoters, LMP1 has transforming or "oncogene" effects in continuous rodent fibroblast cell lines.[718] LMP1 alters Rat-1 or NIH 3T3 cell morphology, enables growth in medium supplemented with low serum, causes loss of contact inhibition, and enhances growth as tumors in nude mice. Rat-1 or Balb/c 3T3 cells also lose anchorage dependence and grow in soft agar after LMP1 expression.[541,718] The growth of Balb/c 3T3 cells in soft agar correlates quantitatively with the extent of LMP1 expression up to the levels ordinarily expressed in LCLs.[29,472,541]

LMP1 is transcribed from one of two viral promoters separated by approximately 600 bp. In B cells, LMP1 is encoded by a 2.8-kb mRNA, which initiates from the ED-L1 promoter that is dependent on EBNA2.[296] ED-L1 can also be activated independently of EBNA2 by cellular factors, such as the STATs, IRF7, NF-κB, ATF4, PAX5, AP-2, and EBF1.[102,150,369,489,507,720] The p38 signaling pathway also up-regulates LMP1 expression.[299] Enhancement of LMP1 expression up to 200-fold can be mediated by the EBNA1-dependent transcriptional enhancer FR in *oriP* acting across the fused TRs.[203] Looping of the *oriP* enhancer to the LMP1 promoter also contributes to LMP1 expression.[685] LMP1 transcripts are detectable within 48 hours of B-cell infection and steadily increase over the first 2 weeks postinfection.[558] LMP1 also activates the

unfolded protein response to drive its own synthesis, and LMP1 levels in individual cells vary by over 100-fold in clonal LCL cultures.[369] Highly elevated MYC levels early after EBV infection dampen B-cell LMP1 expression.[557]

In epithelial cells, LMP1 transcription is mediated by the upstream L1-TR promoter that initiates transcription from multiple TATA-less sites in the nearest copy of TR, resulting in a 3.5-kb transcript with a long untranslated 5′ exon.[208,529] Transcription is in part dependent on the cellular factors Sp1 and STAT3.[208,529] LMP2A can negatively regulate the expression of LMP1 from this promoter,[667] whereas TR copy number varies inversely to LMP1 expression.[578] The LMP1 ORF has two short introns.[35,182] Epithelial cell differentiation regulates LMP1 expression, where the host transcription factors KLF4 and BLIMP1 jointly up-regulate LMP1 through coactivation of the two LMP1 promoters.[497] L1-TR is active in NPC and interestingly also in Hodgkin lymphoma.[102,578]

LMP1 induces many of the changes usually associated with EBV infection of primary B cells or with antigen activation of primary B cells, including homotypic adhesion, villous projections, increased vimentin expression, increased cell surface expression of CD23, CD39, CD40, CD44, and class II MHC, increased IL-10 expression, decreased expression of CD10, and increased expression of the cell adhesion molecules LFA-1, ICAM-1, and LFA-3.[2] LMP1 is not required for EBV-induced B-cell outgrowth over the first week of infection.[543,558] EBV-infected cells become dependent on LMP1 and NF-κB approximately 1 to 2 weeks postinfection *in vitro,*[558] and conditional LMP1 inactivation or NF-κB blockade triggers LCL growth arrest and apoptosis.[70–73,327]

Reverse genetic experiments defined key LMP1 domains important for B-cell transformation (Fig. 11.12). Deletion of the 24 residue N-terminal cytoplasmic tail reduces transforming efficiency, possibly because of effects on trafficking or stability.[281] The LMP1 six transmembrane domains induce intra- and intermolecular association that drive LMP1 signaling. The 200 residue LMP1 C-terminal tail contains three signaling regions and is critical for B-cell transformation. Of these, CTAR/transformation effector site (TES) 1 and 2 are critical for EBV-mediated B-cell transformation into LCLs.[282,314–316] An EBV recombinant lacking CTAR1 residues 185 to 211 is unable to transform primary human cells into LCLs *in vitro*, suggesting obligatory CTAR1 role(s).[282,314–316] Interestingly, recombinant EBV that expresses only the first 231 LMP1 residues and therefore lacks CTAR2/TES2 and CTAR3 transforms primary B cells into LCLs, so long as they are either grown on fibroblast feeder layers or high-titers of EBV are used.[282,314–316] While deletion of LMP1 residues encompassing CTAR3 does not abrogate B-cell growth transformation,[280,282] *in vivo* roles remain possible. Indeed, CTAR3 alters cell migration and promotes the establishment of latency.[40,42,279] CTAR3 associates with the SUMO ligase Ubc9, which itself is induced by LMP1 CTAR1/2.[42,199,601]

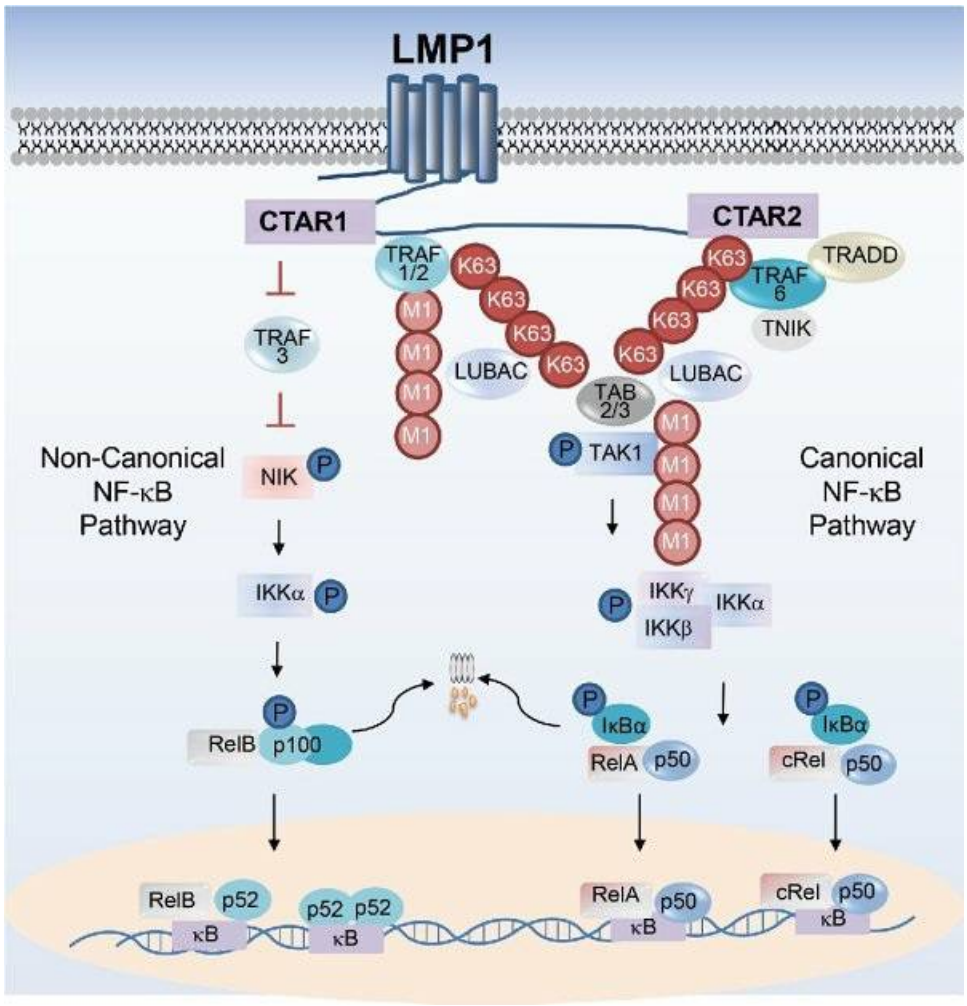

FIGURE 11.12 Schematic diagram of biochemical mechanisms by which latent membrane protein 1 (LMP1) activates NF-κB pathways. The six LMP1 transmembrane domains enable LMP1 aggregation and activation of signaling. The LMP1 C-terminal tail has two regions that activate NF-κB pathways, termed CTAR1/TES1 and CTAR2/TES2. CTAR1/TES1 sequesters TRAF3 to de-repress its negative regulation of the kinase NIK. In the absence of suppression by TRAF3, NIK activates the noncanonical NF-κB pathway by phosphorylating the kinase IKKα. IKKα triggers processing of p100 to p52, which translocates to the nucleus as homodimers or as heterodimers with RelB. LMP1 CTAR2/TES2 associates with the TNFR1-associated death domain (TRADD) and activates the canonical pathway. CTAR2/TES2 activates TRAF6 and the linear ubiquitin assembly complex (LUBAC), which synthesize lysine 63-linked (K63) and linear (M1 Ub) polyubiquitin chains, respectively, culminating in activation of the kinases TAK1 and IKKβ. IKKβ phosphorylates IκBα, causing its proteasomal degradation and nuclear translocation of RelA/p50 and cRel/p50 complexes. TRAF1 enables CTAR1 to cross-talk with the canonical NF-κB pathway through polyubiquitin signaling. Not shown here, LMP1 CTAR1/2 also activates p38, JNK, ERK, and IRF7 pathways, and the linker region between CTAR1/2 contains the LMP1 CTAR3 region that activates UBC9, but which is not required for B-cell transformation.

LMP1 activates two NF-κB pathways, termed canonical and noncanonical. CTAR2/TES2 associates with TRADD and TNIK and activates the ubiquitin ligase TRAF6 to initiate canonical NF-κB signaling.[280,619,621,634] In turn, TRAF6 activates the kinase TAK1, which phosphorylates the IκB kinase (IKK) IKKβ[724] (Fig. 11.12). The linear ubiquitin assembly complex (LUBAC) also plays a key role in IKK activation.[206] IKK phosphorylates IκBα, promoting its ubiquitination by β-TRCP and proteasomal turnover. IκBα degradation releases dimeric NF-κB transcription factors, typically RelA:p50 or cRel:p50 for nuclear translocation and to target gene activation. CRISPR loss-of-function analysis identified TRAF6, TAK1, LUBAC, IKKβ, RelA, and cRel as important for LCL growth and survival.[416]

CTAR1 induces a complex NF-κB response, as determined by electrophoretic mobility shift assays.[313,457] Recombinant LMP1 lacking CTAR2 efficiently induces NF-κB target genes including ICAM-1 at levels similar to wild-type virus.[282,314-316] LMP1 CTAR1/TES1 uses a PXQXT motif to recruit TRAFs 1, 2, 3, and 5.[152,476,745] PxQxT motifs were subsequently found to also be used by immune receptors including CD40. CTAR1 sequesters TRAF3, which likely prevents it from suppressing levels of the NF-κB inducing kinase (NIK).[34] NIK then likely autophosphorylates to activate the IKKα kinase, which triggers production of the active p52 NF-κB subunit. p52 homodimers or heterodimers then regulate target genes. p52 is necessary for LCL growth and survival, though interestingly RelB is not, perhaps because of redundancy.[416] Association with TRAF1 enhances CTAR1/TES1 activation of the canonical NF-κB pathway, where TRAF1:TRAF2 heterotrimers recruit LUBAC and lysine-63 ubiquitin ligases to activate TAK1.[216]

In epithelial cells, a key LMP1 target is the epithelial growth factor receptor (EGFR), which is induced by CTAR1 signaling through NF-κB, BCL3, and STAT3. LMP1-activated STAT3 induces BCL3, which co-occupies the EGFR promoter together with p50 homodimers.[349,691] Similarly, LMP1 suppression of the junctional protein plakoglobin influences a cadherin switch, with effects on cell migration relevant to NPC metastasis.[627] LMP1 also blocks p53-mediated apoptosis through induction of the NF-κB target gene A20.[198]

Constitutive LMP1 activation of canonical and noncanonical pathways gives rise to a complex genomic NF-κB binding landscape. Indeed, as many as 13 NF-κB dimeric transcription factors may form in LCL nuclei.[750] NF-κB occupies 73% of LCL active enhancers but does not readily reflect the two NF-κB pathway paradigm. Rather, 11 distinct NF-κB profiles were present at enhancers and 10 at promoters, suggesting that there is significant cross-talk between the canonical and noncanonical NF-κB pathways at the level of the host genome.[750] NF-κB targets critical for LCL survival include c-FLIP[416] and BCL2 family members.[240,555] Proteomic analysis found that greater than 80% of LMP1 gene targets were encoded by genes identified to be targeted by NF-κB.[149] LMP1 further influences host target gene regulation through effects on PARylation.[430]

LMP1 strongly activates the JNK, p38, and ERK MAP and PI3 kinase pathways.[326,714] Experiments with dominant negative JNK or with JNK chemical inhibitors indicate that JNK activation is critical for LMP1 effects on transformed cell growth. TAK1 plays multiple roles in MAPK activation, including a kinase-independent role in LMP1 signaling complex formation that contributes to downstream TPL2 and JNK kinase activation. This does not appear to be shared with CD40.[712] TRAF1 enables LMP1 TES1 to also strongly activate MAPK pathways.[216]

Also differing from CD40, LMP1 activates IRF7.[739] LMP1 CTAR2 binds to IRF7 and induces K63-linked ubiquitination in a RIP1- and TRAF6-dependent fashion.[506,508,657] LMP1 induces IRF7 sumoylation,[41] which limits IRF7 DNA binding and transcriptional activation and thereby potentially limits innate immune responses. LMP1 associates with PI3 kinase through CTAR1.[146,358] CTAR1 but not CTAR2 is necessary for LMP1-mediated rodent and human fibroblast transformation through the activation of the PI3K and AKT kinases.[421] The cytoskeleton protein vimentin, which associates with LMP1, is important for LMP1-mediated PI3K/AKT pathway activation.[445]

LMP1 oligomers form patches at the plasma membrane and endosomal membrane sites.[388] LMP1 signals from cholesterol-rich membrane microdomains termed lipid rafts,[311] and egress from the endoplasmic reticulum is necessary for LMP1 signaling.[357] The Rab family protein Rab13 is induced by EBV within the first days of B-cell infection, colocalizes with LMP1 and LMP2A, and has key roles in their intracellular trafficking to signaling sites.[723] LMP1 is released from infected cells in extracellular vesicles, which regulate LMP1 levels and affect the nearby microenvironment.[447,511,567,711]

Mouse models have highlighted LMP1 oncogenicity. Transgenic LMP1 expression causes B-cell lymphoproliferative disease in mice.[348,748] Mice expressing an LMP1/CD40 chimera, in which the LMP1 transmembrane domains (TMs) drive constitutive signaling from the CD40 cytoplasmic tail develop B-cell lymphomas as result of hyperactive CD40 signaling.[236,256,572] By contrast, transgenic mice expressing a chimeric CD40 extracellular and transmembrane domain fused to the LMP1 C-terminal tail are relatively normal. Immunoglobulin heavy chain promoter and enhancer driven LMP1 expression results in B-cell hyperplasia and lymphomas in aged mice.[348] By contrast, when expressed from a CD19 promoter, LMP1-positive cells are recognized and destroyed by T and NK cell responses.[748] T-cell depletion causes fatal lymphoproliferative disease, which was also seen in mice with conditional LMP1 and LMP2A coexpression following T and NK cell suppression.[463,734] LMP1 is not absolutely necessary for EBV-driven lymphomagenesis in a cord blood humanized mouse model, apparently because CD40 signaling may compensate to some degree.[417] Likewise, EBV deficient for LMP1 and LMP2A could cause lymphoma in a cord blood-humanized mouse model, albeit at reduced frequency from wild-type EBV.[415]

LMP1 remodels host metabolic pathways, in part through effects on PARP1-mediated posttranslational modification of target genes, including hypoxia-inducible factor 1-alpha (HIF-1a). This potentiates glycolytic Warburg metabolism.[267] PARP1 inhibition causes accumulation of repressive histone methylation marks and results in EBV lytic reactivation, likely through effects on the BZLF1 promoter.[411] EBV similarly up-regulates glycolysis in transformed epithelial cells, and EBV-driven cell metabolism remodeling likely has key roles in NPC pathogenesis.[747]

LMP2A and LMP2B

LMP2A acts as a broad inducer of cellular signal transducers in part by acting as a B-cell receptor mimic but also by rewiring B-cell signal transduction resulting in differential phosphorylation of kinases, phosphatases, adaptor proteins, transcription factors such as NF-κB and TCF3, as well as widespread changes in the transcriptional output of LMP2A-expressing B

cells[91,185] (Fig. 11.13). As a result, the two EBV latent membrane proteins provide two signals that are essential for normal B-cell development and function—LMP1 providing a CD40-like signal and LMP2A a BCR-like signal. Together, LMP1 and LMP2A direct EBV-infected B cells to the memory B-cell compartment where EBV establishes a latent infection. LMP2B is related to LMP2A but lacks the amino terminal domain required for LMP2A signaling function (Fig. 11.13). LMP2A and LMP2B in latency III are expressed from unique EBNA2 responsive promoters with RBP-Jκ and PU.1 binding sites.[448,605,763]

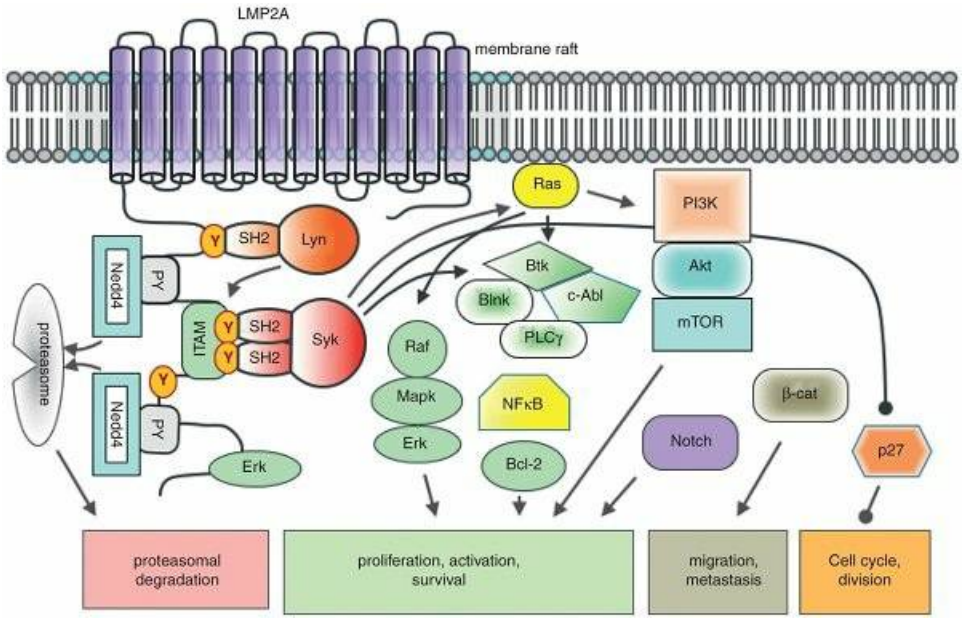

FIGURE 11.13 Latent membrane protein 2A (LMP2A) activates B-cell signaling pathways by constitutively mimicking an activated BCR. LMP2A is constitutively localized to lipid rafts and binds Src family tyrosine kinases such as Lyn leading to constitutive phosphorylation of LMP2A at multiple tyrosine residues. Syk is recruited to LMP2A by the phosphorylated ITAM in the amino-terminal domain of LMP2A and becomes activated. LMP2A also binds E3 ubiquitin ligases in the Nedd4 family and MAPK. LMP2A blocks BCR entry into lipid rafts. PI-3K is constitutively phosphorylated in cells expressing LMP2A, as is BLNK, and Btk. The antiapoptotic serine/threonine kinase Akt is constitutively phosphorylated in cells expressing LMP2A, representing one mechanism, by which LMP2A inhibits apoptosis. MAPK and Ca2+ dependent signal transduction may result from activation of PI-3K, BLNK, and Btk. LMP2A also activates β-catenin that is important in LMP2A effects in epithelial cells. In latency IIa, in which EBNA2 is not expressed, LMP2A may autoactivate its own expression through Notch providing a mechanism for expression independent of EBNA2.[15] The LMP2A first exon encodes 119 N-terminal cytosolic amino acids that precede a methionine,

which is the translational start site for the LMP2B mRNA. LMP2A and 2B mRNAs share the remaining exons, which encode 12 transmembrane (TM) spanning domains separated by short reverse turns and a 27 amino acid C-terminal cytosolic domain[363,605] (Fig. 11.13). Several studies have suggested that LMP2B can augment LMP1 signaling and negatively regulate the function of LMP2A.[574,575,591] LMP2A colocalizes with LMP1 in patches in membranes of latently infected B lymphocytes.[401] LMP2A is palmitylated[250,312,436] and associates with lipid rafts, which is likely important for initial contact with Src family tyrosine kinases such as Lyn. Along with lipid raft association, Lyn is likely recruited to LMP2A by the amino acids DQSL in the LMP2A C-terminal cytoplasmic domain, which is similar to the amino acids DCSM in the BCR-associated protein Ig-α. This interaction is required for the phosphorylation of LMP2A tyrosines found within the LMP2A amino terminal domain, including an ITAM motif, which binds the Syk tyrosine kinase via two Syk SH2 domains.[66,456,592] This results in the activation of a variety of cellular signal transducers, including RAS, PI3K, Btk, BLNK, Akt, mTor, and MAPK[91,171,451,452,456,470,674] (Fig. 11.13).

Antiphosphotyrosine antibodies localize to LMP2A sites of constitutive tyrosine phosphorylation in the plasma membrane of infected cells.[400] LMP2A is also serine/threonine phosphorylated. LMP2A S15 and S102 bind MAPK *in vitro* and are substrates for MAPK phosphorylation.[523] The LMP2A N-terminus has two PPPPY motifs, which bind WW domains of Nedd4 family ubiquitin ligases, such as AIP4/Itchy, WWP2, Nedd4, or Nedd4-2.[273,274] This interaction results in the ubiquitination and degradation of LMP2A and LMP2A-associated proteins.

LMP2A and 2B have been extensively mutated within the EBV genome indicating that LMP2A and LMP2B are not absolutely essential for transforming primary B lymphocytes in culture, but in some cases can provide a growth advantage.[60,423,424,543,587,662] Compatible with this observation, CRISPR/Cas9 dependency screens have shown that LMP2A targets such as Syk, Btk, BLNK, PI3Kinase, and cell cycle regulators are important for LCL growth in culture.[416] LMP2A, like LMP1, provides survival and differentiation signals to B cells *in vivo*. This was first shown using transgenic mice where LMP2A expression in transgenic mice was directed to B cells, which allowed BCR negative B cells to escape from the bone marrow and colonize peripheral lymphoid organs, bypassing normal B-cell developmental checkpoints by constitutive activation of BCR signal transducers.[16,78] The LMP2A effect is also evident in RAG1 KO mice and a number of proteins important for BCR signaling, such as Syk, Btk, and BLNK. The LMP2A ITAM is important for this effect.[171,451,452] Thus, LMP2A has a role in latency type II infected lymphocytes in enhancing B-cell survival through activation of B-cell signal transducers.

In transgenic mice, high level LMP2A expression results in B-1 cells in bone marrow, spleen, and the periphery, whereas low level expression results in spontaneous germinal centers.[87,276] More recent studies using engineered mice confirm the role of LMP2A and LMP1 to mimic signals B cells receive in a germinal center reaction. LMP2A provides an antigen-independent signal, and a T-cell help signal mediated by LMP1 allows antigen-independent proliferation.[463,757]

The level of LMP2 expression is regulated by N-terminal monoubiquitination, which is mediated by Nedd4 ubiquitin ligases that bind to the PY motifs found in the LMP2A amino terminus.[273,275] In murine models of Burkitt lymphoma using a *myc* transgene expressed in B

cells, LMP2A has been shown to dramatically accelerate tumor development, by bypassing the requirement of mutation of the p53 pathway[46] and by activating the cell cycle through increasing p27kip1 degradation.[658] Remarkably, tumors derived from LMP2A/MYC mice share a similar pattern of gene expression with MYC tumors derived from transgenic mice, despite the absence of p53 pathway mutations in LMP2A/MYC mice.[47] LMP2A expression is detected as mRNA transcripts and protein in Burkitt and Hodgkin lymphoma biopsies. Like Burkitt lymphoma, Hodgkin lymphoma exhibits latency II, which includes EBNA1, LMP1, and LMP2A. EBV-associated diffuse large B-cell lymphoma shows latency II or III, including LMP1 and LMP2A. In HIV/AIDS-related lymphomas, EBV latent gene expression is heterogeneous, and LMP1 and LMP2A, in addition to EBNA2 and EBNA3A/B/C, are variably expressed.

Constitutive activation of important cellular signal transducers by LMP2A is likely important in the pathogenesis of EBV-associated malignancies. An important role for LMP2A in classical Hodgkin lymphoma can be surmised, since crippling mutations in the immunoglobulin genes are found, which would normally result in the death of these cells. LMP2A and LMP1 are uniformly expressed, providing a role for LMP2A and LMP1 in classical Hodgkin lymphoma, by allowing bypass of apoptotic signals that should normally result in cell death due to the absence of the expression of the BCR. Also in support of a role of LMP2A in classical Hodgkin lymphoma, LMP2A expression during B-cell development in mice results in decreased expression of E2A, EBF, and Pax-5, which are important for normal B-cell development.[553,554] Furthermore, LMP2A activates Notch, which alters B-cell identity.[17] Similar changes and loss of B-cell identity are observed in classical Hodgkin lymphoma.

Studies have shown that LMP2A is an important factor in NPC and gastric carcinoma. LMP2A expression in epithelial cells line results in hyperproliferation in raft cultures, alterations in differentiation, increased cloning efficiency in soft agar, and promotes epithelial cell spreading and migration.[10,194,345,406,620] AKT activation increases β-catenin and cell growth through the LMP2A ITAM and PY motif.[474,475,533] LMP2A inhibits TGF-β associated apoptosis.[202] In summary, LMP2A, like LMP1, delivers a potent cell survival signal to B lymphocytes and may provide a therapeutic target in EBV-associated cancers.

EBERs

EBERs 1 and 2 are transcribed by RNA pol III in a manner enhanced by EBNA1 as nonpolyadenylated transcripts of 167 and 172 nucleotides, respectively. The EBERs have intragenic A and B box transcriptional control regions common to pol III transcripts.[647] At steady state levels in latently infected B lymphocytes, the EBERs are the most abundant viral RNAs, reaching 1 to 5 million copies per cell. Since EBERs are expressed in all B-cell latency states, they are widely used to identify EBV-infected cells in histological samples. EBERs localize to the nucleus, where they are complexed with the cellular La and L22 proteins. Despite their high expression levels, the role of the EBERs in EBV pathogenesis remain incompletely defined.

EBER2 associates with the EBV genomic terminal repeats, where it has a role in recruiting the transcription factor PAX5 to down-modulate LMP expression.[366] In support, LCLs established from EBV deficient for EBERs express elevated LMP2 RNA levels, though protein levels were unaffected.[218] Several overexpression studies suggest that EBERs have a role in EBV oncogenicity. However, the effects of EBER expression can be opposed by concomitant

L22 expression, suggesting that the interaction between EBERs and L22 is functionally significant. Indeed, overexpression of an EBER1 mutant deficient for binding L22 in EBV-negative Akata cells failed to enhance soft agar colony formation.

EBERs are similar in size and structure to adenovirus VA1 and VAII RNAs, which block PKR phosphorylation and translation inhibition and are important for adenovirus replication. EBER1 and EBER2 can partially substitute for VA1 in adenovirus replication and can inhibit PKR *in vitro*, at levels similar to VA1 RNA. In contrast, PKR activation *in vivo* is unaffected by EBER expression. This may reflect the distinct subcellular compartmentalization, of the EBERs being exclusively nuclear, while PKR is predominately found in the cytoplasm. Both EBERs can activate the cytosolic double-stranded RNA sensor RIG-I and stimulate type I interferon production when overexpressed,[602] but like PKR, RIG-I is thought to be a cytosolic protein, calling into question the physiological significance of this interaction.

Studies of the effects of EBER deletion on primary human B-cell outgrowth have yielded conflicting results. EBER-deleted EBV generated by homologous recombination into the P3HR-1 genome was equivalent to wild-type EBV in efficiency of primary B-cell conversion to LCLs, in time to LCL outgrowth, and in lytic reactivation.[673] No significant change in B-cell outgrowth was observed between wild-type and EBER-deficient recombinant B95-8 virus over 8 days of infection.[543] Yet, the 50% transforming dose was 100-fold less for wild-type than recombinant Akata EBER deletion mutants. Restoration of EBER expression resulted rescued transformation efficiency. LCLs established from EBER-deleted Akata virus had reduced growth rates.[741] Differences in methodology or in virus strains utilized may explain discrepancies between these studies. EBER-deficient recombinant EBV established infection of humanized mice with similar efficiency as wild-type mice, with similar spleen and blood viral loads at 4 weeks postinfection.[218] Nonetheless, EBER functions are likely to be important *in vivo*, as recent experiments with the closely related murine gammaherpesvirus 68 found that the noncoding RNA TMER4 promotes infected B-cell egress from lymph nodes into the peripheral circulation. Interestingly, this TMER4 function could be replaced by EBER1.[254]

EBV miRNAs

EBV was the first human virus identified to encode miRNAs.[542] miRNAs are 20 to 22 basepair noncoding single-stranded RNAs that broadly regulate virus and host gene expression through repression of translation or through mRNA degradation. miRNAs usually fine-tune target gene expression by less than 50%, but summed activities of miRNAs on a given transcript can strengthen phenotypes. EBV miRNAs are incorporated into the RNA-induced silencing complex (RISC), which then associates with viral and host mRNA 3′ untranslated regions. Around 25 viral pre-miRNAs encoded by two viral genome clusters give rise to at least 44 miRNAs, which are expressed in LCLs and in tonsils.[485] The majority of EBV miRNAs are encoded in the BART cluster, with several also encoded in the BHRF1 cluster. Both clusters are expressed within 48 hours of EBV B-cell infection and increase over the first week.[647] A total of 21 EBV miRNAs are conserved with rhesus LCV.[647] EBV miRNAs can be expressed as abundantly as cellular miRNAs.

The BART cluster encodes 22 miRNA precursors (ebv-miR-BART1-22), from which 44 miRNAs are produced.[177] Two clusters of BART miRNAs are separated by an intron. BART miRNAs are expressed at highest levels in latently infected epithelial cells, including

nasopharyngeal and gastric epithelial cells.[569] BART miRNAs are also highly expressed in EBV-infected primary effusion lymphoma. By contrast, BART miRNAs are expressed at low levels in all stages of B-cell infection, with the lowest expression found in latency I.[74] Two TATA-less promoter regions, P1 at nucleotide 150641 and P2 at nt 150357 in the B95 sequence, likely transcribe the BARTs.[11,27,287,651] P1 is active in epithelial cells, is the initial B-cell promoter, and is down-regulated by IRF7 and IRF5, whereas P2 is more active in epithelial cells and is up-regulated by c-MYC and C/EBP.[11] Other studies have suggested that the EBV-encoded miRNA profile in infected cells may differ when normal infected tissues are compared to neoplastic tissues.[564] Interestingly, BART miRNAs promote tumor growth in murine xenograft gastric carcinoma models, suggesting epithelial transforming properties *in vivo*.[565]

The commonly used B95-8 laboratory strain lacks most BART miRNAs.[566,648] Consistent with this observation, studies with BART locus miRNAs did not uncover any gross defect in regard to EBV transformation as monitored in cell culture.[626] However, BART miRNAs may have important *in vivo* roles in immunoevasion, for example suppressing transcripts encoding RIG-I and Toll-like receptors, the NK cell ligand MICA, the IL-1 and IL-6 receptors, the NLRP3 inflammasome, the cytokine IL-12, and the NK and T-cell chemoattractant CXCL11. EBV miRNAs also suppress class I and II major histocompatibility complex antigen presentation at the levels of the TAP transporter and lysosomal proteases, respectively.[7,677] This may explain why EBV miRNA KO decreases titers and diminishes B-cell proliferation in humanized models.[492] T-cell depletion allowed miRNA-deficient EBV to achieve similar viral loads as wild-type EBV and to induce tumors. In epithelial cells, high level BART expression contributes to immunoevasion.[271]

BART miRNAs target tumor suppressor gene mRNAs, including those encoding BIM, PUMA, and PTEN.[427] BART miRNAs inhibit etoposide-triggered apoptosis in epithelial cells through effects on the BIM 3′UTR.[427] BART miRNAs enhance gastric carcinoma tumorigenicity in a murine xenograft model and block apoptosis responses in EBV-infected Burkitt cells through effects on caspase 3.[709] Burkitt cells with induced EBV-genome loss could be propagated so long as BART miRNAs were ectopically expressed.[709] EBV re-infection of these EBV-negative Burkitt cells restores their growth on soft agar and tumorigenicity in SCID mice.[344]

BART miRNA viral targets include mRNAs encoding LMP1, LMP2A, the immediate-early BZLF1, and the viral polymerase BALF5. BART9 miRNA alters LMP1 levels and affects the growth rate of NK T-cell lymphomas.[571] Interestingly, editing of BART6 miRNA results in suppression of EBNA2.[272] Induction of lytic replication enhances expression of many EBV miRNAs, even though miR-BART20-5p targets BZLF1 and BRFL1.[302] Recombinant EBV lacking BART miRNAs cause increased lytic replication, likely given increased BZLF1 expression.[391] EBV genomic deletions observed in NK and T-cell lymphomas affect the BART miRNAs, perhaps increasing lytic gene expression.[517] Indeed, the BART miRNAs most frequently deleted were mir-BART6-5p and mir-BART6-p, which target BZLF1 and BRFL1. Alternatively, multiple EBV miRNAs target B-cell receptor signaling mediators to promote EBV B-cell latency by desensitizing infected cells to antigen receptor stimuli.[99]

Alternatively spliced BART transcripts are the most abundant viral-encoded polyadenylated RNAs in EBV-infected epithelial cancers.[426] Highly spliced, nuclear polyadenylated exons, from

which the primary BART miRNA intronic sequences are removed, do not appear to be translated. Rather, they function as nuclear long-noncoding RNAs (lncRNAs). In gastric carcinoma cells, these target thousands of cellular genes, with approximately equal numbers of up-regulated and down-regulated targets. Targets include components of the unfolded protein response. Interestingly, many of the BART lncRNA target genes have also been identified as being regulated upon EBV infection.[426]

miR-BHRF1-3 are encoded within EBNA transcripts and are strongly expressed in B cells with latency III expression but are nearly undetectable in B cells or epithelial cells with latency I or II infection.[74] Two BHRF1 miRNAs accumulate with lytic replication.[13] BHRF1 miRNAs promote cell cycle progression and block apoptosis. BHRF1 miRNAs target the tumor suppressors PTEN and p27.[548] miR-BHRF1-2 reduces NF-κB activation in response to IL-1.[649] BHRF1 miRNAs also down-modulate expression of *EBNA2*, *LMP1*, and *LMP2* and up-regulate SUMO-conjugation via down-regulation of the SUMO-targeted ubiquitin ligase RNF4 SUMO to promote secretion of infectious virus.[377] miR-BHRF1-2-5p targets the 3′ UTR of the mRNAs encoding immune checkpoint PD-L1 and PD-L2.[137]

EBV miRNAs predominantly target host gene products, many of which are evolutionarily conserved RISC-accessible sites.[647] LMP1 and NF-κB up-regulate the oncogenic miR-155, whose overexpression induces lymphomas in mice and is required for LCL proliferation.[395] EBNA3A/C induce host miR-221 and 222, which targeted the mRNA of the p57KIP2 cyclin-dependent kinase inhibitor.[37] Even in LCLs established with B95-8 EBV, PAR-CLIP identified nearly 8,000 miRNA interaction sites in approximately 3,500 transcript UTRs.[646]

Extracellular vesicles (exosomes) can transfer EBV miRNAs to cells in the microenvironment, including on neighboring dendritic cells.[446,532] Viral miRNAs, which are stable within exosomes, therefore have potential for serving as biomarkers for EBV-associated diseases.

Gammaherpesviruses encode circular RNAs (circRNAs), which are small noncoding RNAs that are produced by backsplicing of a 3′ donor to a 5′ acceptor.[706] EBV circRNAs are expressed from *Cp*, the EBNA U exon, *LMP2*, *BHLF1*, and from the *RPMS1* locus. CircRNA roles remain to be defined but may include functions in sequestration of miRNAs or interactions with *oriLyt* in lytic DNA replication, as lytic circRNA clusters are located in the vicinity of lytic replication origins in multiple gamma-herpesviruses.

EBV Lytic Replication

Lytic replication is necessary for transmission of EBV between hosts and for cell-to-cell spread. Lytic genes are increasingly recognized to also have oncogenic roles, in particular for NPC, where elevated antibody titers against EBV lytic proteins are disease biomarkers.[443] EBV gene expression follows a temporal and sequential order as with other herpesviruses. Nearly all EBV genes are expressed in the viral lytic cycle, where by late timepoints most of the viral genome is transcribed in both directions.[515] The majority of genes required for EBV lytic DNA replication, cleavage, assembly, and packaging of the viral genome are conserved across the three herpesvirus families. Table 11.1 lists EBV protein-coding genes and their HSV and KSHV homologs. EBV lytic reactivation remodels the B-cell proteome, with multiple effects on cell cycle proteins and immune pathways, including up-regulation of complement and depletion of

the B-cell receptor complex.[174]

Lytic replication may contribute to EBV-associated cancers by at least three mechanisms: (a) expansion and replenishment of the population of infected cells; (b) conditioning of the microenvironment, including induction of angiogenesis, genomic instability, and secretion of proinflammatory cytokines and growth factors[322,485]; and (c) abortive lytic expression of oncogenic noncoding RNA and proteins.[518] Immediate-early and early gene expression contributes to B-cell lymphomagenesis in humanized mouse models.[418]

Immediate-Early Genes

The EBV immediate-early viral genes *BZLF1* and *BRLF1* are transactivators of virus replication. BZLF1 was originally identified in studies using variants of the EBV-positive HR1 cell line. A rare variant spontaneously released virus that could induce early lytic antigens in Raji cells. These early studies identified that a 2.7-kb DNA rearranged in the rare P3HR-1 variant cells was sufficient to trigger lytic replication in latently infected cells.[48,136,462,678] Subsequent studies showed that rearranged BZLF1, contained in this fragment, was sufficient to disrupt latency in HR-1 cells.[135] BZLF1 and BRLF1 are expressed shortly after induction of lytic replication by immunoglobulin cross-linking and are essential for lytic replication.[180] BZLF1 and BRLF1 cross-regulate one another and synergistically induce EBV early genes. Studies comparing BZLF1 and BRLF1 deletion viruses, and analyzing the temporal order of BZLF1 and BRLF1 expression following induction of EBV lytic replication, indicate that BZLF1 is critical in the initial stages of B-cell induction of lytic replication.

BZLF1 is encoded by a three exon transcript initiating from the *BZLF1* promoter (*Zp*). The first exon encodes a TAD.[382,385,387] The second exon encodes a strongly basic domain with homology to AP1 that interacts with DNA sites. BZLF1 and AP-1 bind to similar DNA motifs, although BZLF1 preferentially binds to methylated Z-responsive elements (meZRE). Underscoring their close relationship, several alanine-to-serine point mutants enable AP-1 to phenocopy key BZLF1 functions, including binding to meZREs and inducing BRLF1 and early gene expression.[414] The third exon encodes a coiled-coil leucine/isoleucine heptad repeat.[191]

Phosphorylation by host and viral kinases regulate BZLF1 activity, including casein kinase II (CKII) and protein kinases A and C (PKA and PKC). PKC phosphorylates BZLF1 DNA binding domain serine 186, and this residue is absolutely required for lytic reactivation.[196] CKII phosphorylates BZLF1 serines 167 and 173, the latter of which is required for lytic DNA replication but not for early gene activation.[443] The EBV serine/threonine kinase BGLF4 further regulates BZLF1 activity and supports its expression.[21,22,379]

BZLF1 activates transcription of BRLF1 (also known as RTA or R), which is a DNA sequence specific transcription activator with distant amino acid sequence similarity to the host transcription factor c-MYB. RTA binds to RTA-response elements (RREs) and to viral promoters through association with host transcription factors.[443] BRLF1 and BZLF1 activate their own as well as each others' promoters.[322] BRFL1 has an N-terminal DNA recognition domain, a dimerization domain, and a C-terminal transcription activation domain that is a potent acidic activator similar to VP16. BZLF1 and BRLF1 synergistically induce transcription from viral early gene promoters, which frequently contain DNA elements for both. BRLF1 binds to unmethylated DNA motifs and preferentially induces activating H3K9 histone acetyl marks at

unmethylated promoters, which is important for epithelial cell lytic induction.[733]

The *BZLF1* promoter is tightly repressed to maintain latency. Seven *cis*-acting, BZLF1-bound DNA elements, termed ZIA-D, ZII, ZIIIA, and ZIIIB regulate Z promoter (Zp) activity (Fig. 11.14).[191] Multiple host transcription factors also bind to Zp elements, including Sp1/Sp3 and the myocyte enhancer factor 2D (MEF2D). Depending on cell type, the host repressors ZEB1 and/or ZEB2 bind to the Z promoter ZV/ZV' element to suppress induction of lytic replication.[169,346,347] Mutations that disrupt these silencing elements result in hyperlytic viruses that are deficient in B-cell transformation. The host miRNAs 200b and 429 can induce EBV latently infected cells to undergo lytic replication, in part by reducing expression of ZEB1/ZEB2.[170] STAT3 and PARP1 exert additional repressive effects on EBV lytic reactivation.[342,411] As mentioned above, MYC represses EBV lytic reactivation.[222]

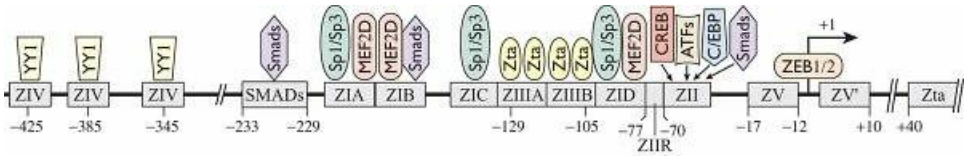

FIGURE 11.14 Schematic representation of EBV BZLF1 promoter elements. The BZLF1 promoter has a large number of binding sites for regulators of gene expression. Shown in the diagram are the cis-acting regulatory elements present within nucleotides −221 through +40 of the BZLF1 promoter relative to the transcription initiation site. *Shaded rectangles* along the BZLF1 promoter indicate approximate locations of identified regulatory elements with the relevant transacting factors indicated above.

Variants of the Z promoter alter the extent of lytic protein expression in B cells. The Zp-V3 variant, found in type 2 EBV strains and in some type 1 strains, contains a binding motif for NFAT. While type 2 EBV causes higher levels of lytic protein expression in cord blood-humanized mouse infection models as well as in LCLs,[588] Zp-V3 is not sufficient for this phenotype. Elevated NFATc1 and NFATc2 abundance may also contribute lytic replication levels in type 2 EBV infected cells. The M81 EBV strain, isolated from a patient with NPC, has high spontaneous lytic replication, linked to lower BART miRNAs levels[391] and to higher expression of the EBV DNA polymerase BALF5.[115] Sumoylation also regulates BZLF1 and BRLF1 activities.[322] EBV lytic factor LF2 induces BRLF1 sumoylation and relocalizes it to the extranuclear cytoskeleton, resulting in repression of BRLF1 activity.[76,238]

Cellular differentiation is increasingly linked to EBV reactivation. B-cell differentiation into plasma cells is a major trigger for EBV lytic replication.[355] Likewise, studies of oral hairy leukoplakia found that EBV lytic replication occurred in the outer most differentiated layers of the epithelium[503] and in raft culture models EBV lytic replication is dependent on epithelial cell differentiation.[89,166] Mechanistically, the plasma cell differentiation master regulators BLIMP1 and XBP-1 are essential for B-cell lytic induction.[44,580] In epithelial cells, differentiation-dependent expression of BLIMP1 and KLF4 synergistically support EBV lytic reactivation. KLF4 and BLIMP1 induce LMP1 in epithelial cells in an immediate-early gene independent manner, and LMP1 in turn supports BZLF1 and BRLF1 expression.[497] Hypoxia, transforming

growth factor beta, and B-cell receptor stimulation also trigger lytic gene expression.[322]

Early Genes

The 38 EBV early genes are operationally differentiated from late genes by their transcription in the absence of viral DNA synthesis. Early genes are transcribed from nucleosome-bound DNA templates, with promoters often initiating nested transcripts that terminate at the same polyadenylation site. Lytic replication leads to amplification of EBV DNA by the BALF5 polymerase by 100 to 1,000-fold within 1 to 2 days, likely by a mixture of semiconservative and rolling circle DNA amplification. EBV lytic replication produces long head-to-tail concatemers that are cleaved and packaged as linear, unchromatinized genomes.[228] Considerable progress has been made in constituting an *in vivo* minimal DNA replication system similar to the Challberg HSV system.[188,189] The components include BALF5, which encodes the core DNA polymerase, BALF2 the single strand DNA binding protein, BMRF1 the processivity factor, BSLF1 and BBLF4 the primase and helicase complex, BBLF2/3 a spliced primase helicase complex component, and BKRF3 the uracil DNA glycosylase.

Lytic DNA amplification is accompanied by extensive nuclear reorganization, with the appearance of large regions termed replication compartments in which EBV DNA is replicated. These occupy approximately 30% of the nuclear volume and result in the margination of host DNA, causing a honeycombing nuclear appearance.[111,494] Host DNA and histones are excluded from these regions. Lytic DNA replication begins synchronously from EBV episomes within a given cell that serve as templates, but is delayed until cells reach S-phase, at which point single EBV genomes seed individual replication compartments. Only approximately 30% of EBV episomal DNA serves as templates for DNA synthesis. Within the replication compartments, the DNA processivity factor BMRF1 forms core structures surrounding newly replicated DNA and late gene mRNAs.[671]

The viral lytic origin *oriLyt* is an approximately 8 kb, cis-acting element with multiple lytic cycle roles.[228] Nearly all EBV strains have two copies of *oriLyt*, located approximately 100 kbp apart. *Orilyt* is comprised of a approximately 1 kb core region with 7 ZREs flanked by upstream and downstream auxiliary regions. BZLF1 occupancy converts *oriLyt* into a strong enhancer and mediates interactions with viral replication proteins.[458,490] Recombinant EBV deficient for all oriLyt ZREs could only support low-level lytic replication.[179] O*riLyt* interacts with multiple viral factors, which assemble into a replication complex, including BALF5 polymerase, BMRF1 polymerase processivity factor, BBLF4 helicase, and BSLF1 primase. *OriLyt* also has key roles in late gene expression and must be present in *cis* for late gene transcription.[157]

The small, nuclear RNA-binding protein BSMLF1 (SM) is essential for lytic replication.[710] SM is the functional homolog of HSV US11/ICP27. SM increases the export and levels of most intronless RNAs, binds to and inhibits PKR, and binds EBV transcripts to enhance their stability, nuclear export, splicing, and translation efficiency. SM is important for the expression of 15 late lytic genes.[688,710] SM also recruits the xeroderma pigmentosum group B-complementing protein (XBV), a component of the transcription factor II H (TFIIH) complex, to EBV lytic promoters to induce lytic genes. The hypertension medication, spironolactone, which triggers XBP degradation, inhibits SM-dependent late gene transcription.[710]

The BGLF4 serine threonine protein kinase, which is homologous to the HSV UL13 and

KSHV ORF36, is necessary for most late gene expression, even following lytic DNA replication.[167] BGLF4 dissociates from the virion and phosphorylates several viral proteins, including BZLF1 and BMRF1. BGLF4 activates topoisomerase II, contributes to changes in nuclear morphology and modification of the DNA damage response. BGLF4 rather than the EBV thymidine kinase encoded by BXLF1 is the viral kinase that activates ganciclovir or acyclovir for inhibition of EBV lytic replication.[450]

Late Genes

EBV encodes approximately 36 late mRNAs, whose expression requires lytic DNA replication. However, a subset of EBV "leaky late" genes are expressed with both early and late kinetics. CAGE-seq analysis identified 16 true-late and 16 leaky-late genes.[158] Late genes include proteins necessary for DNA packing into capsids, virion assembly, virion structure, and glycoproteins. Viral IL-10 is also expressed with late kinetics.[487] Expression of nearly all true late genes is dependent on the viral pre-initiation complex (vPIC), which is assembled by six EBV proteins with orthologs in β and γ, but not in α-herpesviruses. vPIC recruits RNA polymerase II to late gene promoter TATTWAA elements, where W represents either A or T,[158] which drives transcription of late genes. Since vPIC functions in the context of a *cis*-acting *oriLyt*, it is likely that vPIC drives transcription from newly replicated viral DNA, perhaps explaining why late gene mRNAs are found in replication compartments. Therefore, late gene expression is dependent on three factors: viral DNA replication proteins, *oriLyt* in *cis*, and the vPIC.

Precisely why these genes are only expressed from lytic DNA remains an open question, but hypotheses include that these require the absence of histones and/or epigenetic marks or a host repressor that requires these marks, that replication may recruit factors necessary for transcription from late promoters, that topological changes resulting from linear EBV genomes are required, or that replication compartments allow sufficient concentration of viral components important for late gene expression.[115]

Head-to-tail EBV DNA concatemers produced by lytic replication must be cleaved for packaging of unit length genomes into procapsids. EBV BALF3 is homologous to the HSV terminase UL28 and is a component of the viral terminase that cleaves EBV concatemers, together with BGRF1/BDRF1 and BFRF1A.[112] The EBV terminal repeats, comprised of 538 base pair sequences that are located at the ends of the linear EBV genome, are packaging signals. Sequence alignments of EBV and other herpesvirus genomic termini suggest that conserved packaging signals are present within the EBV TRs.[112] The EBV GCATGGGGGG motif, referred to as DR1, brackets the multiple copies of TR. In HSV-1, DR1 is the site of cleavage of headful length DNA for packaging into virions. The sequence $C(G)_5TGT(T)_2CCT(G)_5CC$ occurs 25 base pairs before the EBV DR1, is similar to sequences in HSV and CMV, and is also the key cleavage packaging recognition sequence for EBV. The EBV rightmost TR acquires a short unique sequence from the leftmost TR during cleavage and packaging and that sequence becomes the left end of the DNA.[764] Interestingly, lytic replication of recombinant EBV lacking terminal repeats results in the production of empty capsids and viral particles, demonstrating that DNA packaging is not necessary for virion formation and egress.[181]

Herpesvirus nucleocapsids are greater than 100 nM in size, whereas nuclear pores are 40

nM.[140] Nonetheless, nucleocapsids are observed in the cytoplasm in cells with lytic replication. In common with other herpesviruses, encapsidated EBV genomes exit the nucleus by budding through the inner and outer nuclear membranes for further maturation in the cytosol and secretory pathways. The EBV nuclear egress complex (NEC) is comprised of BFRF1 and BFLF2, which are orthologs of UL31 and UL34 of HSV. The BFRF1 NEC core and BFLF2 hook segments are highly structurally conserved with other herpesvirus NEC complexes.[481]

Tegumentation and maturation occurs in the cytosol. EBV then buds into compartments with cis and trans-Golgi markers. Viral particles subvert cellular secretion pathway machinery to travel through secretory vesicles in a manner dependent on Rab GTPases, including Rabs8, 10, and 11. As in other herpesviruses, EBV gM and gN are important for egress of EBV virions from infected cells. These two proteins form a stable complex in infected cells, and EBV that lacks gN is deficient in envelopment and de-envelopment. Matured EBV particles are released as enveloped virions via fusion with the plasma membrane.[495]

ENTRY INTO HOST—PORTAL OF ENTRY, SITE OF PRIMARY REPLICATION, CELL TYPES INFECTED

Most EBV infections occur through contact with infected saliva from persons infected in the past. Saliva contains virus that is high in EBV gp42. This suggests that the virus is derived predominantly from MHC class II negative cells (i.e., epithelial cells rather than B cells)[290] and will therefore be more efficient in binding B cells than epithelial cells. During primary infection, EBV either infects epithelial cells in Waldeyer's ring in the oropharynx where it replicates[641] and then can infect resting naïve B cells that traffic through the oropharynx, or the virus may infect resting, naïve B cells in the tonsilar crypts directly (Fig. 11.15). In addition to its high gp42 content, the presence of EBV in the blood 3 weeks before the onset of IM and in throat washings only 1 week before the disease suggests that B cells are the first cell type infected.[164] Virus replication has been reported in orally shed epithelial cells during IM,[371] but subsequent studies on tissue sections have found replication only in B cells in the tonsils. While some oropharyngeal B cells undergo lytic infection, most become latently infected. Initially the cells are lymphoblasts with a type III pattern of latency and express each of the EBV latency genes[352] (Table 11.2). Up to 10% of the B cells in the blood are EBV-positive early in infection but it appears that, even by this stage, most of these cells have the phenotype of resting memory B cells and have escaped immune surveillance by down-regulating the latency III program.

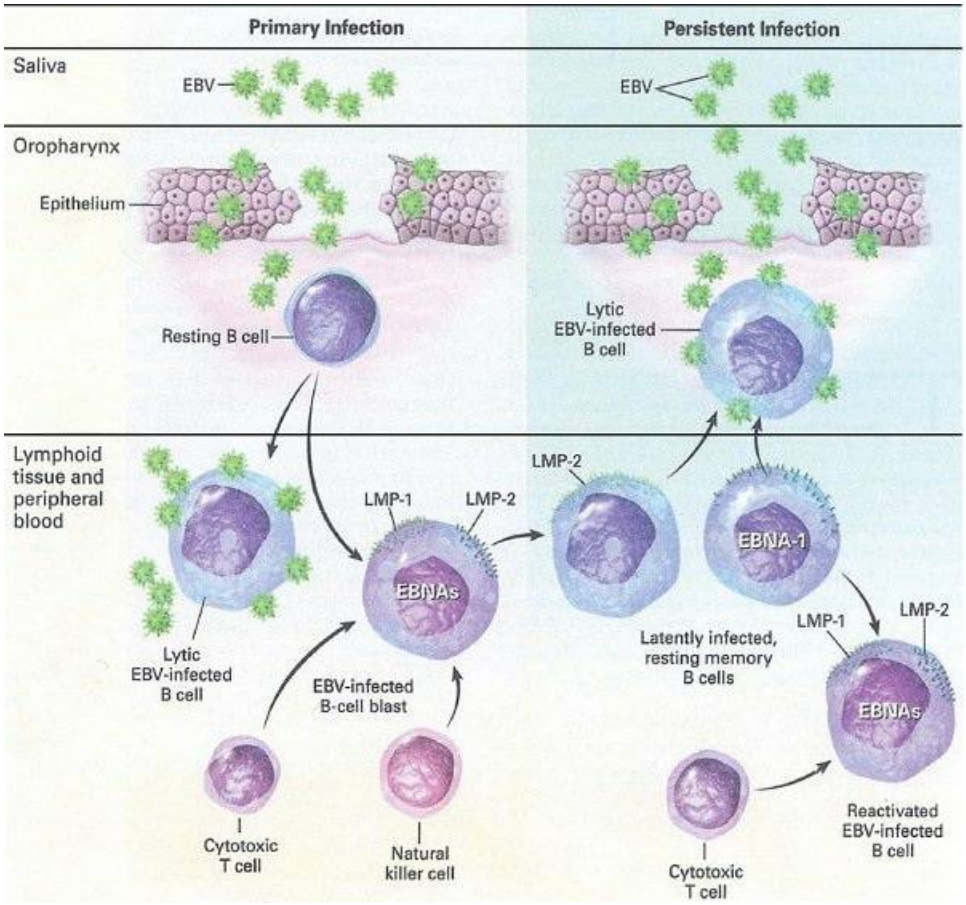

FIGURE 11.15 EBV life cycle. EBV infects resting B cells either directly or by virus released from epithelial cells in the oropharynx. EBV-infected B cells in the lymphoid tissues and blood undergo lytic infection or become B-cell blasts, which are controlled by NK cells and cytotoxic T cells. Latently infected resting memory B cells express no viral proteins unless they divide; if they reactivate, they are controlled by cytotoxic T cells. Some latently infected cells traffic to the oropharynx where they undergo lytic replication and release virus. (Adapted from Cohen JI. Epstein-Barr virus infection. *N Engl J Med* 2000:343(7):481-492. Copyright © 2000 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

These early events remain poorly understood, in particular how an initial growth-transforming infection, potentially involving all infectable B-cell subsets in the oropharynx, results in selective colonization of just the memory B-cell compartment. Thorley-Lawson and colleagues have postulated that EBV preferentially infects and activates only naïve B cells, which then enter germinal centers and differentiate into resting memory B cells, similar to the physiologic process through which naïve B cells are activated by cognate antigen to become B-cell blasts, enter the germinal center of lymphoid follicles, undergo class switch recombination, somatic hypermutation, and, if positively selected, differentiate into resting memory B cells[252] (Fig. 11.16). Physiologically, only B cells whose surface immunoglobulin (B-cell receptor) has a high affinity for antigen are selected, thereby avoiding apoptosis and becoming $CD27^{+}$ memory B cells. Accordingly, it is postulated that naïve B cells infected with EBV express EBV type III

latency genes resulting in B-cell proliferation and blast formation. These cells then migrate to a lymphoid follicle to begin the germinal center reaction. EBV-infected cells then switch to express only EBV latency II genes. Of these, EBV LMP1 up-regulates activation-induced cytidine deaminase (AID) to induce somatic hypermutation or immunoglobulin class switching. EBV LMP2 stimulates antigen receptor signaling.[78] This allows the infected cell to survive its transit through the germinal center. Upon exiting the germinal center into the blood, the virus-infected cells are thought to differentiate into memory B cells and express the EBV latency 0 pattern of gene expression with no viral proteins expressed.[252] Subsequently, some of these cells may undergo differentiation to plasma cells with EBV lytic replication. The resulting virus may then infect nearby naïve B cells, or if differentiation and virus replication occurs after the B cells traffic back to the oropharnyx, the resultant virus may be shed into the saliva directly, or may infect permissive epithelial cells, which can also shed EBV into the saliva.

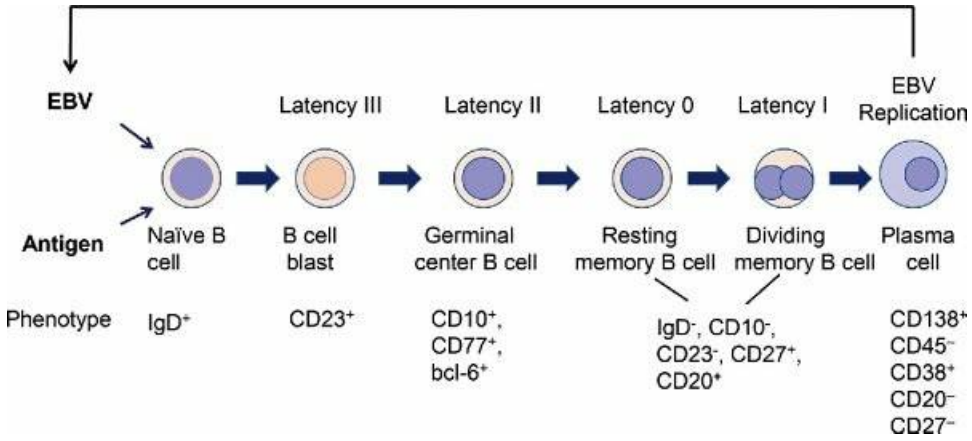

FIGURE 11.16 EBV infection of B cells parallels the response of B cell to antigenic stimulation. EBV infects naïve B cells, which become B-cell blasts with type III EBV latency. The cells undergo a germinal center reaction with type II EBV latency and exit the germinal center with type 0 EBV latency. EBV-infected resting memory B cells can differentiate in plasma cells whereby EBV undergoes lytic replication and can infect new naïve B cells.

While the above model has its attractions, it is worth noting several lines of evidence that remain difficult to reconcile with the model as proposed. First, EBV can infect both naïve and memory B cells not only *in vitro* but also *in vivo*; thus, within the tonsils of persons with IM, Ig gene sequencing of single cells picked from tissue sections reveals clonal expansions of both naïve and fully mature memory B cells, with various patterns of latency displayed even within individual clones.[352] Importantly, however, these expansions are occurring in extrafollicular areas of the tonsil and not in germinal centers; indeed Ig sequencing of the few infected cells that are localized within germinal center areas shows that they are infiltrating B cells and not part of the germinal center reaction.[352,502] Second, in healthy carriers EBV is present in both the non–isotype-switched as well as isotype-switched memory B-cell subset; however, the non–isotype-switched subset is thought by many to be independent of the germinal center. Third, patients with X-linked lymproliferative disease have absent or poorly formed germinal centers, but they clearly become infected with EBV (see below). Likewise patients with X-linked

hyperimmunoglobulin M syndrome cannot form germinal centers and lack class switched (IgD^-, $CD27^+$) classical memory B cells; however, these patients can be infected with EBV and the virus is found in nonclassical memory B cells (IgD^+, $CD27^+$).[130] Thus, EBV infection of the B cells can occur in the absence of germinal centers and a conventional memory B-cell population. Indeed much of the above evidence suggests that, even in the normal course of events, the virus populates the memory B-cell compartment without involving passage through a germinal center.[59]

While EBV infects naïve and memory B cells from tonsils *ex vivo*, EBV is less efficient in infecting memory B cells from the blood.[162] IgA-positive or IgG-positive memory B cells from the tonsils are infected more efficiently with EBV than IgM memory B cells from the tonsils. EBV infects memory B cells in nasal-associated lymphoid tissue more efficiently than memory B cells in other lymphatic tissues. EBV has been detected in plasmacytoid B cells.[14]

B cells are essential for EBV latency. Persons with X-linked agammaglobulinemia who lack mature B cells are not infected with EBV and have no cellular immunity to EBV.[178] Hematopoietic stem cell transplantation, which eliminates host B cells, but not epithelial cells, can eliminate EBV from the body.[215] EBV replication is detected in epithelial cells of the tongue, but not in epithelial cells of the salivary glands. EBV also infects human umbilical cord-derived endothelial cells.

While EBV is present in B cells in the blood of healthy individuals, in some patients with elevated EBV levels in the blood (e.g., patients with HIV, transplant recipients), EBV has been detected in other cell types, usually at a lower frequency than in B cells. EBV has been detected in the blood in cells other than B cells including CD4+ and CD8+ T cells in patients with HIV, γ/δ T cells, and NK cells in patients with chronic active EBV disease, plasmablasts/plasma cells and monocytes in patients with lymphoproliferative diseases and HIV,[75] and pre-Langerhans cells in the blood of persons with HIV as well as healthy individuals. Detection of EBV in cells other than B cells by cell sorting using flow cytometry must be carefully verified by additional techniques due to possibility of contamination with small numbers of B cells during the sort.[195]

IMMUNE RESPONSE

Innate Immune Response

The innate immune response is comprised of rapidly mobilized humoral and cellular processes that limit the replication and spread of pathogens prior to the development of antigen-specific adaptive responses, but that by themselves do not result in the generation of immunological memory. Key components of the innate immune response to EBV include natural killer (NK) cells, **γ/δ,** and invariant natural-killer (iNKT) T cells.

NK cell expansion is observed with acute infection and the levels of proliferating NK cells correlate with the EBV load.[30,486,683] Cytokines that regulate NK cell activation (IFN-α, IFN-β, IFN-γ, and IL-12) are significantly increased in persons with IM compared with healthy controls. In the peripheral blood of patients with IM, the $CD56^{dim}$ $CD16^-$ NK subset preferentially

expands. These NK cells recognize and lyse cells undergoing EBV replication *in vitro*.[683] The expansion of early differentiated NK cells persists for at least 6 months. However, in the months after acute infection, these cells up-regulate senescence markers and cease to proliferate. The $CD56^{dim}/KIR^{-}/CD57^{-}$ NK cell frequency is higher in early childhood than later in adulthood, raising the possibility that more robust CD8+ T-cell responses may be required to control EBV when acquired at later ages, and that this may in turn drive IM.[486]

Differentiated $CD56^{dim}$ $CD16^{+}$ cells are primed for cytotoxic activity against EBV-infected cells and are also found in the peripheral blood. Less mature $CD56^{bright}/CD16^{-}$ NK cells predominate in secondary lymphoid organs, including the tonsils. These early differentiated NK cells do not appear to exert cytotoxic effects against EBV-transformed B cells, and instead limit EBV-driven B-cell growth transformation *in vitro*, likely due to IFN-γ secretion.[683]

Humanized mouse models highlight roles for NK cells in control of B-cell EBV infection. Early differentiated NK cells expand by 3 weeks post-EBV infection, the timepoint at which lytic replication is also first seen in this model. NK cell depletion results in elevated EBV genome copy numbers in humanized mice infected with wild-type virus, but not in mice infected by BZLF1 KO virus, underscoring a key role for NK cells in control of B-cell EBV lytic replication.[109] NK cell depletion also results in CD8+ T-cell expansion, splenomegaly, and monoclonal B-cell lymphoproliferation, reminiscent of IM. Indeed, impairment in NK cell differentiation by loss-of-function *IRF8* mutation is associated with severe EBV disease, including fulminant infectious mononucleosis.

Invariant NK T (iNKT) cells are innate-like T cells with α/β receptors that may also exert an important layer of control over newly EBV-infected B cells. iNKT cells express a semi-invariant T-cell receptor that recognizes glycolipid antigens presented by the MHC class-1 related CD1d molecule. Activated iNKT cells secrete large quantities of cytokines, including IFN-γ, have cytotoxic activity, and limit EBV-driven B-cell growth transformation *in vitro*. However, iNKT cells may preferentially control newly EBV-infected B cells, because CD1d is down-modulated early during EBV-driven B-cell transformation *in vitro*.[114] Notably, patients with X-linked lymphoproliferative disease lack iNKT cells, and this may be linked to their susceptibility to EBV.

γ/δ T cells may also exert important anti-EBV responses.[399] Activated **γ/δ** T cells exert cytotoxicity toward EBV-transformed B cells in cell culture and in a murine LCL xenograft model.[736] Interestingly, Vg9Vd2 T cells could be expanded *in vitro* by administration of bisphosphonate pamidronate and then adoptively transferred to humanized mice, where they inhibited xenograft LCLs.

Antibody Response

Acute EBV infection induces polyclonal B-cell activation with elevated levels of IgG, IgM, and IgA. Humoral responses to many EBV lytic and latent antigens are observed in IM. Heterophile antibodies are produced, which are not EBV-specific, and instead are largely IgM antibodies directed toward glycoplipid antigens on red blood cells.[454] One type of heterophile antibody used for diagnosis of acute infection measures the dilution of serum that agglutinates sheep, horse, or cow erythrocytes after absorption with guinea pig kidney. Heterophile antibodies persist for up to 1 year after IM and are often absent in children less than 5 years old or in the elderly. IgM and

IgG antibodies to VCA are usually present at the onset of symptoms of IM (Fig. 11.17).[454] Later in infection, antibody to EBNA is detected and IgM to VCA disappears. IgG antibody to VCA and EBNA persists for life.[683] Antibodies to EBV early antigens (EAs) are classified as either diffuse (EA-D, diffusely in the nucleus and cytoplasm, methanol resistant) or restricted (EA-R, restricted to the cytoplasm, methanol sensitive). EA-D antibodies are often present 3 to 4 weeks after the onset of IM, especially in patients with severe illness, and are frequently detected in patients with NPC or CAEBV. EA-R antibodies are often detected in CAEBV or African BL. IgA antibody to EBV is often elevated in patients with NPC and IgA antibody to EBV EA is present in patients with IM.[43]

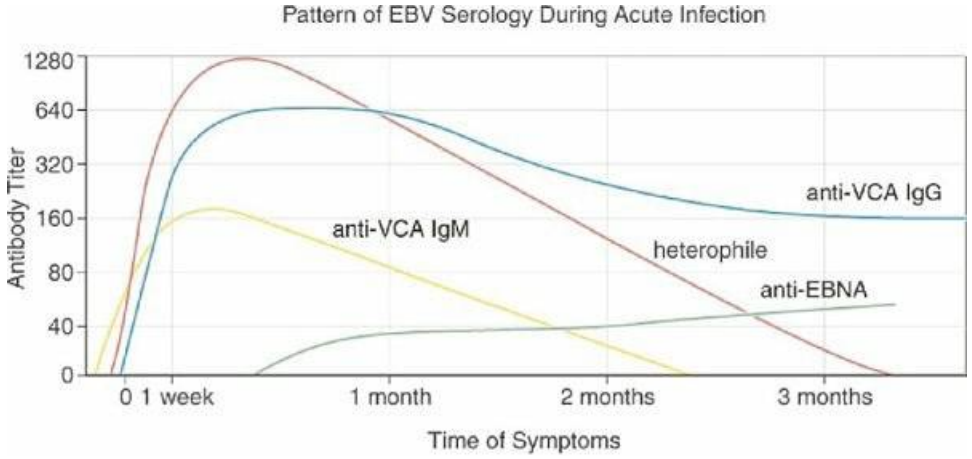

FIGURE 11.17 Pattern of antibodies to EBV during acute infection. (Reprinted from Cohen JI. Epstein-Barrr virus. In: Young NS, Gerson SL, High KA, eds. *Clinical Hematology*. Philadelpha, PA: Elsevier; 2006:956–966. Copyright © 2006 Elsevier. With permission.)

There has been growing interest in the identification of anti-EBV glycoprotein antibodies that block EBV entry into epithelial and/or B cells. Neutralizing anti-gp350 antibodies reached their highest levels at approximately 6 months postinfection, and these were not found to be more abundant in individuals with symptomatic disease. Anti-gH/gL and gp42 antibodies contribute to neutralization of B-cell infection,[65] and anti-gH/gL antibodies also neutralize EBV epithelial cell infection.[65] Monoclonal antibodies targeting gH/gL potently neutralize both epithelial and B-cell infection.[65,653] Interestingly, elevated levels of antibodies that bind gp350 and neutralize B-cell infection are associated with a lower risk of NPC in certain populations.[117]

T-Cell Immune Response

The importance of T-cell immunity toward EBV is highlighted by the high frequency of EBV-associated malignancies in patients with congenital immunodeficiency syndromes that restrain T-cell responses, in patients with HIV/AIDS, or who receive T-cell immunosuppression posttransplant. Nearly eighty EBV-encoded polypeptides are a potentially rich source of epitopes for CD4+ and CD8+ T-cell activation. CD8+ T cells, which recognize infected cells through viral peptides presented by MHC I molecules on the cell surface, play key roles in control of

both acute and persistent EBV infection, and the CD8+ T-cell response in infectious mononucleosis (IM) is one of the strongest human T-cell responses described.[220] These are the "atypical lymphocytes" whose presence is used clinically to help establish the diagnosis of IM. The increase in anti-EBV CD8+ T-cell abundance correlates with the onset of IM symptoms (Fig. 11.18), consistent with the hypothesis that antiviral and proinflammatory cytokines secreted by this population of cells drives IM symptoms. Anti-EBV responses can exceed 50% of the CD8+ T-cell population.[683] Anti-EBV CD8+ T cells proliferate and have activated/memory phenotypes.

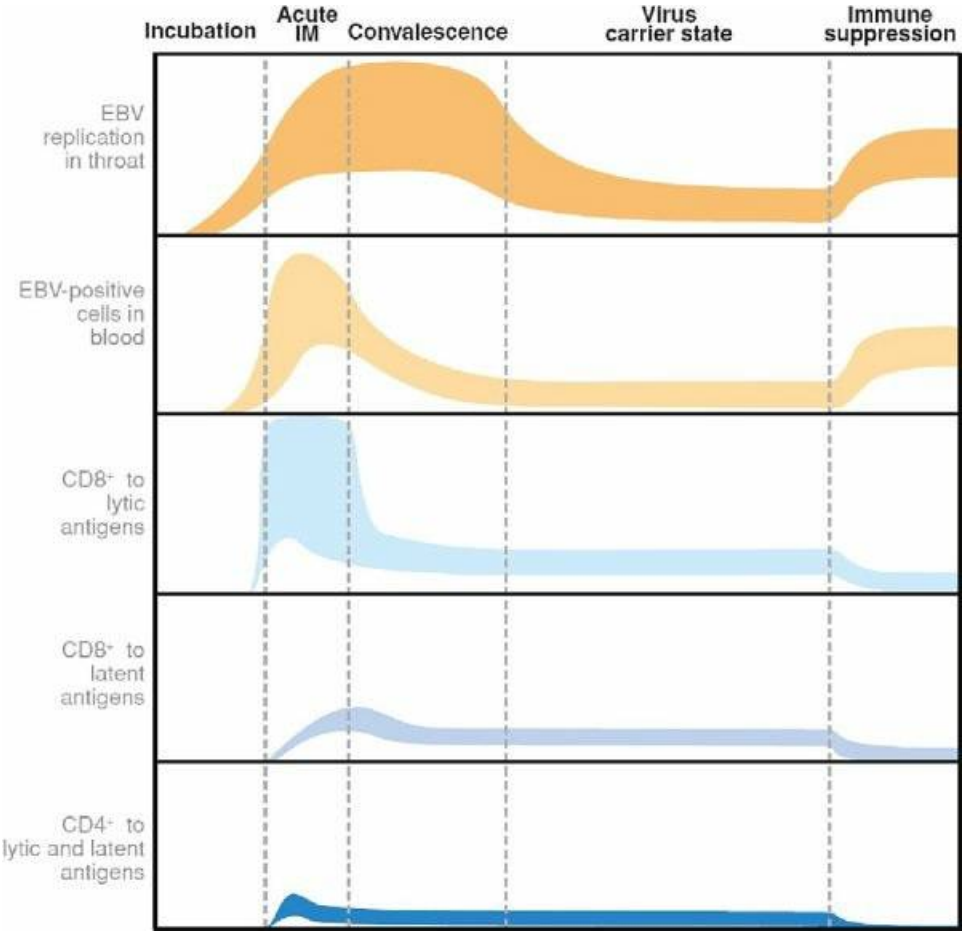

FIGURE 11.18 Levels of EBV in the throat and blood and cellular immunity during the course of infection. Cellular responses to viral infection in humans: lessons from Epstein-Barr virus. *Annu Rev Immunol* 2007;25:587–617; permission conveyed through Copyright Clearance Center, Inc.)

Primary CD8+ T-cell responses to EBV, as seen in acute IM patients, are most robust against immediate-early and to a lesser extent to certain early antigens, including BMRF1 and BMLF1[683] (Fig. 11.19). This hierarchy appears to follow the abundance of viral peptides presented by MHC I molecules on the infected cell surface prior to the induction of EBV

immunoevasins that perturb antigen presentation.[193] While responses to immediate-early and particular early antigens dominate the primary response, a recent study has shown that the response broadens over time to reveal new late antigen responses in the blood of long-term carriers.[4] Although T-cell responses to EBV contract after resolution of IM, even in chronic carriers, EBV-specific memory cells can account for up to 3% of the circulating CD8+ T-cell pool.[399] In humans, a virus-driven memory response of this magnitude in the blood is only exceeded by memory to another herpesvirus, CMV.

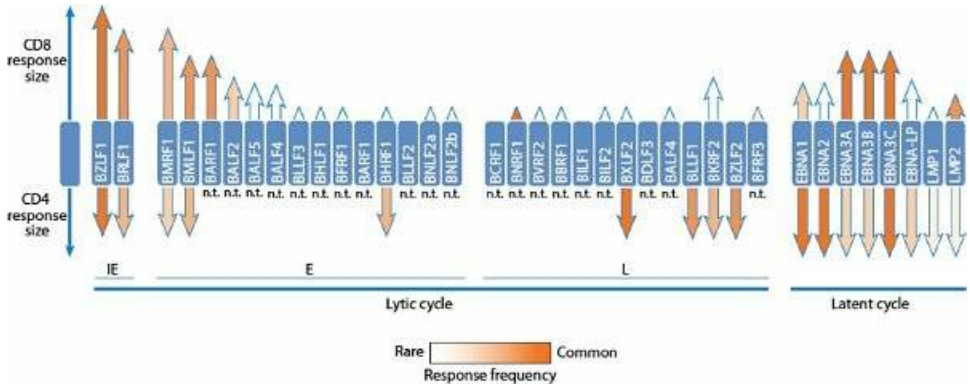

FIGURE 11.19 CD8+ and CD4+ T-cell responses to EBV immediate-early (IE), early (E), late (L), and latent proteins. (Republished with permission of Annual Reviews, Inc. from Taylor GS, Long HM, Brooks JM, et al. The immunology of Epstein-Barr virus-induced disease. *Annu Rev Immunol* 2015;33:787–821; permission conveyed through Copyright Clearance Center, Inc.)

Plasmacytoid dendritic cells (pDCs) detect EBV, produce interferons, and prime CD8+ T-cell responses but may not be required for control of EBV infection.[220] Expression of programmed death receptor 1 (PD1), a marker of T-cell exhaustion, is elevated on EBV-specific CD8+ T cells during IM, correlates with the EBV viral load, and returns to low levels during convalescence. PD-1+ T cells expand in IM and in humanized mice infected by EBV, where they and other expanded T-cell subsets are important for control of EBV.[97] EBV-specific CD8+ T cells persist and have cytotoxic activity. In healthy carriers, the frequency of EBV-specific CD8+ T cells is about 0.2% to 2% for viral lytic proteins and 0.05% to 1% for latent proteins and remains stable over time. A large proportion of these responses are directed at EBNA3A, EBNA3B, and EBNA3C antigens. BZLF1, BRLF1, BMRF1, and BMLF1 antigens are also prominent targets (Fig. 11.19).[165,683] A smaller number of CD8+ T cells are specific for EBNA2, EBNA-LP, LMP1, or LMP2. However, CD8+ T cells responsive to EBNA2 and EBNA-LP peptides can recognize newly infected B cells *in vitro* and inhibit outgrowth of these cells in culture, suggesting a possible role for these cells in adoptive or vaccine approaches.[63] During chronic infection, T cells specific for EBV epitopes are typically antigen-experienced, resting cells that do not express activation markers. However, these T cells secrete cytokines and exhibit potent cytotoxicity upon re-challenge.[399]

T-cell responses may be different during asymptomatic infection in early childhood, but the differences appear to be quantitative rather than qualitative. Thus, studies of newly infected

African children show that, although they have high IM-like EBV genome copy numbers in the blood, they do not show a gross expansion of the CD8+ compartment; there is a detectable EBV-specific CD8+ T-cell response against the known immunodominant antigens but the response does not amplify to the unusually high level seen in IM.[285,399] Despite these differences, once the long-term virus carrier state is established, anti-EBV CD8+ T-cell frequencies are similar in individuals who experienced asymptomatic or symptomatic primary infection.[683] There is growing interest in the use of adoptive CD8+ T-cell therapy to augment anti-EBV responses in patients with primary or secondary immunodeficiency.

CD4+ T cells recognize peptide antigens presented by major histocompatibility class (MHC) II molecules on the surface of professional antigen presenting cells such as dendritic cells and macrophages. Such cells engulf virion particles or viral antigens released from infected cells and then present them to CD4+ T cells.[398] However, B cells also naturally express MHC class II molecules and have antigen-processing capacity, as do certain other cell types when induced to express MHC II by IFN-γ. Though classically seen as providing help for CD8+ T-cell responses, CD4+ T cells can themselves become cytotoxic after activation, as recently shown for the EBV-specific T-cell response.[399] The CD4+ T-cell response to EBV is different in several respects from that shown by CD8+ T cells; the response is numerically smaller, latent cycle reactivities tend to be dominant, and lytic cycle responses are more evenly spread across IE, E, and L antigens, both in primary and persistent infection (Fig. 11.19).[30,683] The breadth of the CD4+ T-cell response presumably reflects the large array of antigens released from infected cells and available for processing by professional antigen-presenting cells. In addition, cross-presentation of intracellular EBV antigens between infected B cells themselves, as has been observed *in vitro*, may also play a role both in priming the response and in rendering infected cells susceptible to direct CD4+ T-cell recognition.

In children, CD4+ T-cell responses emerge within the first year of infection and are directed at multiple viral latent and lytic antigens.[356] Anti-EBV CD4+ responses are amplified with primary infection and individual epitope restricted T-cell frequencies can reach 1% to 2% of the peripheral blood CD4+ T-cell compartment (Fig. 11.18).[399,683] In chronic infection, similar numbers of CD4+ T-cell CCR7+ central memory and CCR7-effector memory are detectable.[399] CD4+ T cells in IM have a Th1-like profile, with expression of the transcription factor T-Bet and robust IFN-γ expression upon *ex vivo* stimulation. Particular CD4+ T cells responding to EBV antigens also express perforin and granzyme B and exert cytotoxic activity. Most of these cells have a very short half-life and undergo apoptosis when the level of EBV antigen declines. For incompletely understood reasons, CD4+ T-cell responses to EBNA1 epitopes are delayed, which likely connects to the similar delay in appearance of anti-EBNA1 IgG. Ultimately, anti-EBNA1 responses are a major component of anti-EBV CD4+ T-cell responses in healthy EBV carriers. To a lesser extent, EBNA2 and EBNA3C peptide-restricted T cells are also present in the peripheral blood.[399]

Despite the exaggerated size of the T-cell response, particularly the CD8 response, seen in the blood of IM patients, virus replication and shedding in the oropharynx continues at high levels after disease symptoms and the atypical blood picture have resolved.[399] This may reflect the fact that relatively few of the activated EBV-specific T cells in the blood seem able to traffic to the tonsils, perhaps because the necessary lymphoid homing receptors CCR7 and CD632L are down-modulated by activation. Anti-EBV T-cell frequency increases over time in the tonsils, perhaps reflecting the recovery of the T cells' homing markers and/or antigen drive from the

persistent EBV infection in oropharyngeal tissues. Remarkably, in long-term carriers, the tonsils show a 10- to 20-fold enrichment of CD8+ T cells that recognize latent epitopes and a 2- to 5-fold enrichment of CD8+ T cells that recognize lytic epitopes compared with the peripheral blood.

EBV Evasion of the Immune Response

EBV has evolved multiple mechanisms to down-modulate presentation (Table 11.3). BNLF2A blocks the transporter associated with antigen processing (TAP) to prevent translocation of peptides from the cytoplasm to the endoplasmic reticulum.[294] Furthermore, the large tegument protein BPLF1 is a deubiquitylating (DUB) enzyme that blocks the proteasomal degradation of cytosolic proteins by removing poly-ubiquitin tags.[173] The EBV late gene *BDLF3* encodes a 150 kDa protein that inhibits MHC class I and II as well as lipid antigen presentation by CD1 molecules. Abundant glycosylation of gp150 shields surface presentation of the antigen to the immune system. Similarly, the EBV lytic protein BILF1, which is a constitutively active G protein-coupled receptor, targets HLA-A and HLA-B molecules for destruction, but spares HLA-C, presumably because this allele can activate NK inhibitor receptors. EBV also targets the MHC class II pathways via gp42 (BZLF2), which binds the HLA-DR β chain and soluble gp42 inhibits antigen presentation. gp42 binds to class II peptide complexes and inhibits MHC class II antigen presentation to T cells.

TABLE 11.3 EBV proteins and RNAs that inhibit the immune system

EBV Protein	Effect
EBNA1	Inhibits its own proteasome processing Reduces translational efficiency and initiation of translation
LMP1	Up-regulates galectin promoter to induce apoptosis of CTLs Up-regulates IL-10, up-regulates A20 and bcl-2 to inhibit apoptosis
LMP2	Increases degradation of IFN receptors Up-regulates galectin promoter to induce apoptosis of CTLs
BARF1	Soluble colony stimulating factor receptor, inhibits IFN-α secretion
BCRF1	IL-10 homolog, inhibits synthesis of IFN-γ by T cells, reduces MHC class II expression, reduces IL-1α, IL-1β, TNF-α, and IL-6 production in monocytes, reduces levels of MHC class I, ICAM1, CD80, and CD86 on monocytes, reduces mRNA levels of TAP1 and proteasome protein LMP2
BDLF3	Inhibits presentation of MHC class I and II
BGLF2	Binds TYK-2 and inhibits type I IFN
BGLF5	Blocks synthesis of MHC I and II molecules Down-regulates TLR9
BHRF1	Bcl-2 homolog, blocks apoptosis
BILF1	Binds MHC class I molecules and removes MHC class I from cell surface Reduces rate of newly synthesized class I molecules on the cell surface by diverting them from the exocytic pathway Forms heterodimers with CXCR4 and impairs binding to CXCL12
BLLF3 (dUTPase)	Up-regulates IL-10, TNF-α, IL-1β, IL-8, and IL-6
BNLF2a	Interacts with TAP, inhibits its ATP and peptide binding functions, reduces MHC class I at the cell surface
BORF2	Inhibits APOBEC3B to evade innate immunity
BPLF1	Blocks proteasomal degradation of cytosolic proteins by removing polyubiquitin tags
BZLF1	Up-regulates IL-10, inhibits IRF7 (and type I IFN), inhibits IFN-γ-induced MHC class II expression, inhibits activation of IRF1, CIITA, and p48, nuclear translocation of STAT1, decreases levels of IFN-γ receptor-α mRNA and level of TNF receptor 1
BZLF2 (gp42)	Binds the HLA-DRβ chain of class II and inhibits antigen presentation, inhibits generation of CTLs in mixed lymphocyte reactions
LF2	Inhibits dimerization of IRF7, inhibits IFN-α production
EBV RNA	
EBER	Up-regulates IL-10, induces resistance to IFN-α-mediated apoptosis
miR-BART2-5P	Reduces expression of MICB, a stress-induced NK cell ligand to reduce killing by NK cells
miR-146a	Inhibits expression of IFN-responsive genes

The dominant role of the EBNA1 Gly-Ala repeats is to reduce the translation efficiency of EBNA1, resulting in fewer EBNA1 peptides and less efficient recognition by EBV-specific CD8+ T cells.[399] Defective ribosome EBNA1 products are the major source of EBNA1 epitopes presented to CD8+ T cells.

LMP1 inhibits its presentation to MHC class I by self-aggregation and possible destruction of LMP1 epitopes in proteasomes. LMP1 levels in EBV-infected cells vary over time, and this may allow cells expressing low levels of the protein to avoid killing by CD8 T cells.[62] LMP1 peptides suppress T-cell activation, inhibit T-cell proliferation, and reduce NK cell cytotoxicity; however, it is not clear if such peptides are present and at levels required to have immunosuppressive activity. LMP1, secreted in exosomes from virus-infected cells, inhibits T-cell proliferation.[190,324] LMP2A and LMP2B increase the degradation of IFN receptors in epithelial cells, which may limit the antiviral response in virus-infected cells. LMP1 and LMP2A up-regulate the galectin-1 promoter; galectin-1 triggers apoptosis of EBV-specific cytotoxic T cells.

The EBV late gene *BCRF1* encodes a viral homolog of the cytokine IL-10, which protects newly infected B cells from killing by NK cells and has inhibitory effects on CD4+ T-cell cytokine secretion.[294] BCRF1 shares 70% amino acid identity with human IL-10 and inhibits T-cell IFN-γ synthesis. EBV BLLF3 (dUTPase) up-regulates IL-10, as well as TNF-α, IL-1β, IL-8, and IL-6 in resting PBMCs. The EBV-encoded alkaline exonuclease BGLF5 exerts host shut-off activity. However, host-shutoff unmasks a 5S ribosomal RNA pseudogene, *RNA5SP141*, which then binds to and activates RIG-I, resulting in TNF-α but not type I IFN secretion.[107] EBV lytic genes further perturb interferon pathways. The EBV tegument protein BGLF2 binds to Tyk-2 and inhibits type I, but not type II IFN signaling.[397] Similarly, the LF2 tegument protein interacts with IRF7, inhibiting its dimerization, and reducing production of IFN-α.

Monocytes and plasmacytoid dendritic cells sense EBV, in part through recognition of EBV virion-associated unmethylated DNA or through release of EBERs.[683] EBV-encoded BARF1 inhibits monocyte-colony stimulating factor, and BARF1 knockout recombinant rhesus LCV had lower EBV viral loads in acute and chronic infection.[516]

EBV perturbs inflammasome pathways on multiple levels. Lytic replication in Burkitt cells causes depletion of AIM2, a component of a double-stranded DNA sensing inflammasome.[174] Interestingly, EBV subverts caspase pathways to regulate the lytic switch.[68,413] EBV targets JAK-STAT signaling pathways, where BZLF1 inhibits JAK1/2 tyrosine phosphorylation and together with BGLF4 inhibits STAT1 phosphorylation. Lytic replication also results in depletion of IRF1 and STAT2.[174]

The EBV ribonucleotide reductase large subunit BORF2 inhibits the host DNA cytosine deaminase APOBEC3B to evade this important innate antiviral pathway.[105] Interestingly, BORF2 stoichiometrically inhibits APOBEC3B DNA cytosine deaminase activity and sequesters APOBEC3B to perinuclear bodies. In the absence of BORF2, APOBEC deaminates EBV genomes in cells with lytic reactivation, resulting in diminished EBV titers and lower infectivity of target cells.

Several EBV gene products inhibit apoptosis. EBV BHRF1 is a viral BCL2 homolog that binds to proapoptotic BIM, BID, PUMA, and BAK.[187] BHRF1 is expressed in newly infected B cells as well as upon lytic reactivation, and has pro-survival roles in *Wp*-restricted Burkitt cells.

The role of a second putative EBV-encoded BCL2 homolog, BALF1, remains less well characterized. EBV also induces multiple BCL2 family members at different stages of growth transformation. LMP1 also inhibits apoptosis. EBV-encoded and up-regulated host miRNAs also perturb apoptosis pathways.

EPIDEMIOLOGY

Over 90% of adults in all human populations are infected with EBV. In many developing countries, primary infection typically occurs between the ages of 2 and 4 and is usually asymptomatic or results in nonspecific symptoms.[501] Infection may occur even earlier, with 50% of children in areas of Africa where Burkitt lymphoma is common acquiring the virus before 1 year of age. In the developed world, especially in more affluent populations, infection is often delayed until the second decade or later. In the United States, for example, white children tend to acquire the virus later than their black, Asian or Hispanic counterparts.[131] Overall the proportion of seronegatives among 6 to 19 year olds in United States increased in the period from 2003–2004 to 2009–2010, mostly in whites.[31] Accordingly, the incidence of IM is increasing.[351] How many delayed infections become symptomatic has long been of interest. A recent detailed prospective study of EBV seronegative freshman college students showed that 46% became infected during the next 3 years and 77% of infections resulted in 2 or more symptoms of IM.[30] Increased numbers of CD8+ and NK cells were observed, and the severity of disease correlated both with EBV viral load and with CD8+ T-cell numbers.

EBV is usually spread by infected saliva. Parents or siblings are likely the source of EBV transmission to young children.[90] Transmission among sexually active young adults may be due to kissing with sharing of oral secretions, but some observations suggest that the virus may be spread by sexual intercourse. Thus the risk of IM was lower in students who always used condoms,[249] was higher in women than men in sexually active persons, and in those with a higher number of sexual partners. In addition, EBV has been detected in both male and female genital secretions, albeit at lower levels than in saliva. EBV has also been transmitted iatrogenically, notably by latently infected B cells through blood transfusion or bone marrow transplantation from seropositive donors.

EBV is classified into two types, 1 and 2, based on sequence polymorphisms in EBNA2, EBNA3A, EBNA3B, and EBNA3C. Type 1 EBV isolates are more efficient in B-cell transformation *in vitro* than type 2 isolates, although to date differences in EBV type have not correlated with disease potential. Both EBV types coexist in all populations that have been studied. While type 1 strains are believed to be more common in most populations, type 2 isolates are nearly equal in prevalence to type 1 isolates in New Guinea and equatorial Africa. Coinfections with both virus types have been observed, often in immunocompromised individuals, and indeed intertypic recombinants containing portions of type I and type II EBV strains have been found. Type 2 viruses are reported to have a predilection for infection of T cells *in vitro*, with production of numerous cytokines.[128] Type 2 infection of T cells has also been seen in Kenyan children,[127] but adults in Kenya and patients with EBV T-cell CAEBV are usually infected with type 1 virus.

EBV is further classified into strains based on sequence differences. Strain differences are generally segregated with different ethnicities (African, Southeast Asia, and Caucasian), presumably reflecting many thousands of years of virus–host coevolution within geographically separate host populations. This has complicated work investigating the possible existence of "more oncogenic" EBV strains. For example, particular polymorphisms in EBNA1 and LMP1 sequences have been linked to endemic Burkitt lymphoma and NPC respectively, but it is likely that they were in fact a reflection of naturally prevalent strains in the risk populations. Asymptomatic carriers have multiple strains of EBV that are often different in the blood and in the throat and the balance between individual strains may change over time.[638] Patients with IM have multiple strains of EBV in the oropharynx, plasma, and PBMCs, suggesting simultaneous acquisition; indeed, multiple strains have been shown to be transmitted from a carrier resulting in primary infection.[639]

PRIMARY INFECTION

Healthy Carriers

In healthy carriers in developed countries, EBV is reported to be present in about 1 to 50 per million B cells in the peripheral blood.[465] While the number of latent EBV genomes various between healthy individuals up to 100-fold, within an individual the latent viral load is relatively constant both in healthy persons and in asymptomatic HIV carriers.[465] In Africa, particularly in areas where malaria is endemic, EBV is present in the blood of children at unusually high levels, approaching those seen in acute IM.[510] The latently infected cells in the blood are classic antigen-selected resting memory B cells (IgD^-, $CD27^+$, sIg^+, $CD20^+$) and are isotype-switched and somatically mutated.[24,25,659] All EBV-infected persons shed infectious virus into the saliva, reflecting on-going virus replication in the oropharynx, but levels of virus shedding vary considerably even following the same individual over time.

While transcripts for LMP2 and EBNA1 have been detected in cells of the blood of carriers, more recent studies suggest that virus-infected cells in the blood have a latency 0 phenotype and express no viral genes with the exception of the EBERs[23] and selected BART miRNAs.[564] EBV-infected memory B cells in the tonsils are IgD^- and express a type 2 latency phenotype.[24,25] EBV-infected B cells are present at similar levels in the tonsils, adenoids, and the peripheral blood, but at 20-fold lower levels in the spleen and the mesenteric lymph nodes, suggesting preferential trafficking of circulating infected cells back to oropharyngeal sites.[354] EBV gene expression is similar in the spleen and tonsil (latency II), unlike that of the blood (latency 0). When B cells in the tonsils differentiate into plasma cells, the EBV BZLF1 promoter is activated and viral replication initiates.

While the EBV viral load is similar in the peripheral blood and the bone marrow, there is a 3-fold higher number of EBV lytic antigen-specific T cells in the bone marrow compared with the blood, although the numbers of latent antigen-specific T cells are similar at both sites.

Infectious Mononucleosis

The incubation period for IM is about 4 to 6 weeks. IM presents with fever, lymphadenopathy, and pharyngitis in more than half of patients.[119] Posterior cervical lymphadenopathy and a tonsillar exudate are common. Other signs and symptoms include splenomegaly, hepatomegaly, rash, periorbital edema, and fatigue. Rarely EBV-positive genital ulcers can occur. Serious complications include upper airway obstruction due to enlarged tonsils, aplastic anemia, severe thrombocytopenia, granulocytopenia, autoimmune hemolytic anemia, hemophagocytic syndrome, hepatitis, jaundice, myocarditis, splenic rupture, encephalitis, meningitis, and Guillain-Barré syndrome. Most patients with EBV encephalitis do not present with IM. While most patient's symptoms resolve in 2 to 4 weeks, up to 10% will have fatigue persisting for 6 months or more. Patients with persistent symptoms do not have higher EBV DNA levels or obvious differences in immune responses to the virus.[80]

The peripheral blood in persons with IM shows leukocytosis, an increase in T cells but not B cells, and atypical lymphocytes. These latter cells have large amounts of cytoplasm often with vacuoles (Fig. 11.20) and are predominantly activated T cells (HLA-DR^+), but also include NK cells. There is an increase in CD8+ T cells and a relative decrease in CD4+ T cells. T cells from patients with IM have reduced responses to mitogens *in vitro*. Pathology of lymph nodes and tonsils show reactive follicles with proliferation of immunoblasts with reactive T cells; binuclear immunoblasts that resemble Reed-Sternberg cells are often present, which can confuse the diagnosis of IM with B-cell lymphoma. Polyclonal B-cell activation results in elevated levels of immunoglobulins, production of heterophile antibody (see Diagnosis below) and in some cases antinuclear antibodies, cold agglutinins, rheumatoid factor, or antiplatelet antibodies. Tissues have elevated levels of IL-1β. IL-6, IL-10, TNF-α, lymphotoxin, and IFN-γ-induced chemokines (MIG, IP10). The serum shows elevated levels of liver enzymes including serum transaminases and alkaline phosphatase. Symptoms of IM are due to the large expansion of CD8+ T cells and the cytokines they produce (IL-6, IL-10, IL-12, IFN-γ, TNF-α, TGF-β), rather than to lytic infection of B cells. In contrast, asymptomatic EBV infection is associated with a high level of EBV in the blood, but not the large expansion of CD8+ T cells, which occurs in IM.[3] Therefore. the large expansion of CD8+ T cells in IM that are associated with symptoms might not be required for control of virus infection.

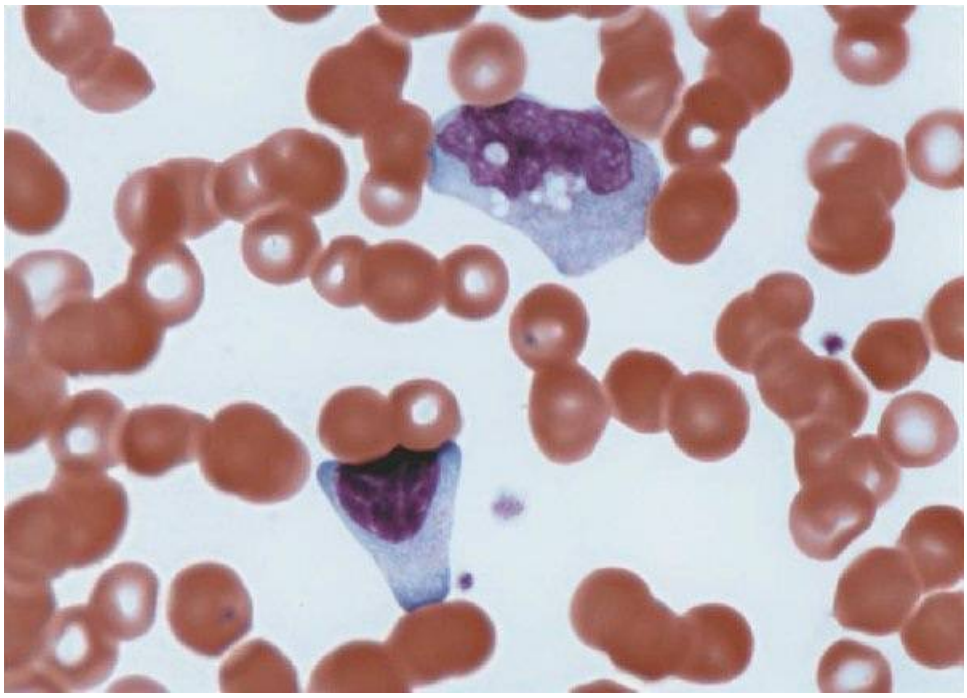

FIGURE 11.20 Atypical lymphocytes with prominent cytoplasm and vacuoles. (Reprinted from Cohen JI. Epstein-Barrr virus. In: Young NS, Gerson SL, High KA, eds. *Clinical Hematology*. Philadelpha, PA: Elsevier; 2006:956–966. Copyright © 2006 Elsevier. With permission.)

MHC class I polymorphisms in HLA-A01 correlate with development of IM, severity of symptoms, and viral load in persons with primary EBV infection.[439] HLA DR polymorphisms also correlated with development of IM. Persons with certain polymorphisms in IL-10 have more severe disease with acute infection.

Patients with IM have high levels of EBV in the peripheral blood and shed high titers of virus from the throat (Fig. 11.18). Virus may be produced in lytically infected B cells[310] as well as in epithelial cells. The level of EBV-infected B cells in the blood drops rapidly ($t_{1/2}$ = 7.5 days) after infection, followed by a slow decline during the first year. During the latter slow decline, the half-life of the viral load is 39 days.[258] High levels of virus shedding persist in the throat for prolonged periods (>180 days) of time after IM. After recovery, the number of infected B cells falls to within the same range as seen in healthy carriers with no history of IM.[24] The half-life of EBV-specific T cells during the first 2 weeks of IM is 2.9 days.[258]

Viral replication in the blood is rare during IM, and nearly all the cells are latently infected. EBV-positive cells in the blood have more somatic hypermutation than EBV-negative cells.[660] Patients in the acute phase of IM have reduced memory B cells in the blood, reduced plasmacytoid dendritic cells, and undetectable antibody-secreting cells and EBV neutralizing antibody.[164,521,522] Neutralizing antibody, gp350 binding antibody, and ADCC increase over time after IM and these peak only during convalescence.[64,726] The frequency of regulatory T cells (CD4+, $CD25^{hi}$) in the blood is significantly lower in persons with IM than in seropositive blood bank donors; however, a similar frequency of regulatory T cells was observed in the

tonsils of patients with IM and controls. B cells in tonsils from persons with IM show EBV latency III gene expression along with other forms of latency including type I and type II with variable expression of LMP1.[352]

EBV-ASSOCIATED DISEASES

X-Linked Lymphoproliferative Disease

X-Linked lymphoproliferative disease type 1 (XLP1), first described as "fatal IM," is a complex immunodeficiency with various sequelae, but best characterized by an extreme susceptibility to symptomatic EBV infection. Patients can present with hemophagocytic syndrome (32% of cases), dysgammaglobulinemia (22%), a family history of XLP1 (17%), lymphoma (14%), fulminant IM (8%), or other symptoms.[56] Acute infection with EBV usually results in a fulminant infection with organs infiltrated by proliferating B and T cells; hemophagocytic lymphohistiocytosis (HLH), bone marrow failure with lymphocytopenia, and hepatic failure often occur.[623] Other patients have aplastic anemia, lymphomatoid granulomatosis, or vasculitis. Patients have an excessive Th1 response with elevation of IFN-γ levels and large numbers of activated T cells and NK cells in the blood. Survivors of acute EBV infection often have low levels of IgG and high levels of IgM and IgA; about 20% subsequently develop B-cell lymphomas. Some patients with XLP1 develop B-cell lymphomas, vasculitis, or hypogammaglobulinemia even in the absence of EBV infection, reflecting a broader immune impairment. These patients do not have more severe infections with other viruses. Patients with XLP1 have reduced IgG responses to vaccines, reduced IL-10 production in T cells[5] and absent NKT cells.[528] SAP knock-out mice have impaired B-cell memory.

XLP1 is due to a mutation in SAP (SLAM-associated protein) encoded by the *SH2D1A* gene on the X chromosome[614] (Fig. 11.21A). SAP, an adapter protein containing a single SH2 domain, is expressed in T, NK, NKT, and in some B cells and interacts with SLAM on T, B, and dendritic cells.[82] This interaction negatively regulates the production of IFN-γ, which is normally induced by T-cell activation. This is thought to occur either by (a) impairment of SLAM binding to SHIP[614] or (b) recruitment of FynT, SHIP, Dok1, and Dok2 with activation of Ras-GTPase-activating protein. SAP also interacts with other members of the SLAM family.[82] These include 2B4 and NTB-A, which mediate CD8+ T-cell and NK cell killing, Ly9, and CD84. The interaction of SAP with 2B4 results in recruitment of FynT, SHIP, and Vav-1 that result in increased NK cell cytotoxicity. Impaired SAP interactions with SLAM, 2B4, and NTB-A may reduce CD8+T and NK cell killing of EBV-infected B cells and result in excessive production of IFN-γ, which can contribute to uncontrolled T-cell proliferation and HLH. SAP also has proapoptotic activity and promotes reactivation-induced cell death, which is important for T-cell homeostasis.[654] T cells from patients with XLP1 are resistant to apoptosis mediated by T-cell receptor stimulation, which may contribute to the massive lymphoproliferative disease with the disease.

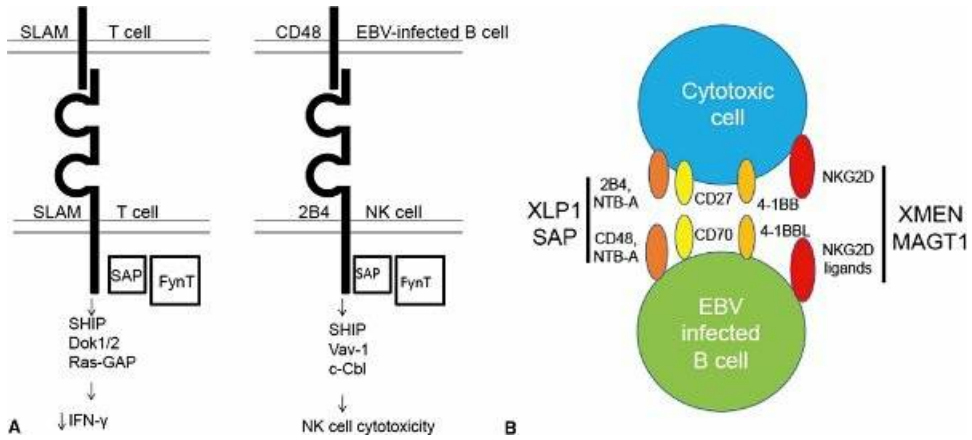

FIGURE 11.21 Interaction of SAP with SLAM and 2B4 and proteins important for B- and T- or NK cell interactions. A: SAP binds to SLAM on T cells and initiates a cascade resulting in decreased IFN-γ. SAP binds to 2B4 on NK cells, which results in increased NK cell cytotoxicity. **B:** Mutations in SAP (which impair 2B4-CD48 and NTB-A self interactions), CD27, CD70, 4-1BB (CD137), or MAGT1 (which up-regulates NKG2D) impair the interaction of EBV-infected B cells with cytotoxic T or NK cells.

Patients with XLP1 who survive infection with EBV have quantitatively normal EBV-specific CD8+ T-cell responses, but their T cells are impaired for recognition of SLAM ligand-positive (but not SLAM-negative) EBV-infected B cells. Patients with XLP1 lack $IgD^{-}CD27^{+}$ class-switched memory B cells, and those who survive carry EBV in nonswitched memory cells (IgM+, IgD+, CD27+).[93] Patients with other family members with XLP1 nearly always have mutations in SAP, whereas sporadic cases are less likely to have mutations. CD4+ T cells from patients with XLP1 do not provide optimal B-cell help, efficiently differentiate into IL-10-positive effector cells, or efficiently up-regulate inducible costimulator (ICOS), a potent inducer of IL-10. Adoptive transfer experiments in mice lacking SAP show that the animals have normal B cells, but defective CD4+ T cells. This results in markedly reduced numbers of virus-specific long-lived plasma cells and memory B cells with impaired long-term antibody responses, but normal or increased levels of virus-specific memory CD4+ T cells. Mice and humans lacking SAP have markedly reduced germinal center B cells; germinal center responses require early and sustained interactions between B and T cells, and SAP is essential for these interactions. SAP expression in T cells, but not B cells, is required for normal antibody production and formation of germinal centers.[708]

Intravenous immunoglobulin has been used to prevent EBV infection in boys with mutations in SAP; fatal breakthroughs have occurred. While antiviral therapy and cytotoxic chemotherapy have not been successful, rituximab (anti-CD20 monoclonal antibody) has been reported to be life-saving in several patients with XLP1 and fulminant IM. Hematopoietic stem cell transplantation (HSCT) cures the disease and survival rates of 80% have been reported with good immune reconstitution. Patients with active HLH have a lower rate (50%) of survival.

Patients with mutations in X-linked inhibitor of apoptosis (XIAP, encoded by *BIRC4*) have many features of XLP1, and this disease is referred to as XLP2.[582] These patients often present with HLH, recurrent splenomegaly, fever, and cytopenia. The disease is usually triggered by

primary infection with EBV. XLP2 is usually less severe than XLP1. HLH is more common with XLP2 than XLP1, while hypogammaglobulinemia and low NKT cell numbers are more common in XLP1. The high incidence of HLH and the lack of lymphomas in patients with XLP2 have caused some authors to reconsider its classification as a form of X-linked familial HLH rather than XLP2.[183] Lymphocytes from patients deficient in XIAP have increased apoptosis in response to Fas and the TRAIL receptor.[582] HSCT is recommended for XLP2.[183]

Several other mutations have been associated with poorly controlled EBV and risk of B-cell lymphoma or lymphoproliferative disease. These include mutations in genes important for (a) T-cell interactions with EBV-infected B cells *CD27*, *CD70*, *4-1BB* (CD137), *MAGT1*, which up-regulates NKG2D (Fig. 11.21B); (b) T-cell signaling including *ITK*; (c) nucleotide metabolism (*CTPS1*); and (d) NK or T-cell degranulation (*PRF1*, *UNC13D*, *STXBP2*). Other genes are important for protection against EBV and other infections including *GATA2*, *STK4*, *CORO1A*, *RAG1*, *RAG2*, *LIG4*, *MCM4*, *FCGR3*, *PIK3CD*, *PIK3R1*, *RASGRP1*, *DOCK8*, *WAS*, and *NFKB1*.[120,361,680]

Chronic Active EBV and Related Disorders

Chronic active EBV (CAEBV) disease is a rare disease more common in Asia and natives of Mexico, Central and South America. Patients present with IM-like symptoms with fever, lymphadenopathy, hepatosplenomegaly, and develop lymphoproliferative disease involving the liver, lungs, nervous system, or other organs.[123,329] HLH is common with fever and pancytopenia. Asian patients may have severe mosquito bite allergy. The disease often presents after primary EBV infection and patients have high viral loads and/or extremely high antibody titers to EBV VCA and EA, and infiltration of tissues with EBV-positive T, NK, or much less commonly B cells. Many patients have absent antibody to EBNA1. In Japanese patients with CAEBV, EBV is often clonal in T or NK cells, while in the United States, the virus has been reported in T, NK, or B cells. Patients with CAEBV have dysregulation of cytokines and often have elevations in both Th1 and Th2 cytokines. Patients often have low levels of EBV-specific CD8+ T cells implying a failure to control infection. Some patients with NK or T-cell CAEBV have somatic mutations in DDX3X and other cancer driver genes in NK cells, or more rarely in T cells; the EBV genome frequently has deletions especially in BART miRNAs, which can otherwise inhibit lytic activation.[518] In contrast, in patients with B-cell CAEBV, some patients have been found to have germline mutations.[120] Patients with EBV in T cells have a poorer prognosis than those with virus in NK cells, while patients with EBV in NK cells often have severe mosquito bite allergy, high IgE, and large granular lymphocytes in the blood. If untreated, most patients die from hepatic failure, refractory T or NK cell lymphomas, or opportunistic infections due to a progressive loss of immune cell function. EBV latency II gene expression is present in the peripheral blood of many patients with CAEBV. While a number of therapies, including antiviral agents, immunosuppressive agents, cytotoxic chemotherapy, and autologous EBV-specific cytotoxic T cells (CTLs) have been tried, only hematopoietic stem cell transplantation (HSCT) has been curative.[54,212]

Hydroa vacciniforme-like lymphoproliferative disorder is associated with chronic active EBV and is more common in Asians and natives of Central and South America. Patients have high levels of EBV in T or NK cells in the blood. The disease presents with papules and vesicles on sun-exposed areas of the skin (e.g., face) that heal with scarring. In Asia and Latin America,

the disease can remain localized to the skin or become systemic similar to CAEBV and require HSCT. In the United States and Europe, Caucasians with the disease usually only have cutaneous disease and the prognosis is often good; some cases resolve spontaneously.[125] EBV-positive cells are usually clonal and can have different forms of EBV latency. Expression of BZLF1 in tissue and age greater than 9 years are indicative of a poor prognsosis.[464]

Severe mosquito bite allergy presents with deep ulcerations and scarring after mosquito bites. Patients have high levels of EBV in NK cells.[122] While some patients have disease limited to the skin, others develop systemic disease with CAEBV.

Hemophagocytic lymphohistiocytosis (HLH) is associated with immune deficiencies, with CAEBV, or as a rare manifestation of primary EBV infection.[428] Patients with HLH present with fever, pancytopenia, and liver dysfunction. Many patients presenting with HLH and primary EBV infection have virus in T cells and if supported with immunosuppressive therapy, using the HLH 2004 protocol, undergo long-term remissions.[343] In contrast, patients with HLH and immunodeficiencies or CAEBV typically require HSCT. Infection of T cells *in vitro* with EBV results in up-regulation of TNF-α and IFN-γ, which activates macrophages and may drive HLH.[364] Elevated levels of IFN-γ, MIP-1α, MIG, and IP10 are present in tissues

Systemic EBV-positive T-cell lymphoma of childhood is a disease of EBV-positive clonal activated CTLs.[122] While it can present after primary EBV infection, it can also be associated with CAEBV. Patients typically have HLH with fulminant disease.

EBV Lymphoproliferative Disease: Congenital, Iatrogenic, and Posttransplant

Patients with congenital (e.g., genetic disorders described above), acquired (e.g., HIV), or iatrogenic (e.g., methotrexate therapy) T-cell immunodeficiencies often have elevated EBV DNA levels in the peripheral blood and throat and are at risk for EBV lymphoproliferative disease and lymphoma (Table 11.4). The underlying defect in these patients is impaired T-cell function and inability to control EBV-infected B cells. Pathology ranges from polymorphic lymphoproliferative disease to diffuse large B-cell lymphoma.

TABLE 11.4 EBV-associated malignancies in immunocompromised persons

Disease	EBV Frequency	EBV Gene Expression	EBV Latency	Genetic Mutations	Cell of Origin	Latency Period After EBV Infection	Comments
Lymphoproliferative disease in immune deficiency	100%	EBNA1,2,3,LP; LMP1,2	3		B cell, GC or post-GC	<3 mo	Reduced T-cell immunity
Posttransplant lymphoproliferative disease	Early: <1 year after transplant >90%; late: EBV less common	EBNA1,2,3,LP; LMP1,2	3	Early: none; late: bcl-6 +/– ras, p53, c-myc	B-cell, GC or post-GC	Early: <1 year; late: >1 year	Reduced T-cell immunity
HIV malignancies							
Burkitt lymphoma	30%–70%	EBNA1	1	c-myc, bcl-6, +/–p53	B-cell, GC	Early in HIV	35% of HIV lymphomas
Hodgkin lymphoma	>95%	EBNA1, LMP1, LMP2	2		B cell, post-GC	Early in HIV	5% of HIV lymphomas
DLBCL-centroblast	30%	EBNA1	1	+/–bcl-6	B cell, GC	Early in HIV	25% of HIV lymphomas
DLBCL-immunoblastic	>90%	EBNA1,2,3,LP; LMP1,2	3		B cell, GC or post-GC	Late in HIV	15% of HIV lymphomas, low CD4+ cell numbers
Primary CNS lymphoma	>95%	EBNA1, 2, 3, LP; LMP1,2	3		B cell, GC or post-GC	Late in HIV	Low CD4+ cell numbers
Primary effusion lymphoma	>90%	EBNA1, +/– LMP1, LMP2	1 or 1/2	bcl-6	B cell, GC or post-GC	Late in HIV	HIV lymphomas HHV-8+
Plasmablastic lymphoma	50%–80%	EBNA1 +/– LMP1	1 or 1/2		B cell, post-GC	Late in HIV	Very rare; CD20–
Smooth muscle tumors	>95%	EBNA2, +/– LMP1	?		Smooth muscle cell	Late in HIV	Rare

GC, germinal center; DLBCL, diffuse large B-cell lymphoma; CNS, central nervous system.

Patients with rheumatoid arthritis or polymyositis who receive methotrexate may develop EBV lymphoproliferative disease that often resolves when methotrexate is discontinued.[466] In this case, methotrexate may increase the risk of virus reactivation as well as impair T-cell function. Patients receiving TNF-α inhibitors for rheumatoid arthritis have also developed EBV lymphoproliferative disease; some cases resolve after stopping the drug.

EBV posttransplant lymphoproliferative disease (PTLD) occurs in 1% of kidney transplant recipients, 1% to 2% of liver transplant recipients, 1% to 3% of heart transplant patients, 2% to 5% of lung transplants recipients, and 20% of small intestine transplant patients. Early-stage PTLD lesions do not necessarily meet the true definition of EBV lymphoma. The risk of EBV PTLD is increased in persons who have a primary EBV infection posttransplant, graft versus host disease, cytomegalovirus infection, or who receive second transplants or anti–T-cell antibodies.[359] Certain immunosuppressive drugs, including tacrolimus and IL-2 receptor antagonists, are associated with an increased risk of disease; other immunosuppressive drugs such as alemtuzumab are associated with a high viral load but a low risk of PTLD.

Patients with PTLD often have elevated levels of IL-6, a B-cell growth factor, in the peripheral blood.[697] Polymorphisms in the TNF-α promoter, the TNF receptor I promoter, Nramp, IFN-γ, IL-10, or TGF-β are more frequent in transplant patients with PTLD. Patients with EBV PTLD have a significantly higher frequency of an HLA B51 allele than transplant patients without the allele. HLA-B18 and HLA-B21 are associated with a higher risk of developing PTLD, while HLA-A03 and HLA-DR7 are associated with a lower risk. EBV PTLD is higher in persons homozygous for HLA-A1 and lower in those homozygous for HLA-A2.[333]

About 55% of patients (especially early after transplant) present with an IM-like illness with fever, enlargement of tonsils and adenoids, and lymphadenopathy; biopsies show plasmacytic hyperplasia and lesions are polyclonal or oligoclonal. PTLD may involve the lymph nodes, but lesions are often extranodal and present in the gastrointestinal tract, liver, lungs, kidney, or

central nervous system. In organ transplant recipients, the lesions are often in the transplanted organ, probably due to antigenic stimulation with production of cytokines and B-cell growth factors. Tumors are usually of donor origin in bone marrow transplant recipients and of recipient origin in solid organ transplant recipients. About 30% of patients have polymorphic PTLD with monoclonal or oligoclonal lesions (Fig. 11.22). About 15% of patients have monomorphic PTLD with monoclonal disease, which include diffuse large B cell lymphoma, Burkitt lymphoma, classical Hodgkin lymphoma-like PTLD, and plasma cell myeloma. Distinct EBV-positive clones can arise at one or more sites. In contrast, T-cell lymphomas after transplant are rarely EBV positive. The polyclonal and polymorphic PTLD lesions that occur during the first year after transplant are almost always EBV positive and have a type 3 pattern of latency. In contrast, the later monomorphic lesions are often, but not always EBV positive, and may have different patterns of latency with variable expression of EBNA2 and LMP1. Early plasmacytic hyperplastic or polymorphic PTLD lesions usually do not have chromosomal abnormalities, providing further evidence that these tumors are driven by EBV. In contrast, monomorphic PTLD lesions that occur later after transplant that are centroblastic diffuse large B-cell lymphomas may have mutations in *bcl-6.*[83] Monomorphic lesions may also have mutations in *p53, N-ras,* and *c-myc.* Unlike many Burkitt lymphoma cell lines that have *c-myc* translocations and often do not require EBV for survival, cells from PTLD patients require EBV to inhibit apoptosis and to drive the cells out of the G1/G0 phase of the cell cycle. Sequencing of immunoglobulin heavy chain (IgH) genes from PTLD lesions show that some (especially early after transplant) have germline IgH sequences indicative of naïve B cells, while others have IgH somatic mutations that arise from antigen-selected memory B cells; in contrast, others (usually late after transplant) have mutated IgH genes (lacking a functional B-cell receptor) that is often not compatible with B-cell survival, but more commonly seen with Hodgkin lymphoma.[493]

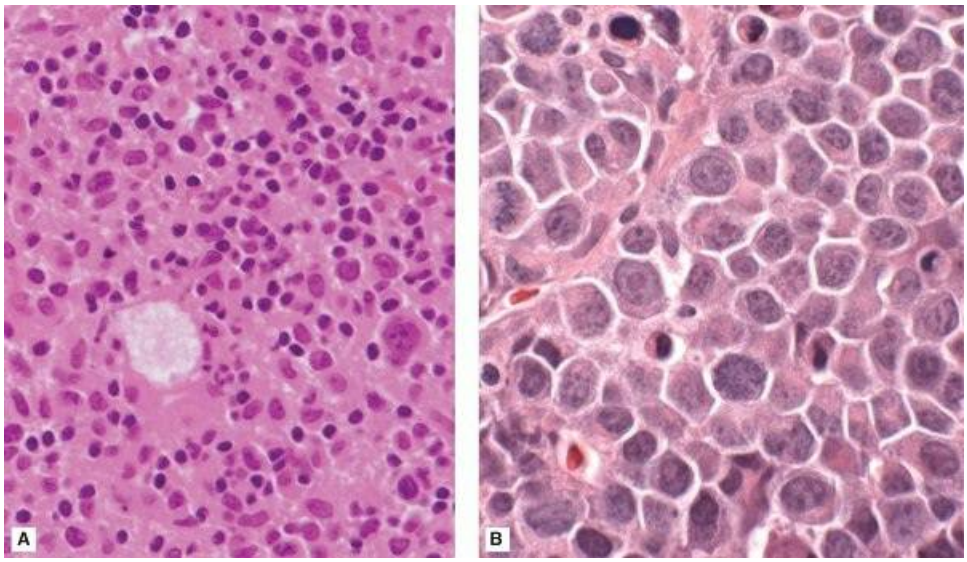

FIGURE 11.22 Biopsy from a patient with (A) polymorphic or (B) monomorphic posttransplant lymphoproliferative disease. (Courtesy of Dr. Elaine Jaffe.)

Detection of elevated levels of viral DNA in the blood or CSF may provide a clue to the

diagnosis of PTLD and also may be useful for follow-up after treatment.[213] In general, very high levels of EBV DNA in the blood are predictive of PTLD. Detection of EBV DNA in the plasma is more predictive of PTLD than detection in whole blood.[332] Patients at risk for EBV PTLD have lower levels of EBV-specific CD8+ T cells in the blood and combined viral load measurements and EBV-specific T cells may be more predictive of PTLD than either alone. Staging of the extent of disease is performed with CT and PET scans. Diagnosis of EBV PTLD requires demonstration of EBV and appropriate histopathology in tissue biopsies. Biopsies of PTLD lesions usually show type III EBV latency; the peripheral blood often shows type 0 EBV latency, while in some cases additional genes (*LMP1*, *LMP2*, *BZLF1*) may be expressed. PTLD biopsies overexpress galectin-1, which tolerizes dendritic cells and induces apoptosis of cytotoxic T cells.

Burkitt Lymphoma

Endemic Burkitt lymphoma (BL) is usually an EBV-positive tumor that occurs in equatorial Africa and New Guinea where *Plasmodium falciparum* malaria is also endemic[469] (Table 11.5). The disease occurs at 5-10 cases per 100,000 children and is the most common childhood tumor in these areas. Endemic BL usually presents as a tumor in the jaw.

TABLE 11.5 EBV-associated malignancies in nonimmunocompromised persons

Disease	EBV Frequency	EBV Gene Expression	EBV Latency	Genetic Mutations	Cell of Origin	Latency Period After EBV Infection
Burkitt lymphoma	Endemic 95%–100%; sporadic 15%–85%	EBNA1	I	*c-myc*, *+/-p53*, *RB2*	B-cell GC centroblast	3–8 y
Hodgkin lymphoma	MC, LD 60%–80%; NS 20%–40%	EBNA1, LMP1, LMP2	II		B-cell post-GC	1 y or more
Nasopharyngeal carcinoma	Anaplastic 100%; keratinizing; 30%–100%	EBNA1, LMP2, +/–LMP1	II	Various tumor suppressor genes	Undifferentiated epithelial cell	>30 y
Gastric carcinoma	Lymphoepithelioma 100%; adenocarcinoma 5%–15%	EBNA1, LMP2 +/–LMP1	I or I/II		Gastric epithelial cell	>30 y
Diffuse large B-cell lymphoma of the elderly	Up to 25%	EBNA1, LMP1,2 +/–EBNA2	II or III		B cell, GC or post-GC	>30 y
Peripheral T-cell lymphoma-associated with CAEBV or acute EBV infection	100%	EBNA1, LMP2, +/–LMP1	2		Mature CD4+ T cell	None or several months
Angioimmunoblastic T-cell lymphoma	>90%	EBNA1, LMP1,2	2	Trisomy 3 or 5	Lymphoma in CD4+ T cells; EBV in B cells, GC	>30 y
Pyothorax lymphoma	100%	EBNA1, 2, +/–LMP1	3	p53	B cell, GC or post-GC	>30 y
Extranodal NK/T Nasal	100%	EBNA1, LMP2, +/–LMP1	2		$CD3^-$, $CD56^+$	>30 y

MC, mixed cellularity; LD, lymphocyte depleted; NS, nodular sclerosis; GC, germinal center; RB2, retinoblastoma-like 2.

Sporadic BL occurs in the United States and Europe at a rate of 0.2 to 0.3 cases per 100,000 persons and only 10% to 20% of tumors are EBV positive. The disease is more common in South America and North Africa with rates of 1 to 2 per 100,000 persons where up to 85% of BL is

EBV positive. Sporadic BL usually presents in children with abdominal tumors. AIDS-related BL represents yet another form of the tumor, seen at high incidence in AIDS patients; about 35% of these tumors are EBV positive. The disease occurs early in the course of HIV when immune function is relatively intact and, unlike the EBV-positive PTLD-like lesions that were often seen in late stage HIV infection, AIDS-BL incidence has not fallen with the advent of effective antiretroviral therapy. HIV, like malaria, also induces B-cell proliferation and impairs EBV-specific CTL activity. Pathology of BL shows atypical B cells with basophilic, vacuolated cytoplasm and irregular nuclei with prominent nucleoli in a background of phagocytic histiocytes resulting in a "starry sky" pattern (Fig. 11.23). The lymphoid tumor cells often show mitotic figures and evidence of apoptosis.

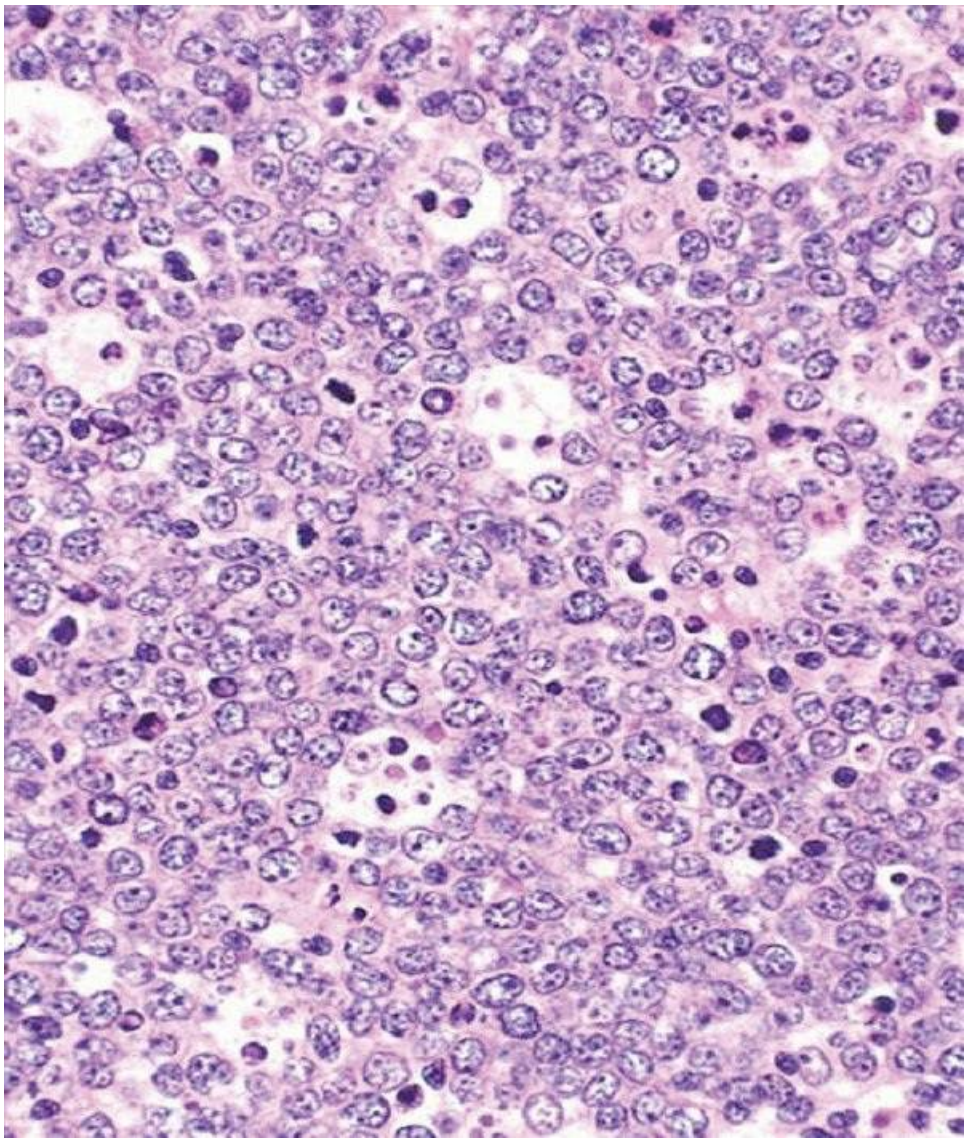

FIGURE 11.23 Biopsy from a patient with Burkitt lymphoma. The intensely stained B cells in a background of lightly stained histiocytes give a "starry sky" appearance. (Courtesy of Dr. Elaine Jaffe.)

BL cells shows dysregulation of the *c-myc* oncogene due to an 8:14, 8:2, or 8:22 chromosomal translocation in which a portion of the immunoglobulin heavy chain (on chromosome 14) or light chain (on chromosome 2 or 22) is fused to *c-myc* (on chromosome 8). Analysis of the structure of the chromosome breakpoints suggest that the *c-myc*/immunoglobulin gene translocations occur during the germinal center reaction either due to somatic hypermutation or to an error during class-switch recombination.[350] Increased expression of *c-myc*, due to its proximity to the immunoglobulin enhancer sequence, is a major determinant of the tumor phenotype, affecting the expression of greater than 15% of genes in BL cells. In particular, c-myc reduces the immunogenicity of EBV-positive cells by inhibiting expression of TAPs, reducing expression of MHC class I, and inhibiting expression of proteasome subunits that are important for antigen presentation. Expression of c-myc also impairs NF-κB and interferon responses in BL cells. Transgenic mice expressing c-myc driven by immunoglobulin light chain sequences develop tumors resembling BL. Expression of c-myc is not compatible with expression of EBNA2 which, if transcriptionally active, is functionally mutated. In addition, EBNA2 down-regulates expression of c-myc. Therefore, high levels of MYC expression limit EBV latency gene expression in B cells and appear to substitute for many of the growth transforming functions of LMP1 and EBNA2.

Infection with malaria not only increases the EBV load but also increases germinal center B-cell numbers and the expression of activation-induced cytidine deaminase (AID) and, thereby, the rate of mutations, including c-myc translocations.[696] EBV-positive BL has a high rate of somatic mutations, which may be associated with activation of AID or defective mismatch DNA repair in the cell.[214] EBV-positive BL has fewer mutations in driver genes that promote lymphoma, particularly those associated with protection from apoptosis including *TP53* than EBV-negative disease. In contrast, EBV-positive endemic BL and AIDS-related BL have high IgH mutation rates with signs of antigen selection, while EBV-negative sporadic BL have low mutation rates without signs of antigen selection. This indicates that endemic and AIDS-associated EBV-positive BL evolve from late germinal center B cells (or memory B cells), while sporadic EBV-negative BL evolve from early centroblasts. Sequencing of immunoglobulin genes from endemic BL cells showed that multiple mutations evolve *in vivo*. BL cells express cell surface markers present on germinal center cells with CD77 (BL antigen), CD10, BCL6, CD38, and PAX5, but not adhesion molecules (e.g., LFA-1, ICAM1), B-cell activation antigens (e.g., CD23, CD70), costimulatory molecules (e.g., CD80, CD86), or BCL2. EBV inhibits expression of the apototic genes *BIM* and *PUMA* to increase survival of BL cells.[186] Endemic EBV-positive BL differs from sporadic disease in having fewer mutations in *CCND3* (a cyclin that regulates the cell cycle in germinal center B cells), *TCF3* (which activates PI3K), and *ID3* (which inhibits *TCF3*).[618] EBV-positive BL has a higher frequency of somatic mutations in the genome; type 1 EBV-positive BL had more somatic mutations than type 2.[520]

EBV endemic BL contains clonal viral genomes and usually has a type I EBV latency pattern in tissues and *in vitro*. The cells express EBNA1 driven by the *Qp* promoter and grow as single cells *in vitro*. EBNA1 expression is critical for survival of BL cells; inhibition of EBNA1 induces apoptosis and reduces survival of EBV-positive BL cells.[320] More sensitive assays indicate that some BL cells express LMP2[39] and some lytic genes, especially BHRF1 and LF3 at high levels. Other endemic BLs have high c-myc expression and grow as single cells *in vitro* but have a different pattern of virus latency called "*Wp*-restricted."[318] Such tumors carry an EBNA2-deleted EBV genome, placing the downstream BHRF1 gene under the control of the latent *Wp*

promoter. These cells express EBNA1, EBNA3A, EBNA3B, EBNA3C, a truncated EBNA-LP, BHRF1 from *Wp*, and low level LMP2, but not LMP1.

While some EBV BL cells lose their EBV genome during passage *in vitro*, this has not been observed *in vivo*, indicating that the EBV genome has an important role in maintaining the tumor even with limited viral gene expression. In addition, BL cells that lost their EBV genomes *in vitro* had a less malignant phenotype with reduced tumorigenicity in mice. Much of the available evidence suggests that the main role of EBV in BL pathogenesis is not to promote cell growth but rather to counteract the high susceptibility to apoptosis as a consequence of high level c-myc expression. In *Wp*-restricted BLs, cell survival is greatly enhanced through expression of BHRF1, due at least in part to antagonizing Bim-mediated apoptosis.[317] With increasing passage in cell culture, some BL cell lines switch from a latency I to a latency III pattern of EBV expression and the EBNAs are driven by *Cp* or *Wp*. These cells now become LCL-like, grow in clumps, express adhesion molecules (ICAM1, LFA3), B-cell activation markers (CD23, CD70), costimulatory molecules (e.g., CD80, CD86), and bcl-2. Though they still carry the myc/Ig chromosomal translocation identifying their malignant origin, these phenotypically switched BL lines express lower levels of c-myc and are no longer representative of the tumor *in vivo*.

Epidemiologic evidence has implied that a high EBV load is a risk factor for endemic BL; high levels of EBV are common in children with chronic malaria. Accordingly, children in Africa with increased antibody titers to EBV VCA were found to be at increased risk of BL.[687] Patients with endemic BL also often have elevated antibody titers to EBV VCA as well as EA-R. Elevated serum antibody titers to EBV lytic and latent proteins were observed in children in areas where malaria was holoendemic and the levels remained elevated, while antibody titers were lower and declined in persons from areas where malaria was sporadic.[545] Children in Africa from an area with a high prevalence of endemic BL were infected with EBV at a younger age and had higher viral loads than those in another area of Africa.[544] Persons in regions with malaria transmission had higher numbers of EBV-specific T cells, especially targeting latent antigens, than those living in areas without transmission.[98] Children aged 5 to 9 years old who lived in an area holoendemic for malaria had lower EBV-specific IFN-γ responses than those in a nonholoendemic area; this coincided with the peak age incidence of endemic BL in this area. A domain in the *P. falciparum* membrane protein 1 is a polyclonal B-cell activator and incubation of this protein domain with PBMCs increases the EBV DNA copy number. This suggests that chronic exposure to malaria may promote B-cell proliferation and BL.

Hodgkin Lymphoma

Classical Hodgkin lymphoma (HL) consists of 4 histologic subtypes. The frequency of EBV positivity, as defined by detection of the viral genome and certain latency proteins in the malignant Reed-Sternberg cells, is 80% to 90% for lymphocyte depleted, 60% to 75% for mixed cellularity, 20% to 40% for nodular sclerosis, and less than 10% for lymphocyte rich.[270] Reed-Sternberg cells (large multinucleated cells of B-cell lineage) have clonal immunoglobulin gene rearrangements and express B-cell activation antigens CD25 and CD70, although they usually do not express conventional B-cell markers such as CD19 or CD20. Patients present with lymphadenopathy and often have involvement of the bone marrow, liver, and spleen. Pathology shows small numbers of Reed-Sternberg cells in a background of nonmalignant lymphocytes, granulocytes, histiocytes, and plasma cells (Fig. 11.24).

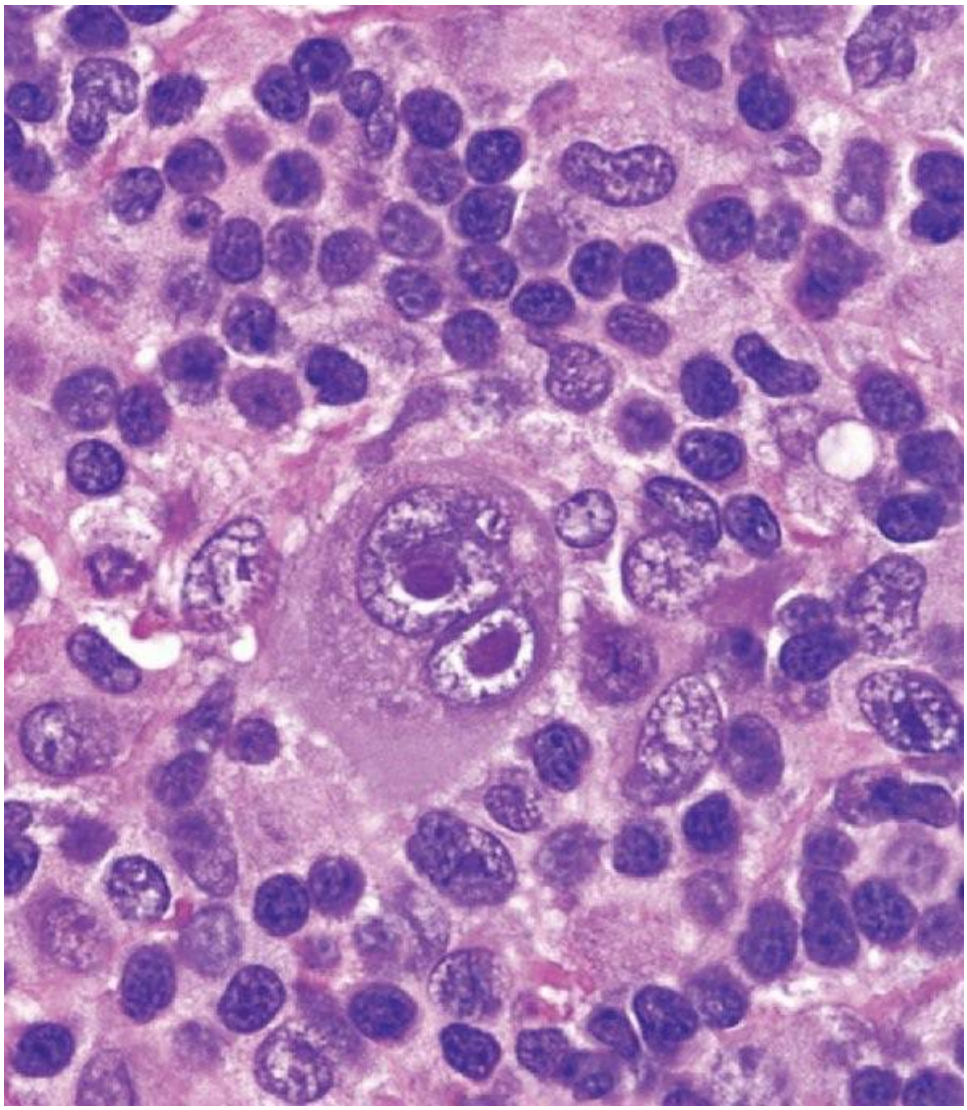

FIGURE 11.24 Biopsy from a patient with Hodgkin lymphoma, mixed cellularity. The large binucleate cell in the center is a Reed-Sternberg cell. (Courtesy of Dr. Elaine Jaffe.)

EBV-positive HL is more common than EBV-negative disease in patients in developing countries including Central and South America (80% to 90% EBV positive) compared with affluent countries (30% to 40% EBV positive) in some, but not all studies. HL is more commonly EBV positive in childhood and older adults than in young adults. HL is nearly always EBV positive in immunosuppressed patients.

Elevations in IgG antibody to EBV VCA, EBNA2, and EA-D are present at a mean of 4 years before diagnosis of HL.[479] Increases in each of these antibodies carries a 3- to 4-fold relative risk of subsequent development of HL. Patients with EBV-positive HL have detectable EBV DNA in the plasma before therapy. EBV DNA in the plasma declines in response to therapy and increases before disease recurs.[661] The level of EBV is higher in the blood of persons with EBV-positive HL compared with EBV-negative disease and higher in patients with

advanced stage disease. Overall there is a 2.6- to 3.4-fold increased risk of EBV-positive HL after IM, reaching 4-fold in younger adults.[251] The risk is highest within the first year and decreases to normal after 10 years; the median time for HL presentation post-IM is 2.9 years. In contrast, there is no increase in other lymphoid tumors after EBV IM, including EBV-negative HL or non-Hodgkin lymphoma.

Sequencing of immunoglobulin genes from HL indicates that the tumor cells have mutated immunoglobulin genes and in some cases are derived from crippled germinal center B cells.[309] Such crippling mutations, which result in loss of functional immunoglobulin, would normally lead to counter-selection and B-cell death. About 90% of EBV-positive HL had crippling mutations compared to about 40% of EBV-negative HL. This is consistent with the hypothesis that two of the EBV proteins expressed in HL cells, LMP1, which inhibits apoptosis by stimulating NF-κB, and LMP2A, which provides a B-cell growth stimulus mimicking the Ig receptor, may help the crippled B cells to survive.

Biopsies from EBV-positive HL have type II EBV latency with expression of LMP1, LMP2A and LMP2B, EBNA1 driven by the *Qp* promoter, EBERs, and BARTs.[147] Expression of LMP1 in germinal center B cells results in reduced expression of genes that are commonly down-regulated in HL such as CD79A, CD19, CD20, and CD22. EBNA1 down-regulates expression of Smad2, which in turn down-regulates expression of the protein tyrosine phosphatase receptor κ, which enhances proliferation and viability of HL cells. LMP1 up-regulates Bim-1 in HL cells, which may increase survival of these cells. EBV infection of HL cells induces expression of autotoxin, which increases lysophosphatidic acid and increases growth and survival of HL cells. EBV-positive HL shows higher levels of CCL20, which can induce trafficking of regulatory T cells into the tumors.

Polymorphisms in the HLA class I region associate with EBV-positive HL, while those in HLA class III correlate with EBV-negative disease.[155] The class I association suggests that the strength of immune surveillance by EBV-specific CD8+ T cells could influence disease development. Further studies showed that Caucasian patients with an HLA-A*0201 allele have a reduced risk of developing EBV-positive HL; conversely those with an HLA-A*0101 allele have an increased risk.[504] In addition, a polymorphism in the IL-10 promoter is more common in persons with EBV-positive HL than in EBV-negative disease. Biopsies from patients with EBV-positive, but not EBV-negative, classical HL show down-regulation of miR-96, miR-128a, and miR-128b.

EBV-specific T-cell function is partially impaired in HL. Galectin-1, an immunomodulatory protein, was expressed in the majority of classical HL tissues examined (and in Reed-Sternberg cell lines from HL) and expression was associated with reduced LMP1- and LMP2-CD8+ T-cell responses and reduced CD8+ T-cell infiltrates in tumor tissues.[205] CD8+ T cells specific for LMP1 and LMP2, but not EBNA or lytic proteins, from patients with HL have impaired function. Galectin-1 reduces degranulation and recognition of epitopes by LMP-specific T cells. Regulatory T cells are increased in the blood of patients with HL with active disease, compared with those in remission. Expression of LAG-3, which is a marker of regulatory T cells, is increased in infiltrating lymphocytes in EBV-positive HL tissue and is associated with impaired EBV LMP1- and LMP2-specific CD8+ T-cell responses. Many patients with EBV-associated HL lack detectable CD4+ specific T-cell responses to EBNA1. Overall survival is higher in patients with EBV-positive HL than EBV-negative disease, independent of gender, stage of

disease, and B symptoms.[284]

Nasopharyngeal Carcinoma

NPC is classified as keratinizing (WHO type I) or nonkeratinizing with differentiated (WHO type II) or undifferentiated (WHO type III) subtypes. Virtually all nonkeratinizing undifferentiated (WHO type III) NPC is EBV positive.[700] Undifferentiated NPC is more prevalent in Southeast Asia (especially Southern China), Northern Africa, and Eskimos in the Arctic. In Southern China, the rate of NPC is 50 per 100,000 in men over 50 years old. The disease has a 2- to 3-fold higher rate in men than in women. The incidence of NPC peaks at ages 50 to 59, with a smaller peak in adolescents and young adults. The rates are also elevated in Chinese persons who migrate from China. Environmental factors, especially dietary habits (use of salted fish and preserved foods), as well as genetic factors, may play a role in development of the disease. The rate of NPC has been declining in developed areas of Southeast Asia, perhaps due to changes in dietary habits. NPC occurs less commonly in the United States and Europe with rates of 0.5 to 2 per 100,000. In the United States, 63% of NPC is undifferentiated.

EBV is clonal in high grade preinvasive lesions (carcinoma *in situ* or dysplasia) as well as in NPC,[529] but not in low grade preinvasive lesions. Thus, the virus likely infects epithelial cells that already have a genetic abnormality. Undifferentiated NPC shows uniform malignant epithelial cells with prominent nuclei in a dense background of lymphocytes (Fig. 11.25). EBV DNA is present in the transformed epithelial cells, but not in the infiltrating lymphocytes. The tumors are sometimes referred to as lymphoepitheliomas. About 30% of NPCs have mutations in the MHC locus that may allow escape from virus-specific CTLs.[378]

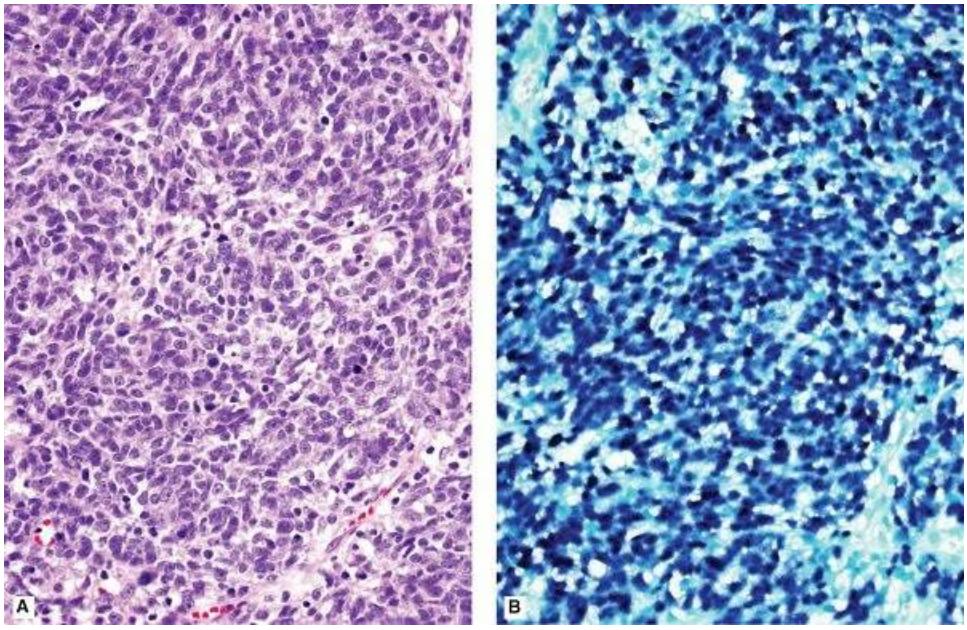

FIGURE 11.25 Biopsy from a patient with nasopharyngeal carcinoma. A: Undifferentiated anaplastic carcinoma. **B:** *In situ* hybridization shows EBV-encoded RNA (EBER)-positive carcinoma cells. (Courtesy of Dr. Paul A. VanderLaan.)

Development of NPC is believed to be a multistep process initially with overexpression of *p53* and loss of expression of the tumor suppressor genes *p16* and *p27* (and in some cases increased *p21Ras*) resulting in a hyperplastic lesion. This is followed by EBV infection and increased expression of *bcl-2* resulting in a dysplastic lesion and then overexpression of *p53* and invasive NPC (Fig. 11.26). A large number of tumor suppressor genes are hypermethylated resulting in reduced expression in NPC including *TFPI-2*, *DLEC1, BLU, and E-cadherin*. Twist and Snail, which are repressors of E-cadherin and regulators of epithelial–mesenchymal transition, are induced by LMP1 and correlate with the metastatic behavior of NPC. Whole exome sequencing and genome-wide association studies identified genetic variants in numerous genes including cancer driver genes (*PIK3CA*, *TP53*, *ERBB2*, *ERBB3*, *KRAS*), chromatin modifier genes (*ARID1A, MLL2, BAP1, MLL3, TET2, TSHZ3*), and autophagy genes (*ATG13, ATG7*).[390] In addition, mutations resulting in loss of function in NF-κB regulators (*CYLD, TRAF3*, *NFKBIA*, *NLRC5*, *TNFAIP3*) are also common in NPC.[378,756] Interesting, the loss of function in NF-κB regulators were only observed in LMP1-negative NPC.

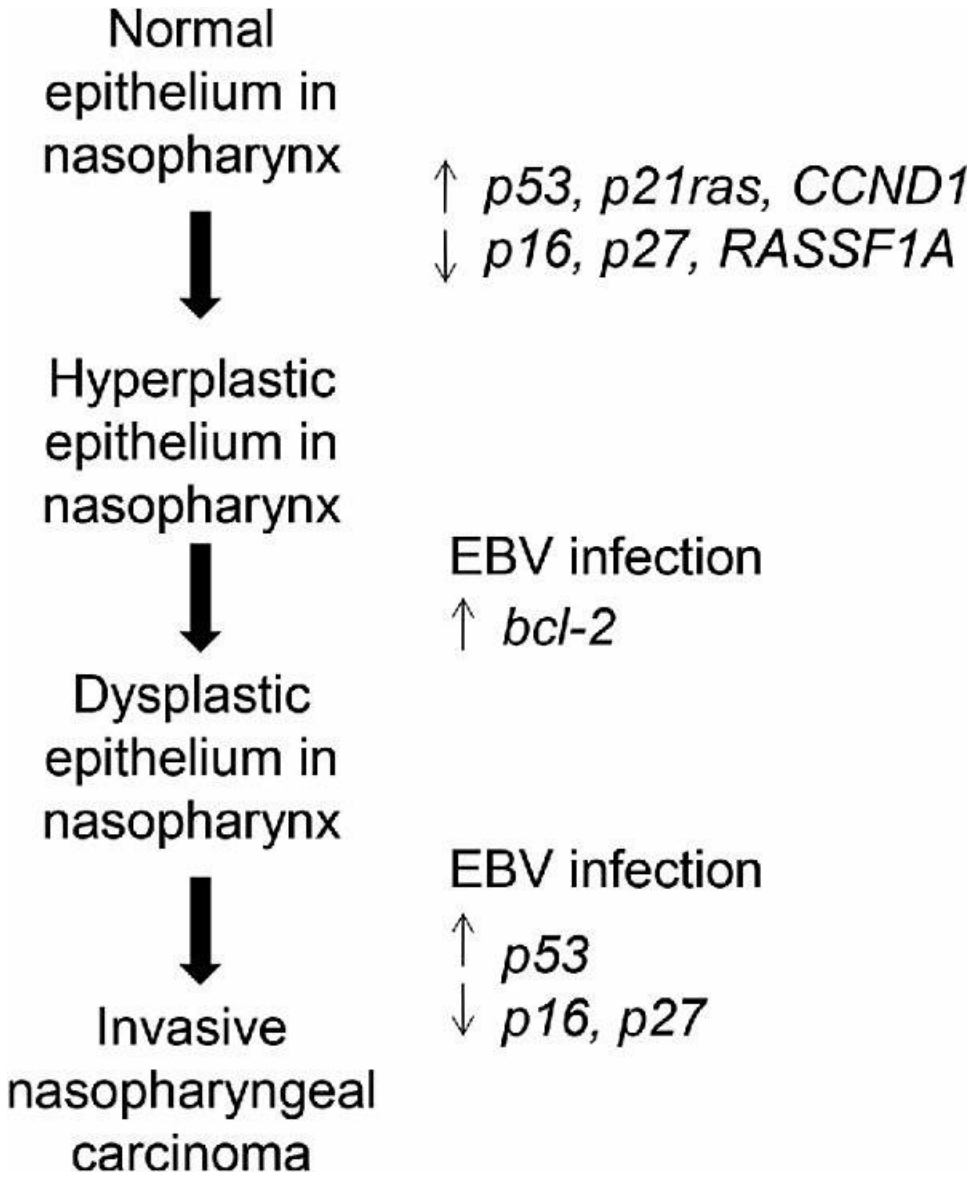

FIGURE 11.26 Steps involved in the development of nasopharyngeal carcinoma. EBV infection occurs after the cells have undergone initial genetic changes and have a hyperplastic or dysplastic phenotype. (Modified from Fan SQ, Ma J, Zhou J, et al. Differential expression of Epstein-Barr virus-encoded RNA and several tumor-related genes in various types of nasopharyngeal epithelial lesions and nasopharyngeal carcinoma using tissue microarray analysis. *Hum Pathol* 2006;37(5):593–605. Copyright © 2006 Elsevier. With permission.)

The risk for NPC is much higher (hazard ratio 6.8) for family members (when one member has the disease) compared with others in the same community.[261] The risk of NPC is higher for those with elevated anti-EBV DNAase antibody or anti-EBV VCA IgA (hazard ratio 2.8) and even higher when both antibodies are elevated (adjusted hazard ratio 15.1). Persons with a family history of NPC and elevated EBV serologies had a higher risk of NPC (hazard ratio was 31) than those without a family history and negative serology for DNAse and VCA IgA. A prospective

study found a 21-fold increased risk of NPC in persons with rising titers of IgA antibody to EBV VCA. Elevated levels of anti-EBV EBNA1 IgA were associated with a 5-fold risk of NPC.

Patients with NPC usually have high titers of antibody to EBV VCA, EBNA, and EA-D IgA; unlike other EBV tumors, elevated antibodies to EBV occur in NPC regardless of the geographical location. IgA to EBV VCA or EBV DNAse in serum or saliva has been used for screening in endemic areas[108]; persons with a four fold increase in IgA VCA have an 18% risk of developing NPC within 3 years in China; some patients have loss of antibody and loss of risk. EBV IgA antibody levels are elevated up to 10 years before the diagnosis of NPC with a mean duration of 37 months before diagnosis.

NPC patients often have elevated levels of EBV DNA in the plasma[392]; this viral DNA is due to apoptosis of tumor cells with EBV DNA released into the blood, not to increased numbers of EBV-infected B cells. The sensitivity of EBV DNA, VCA IgA antibody, and combined EBV DNA and VCA IgA for diagnosis of NPC was 95%, 81%, and 99%, respectively. The specificity of EBV DNA and VCA IgA was 98% and 96%, respectively.[373] Higher EBV plasma levels at the time of diagnosis and rising levels of EBV VCA or EA IgA antibody, or EBV DNA after therapy is associated with a poorer prognosis. After therapy, the serum level of EBV DNA often declines. Another noninvasive test for NPC involves brushing suspicious areas of the nasopharynx and performing PCR for EBV DNA and detecting EBV DNA and RNA. High levels of EBV DNA in brushings had a specificity of 98% and sensitivity of 90% for NPC. EBNA1 and BARF1 mRNA were found in 86% and 74% of brushings, respectively, from NPC-positive patients. A prospective study of over 1,000 persons showed that detection of EBV DNA in plasma is helpful for detecting asymptomatic NPC at an early stage.[96]

Patients with NPC have lower levels of EBNA1-specific CD8+ T cells and lower levels of LMP1- and LMP2-specific T cells than controls.[192] Patients with NPC have lower levels of naïve CD3+CD45+RA+ and CD4+CD25– cells in the blood, and higher levels of activated CD4+CD25+ T cells and $CD3^{-}CD16+$ NK cells than controls. EBV-specific cytotoxic T-cell (CTL) activity could be reactivated in peripheral blood mononuclear cells by incubation with autologous lymphoblastoid cells lines, while tumor infiltrating lymphocytes from NPC biopsies lacked cytotoxic activity and did not produce IFN-γ when incubated with autologous lymphoblastoid cells lines. NPC tumors have high levels of regulatory T cells ($CD4+CD25^{hi}$, Foxp3).

NPC usually has type II EBV latency with EBNA1 driven by the *Qp* promoter, expression of EBER, BARTs, and variable expression of LMP1; in many cases, LMP1 is undetectable. In contrast, LMP1 is routinely expressed in preinvasive lesions.[529] LMP2A is usually expressed in NPC biopsies, and its expression may be important for NPC, since LMP2A expression in epithelial cells increases expression of integrin α6 proteins, which increases their migration and invasiveness. Higher mutation rates in the sequence of LMP2 were seen in NPC tumors than in isolates from the oropharynx of healthy persons. While BARF1 and BZLF1 were present in some tumor cells, other lytic proteins were generally not expressed. miRNAs from BART, but not BHRF1, are expressed in NPC.[1,132,761] BART miRNAs interact with the 3′ NTR of LMP1 and reduce its expression. miR-218 suppresses NPC progression by down-regulating survivin. A polymorphism in one the EBV EBERs was associated with an increased risk of NPC.[265] Two variants in the BALF2 gene resulted in an 8.7-fold and 6.1-fold increased risk of NPC in Southern China, and these variants contributed to 83% of the risk of NPC in the area.[738] A

variant in the EBV BZLF1 promoter is increased in patients with NPC.[61]

NPC cells release exosomes that contain galectin-9, which can induce apoptosis of EBV-specific CD4+ T cells; galectin-9 is also present in exosomes from plasma of patients with NPC.[337] Exosomes from NPC cells also contain LMP1, viral miRNAs, and signal transduction molecules, which activate signaling pathways in recipient cells.[447] Lesions from patients with NPC often show down-regulation of TAP1, tapasin, and MHC class I, and up-regulation of IL-10.

EBV is also present in other epithelial cell tumors (known as lymphoepitheliomas or undifferentiated carcinomas of the nasopharyngeal type) including the tonsils, salivary glands, thymus, larynx, lungs, skin, and cervix. Like NPC, these tumors are more common in certain areas of the world, especially Southeast Asia and Eskimos in the Arctic. Also similar to NPC, pathology shows malignant EBV-positive epithelial cells with a dense infiltrate of lymphocytes. When a family member is diagnosed with NPC, there is an 8.4-fold risk to other members for carcinoma of the salivary gland.

Gastric Carcinoma

EBV is present in about 9% to 10% of gastric carcinomas including over 90% of gastric lymphoepithelioma-like carcinomas, 7% of moderately to well-differentiated gastric adenocarcinomas, and 6% of poorly differentiated gastric adenocarcinomas.[201,277] Since the vast majority of gastric carcinomas are adenocarcinomas, most EBV-positive gastric cancers are adenocarcinomas. Worldwide, gastric carcinomas are the most common EBV-associated malignancy. The prevalence of EBV-positive gastric carcinoma is similar in the United States, Europe, and Asia. Lymphoepithelioma-like carcinomas have a similar pathology to NPC with EBV DNA in malignant epithelial cells and a dense infiltrate of EBV-negative lymphocytes and macrophages surrounding the tumor cells. EBV-positive gastric carcinomas often involve the upper third of the stomach. Meta-analyses found that the prevalence of EBV-positivity in gastric carcinoma was 2-fold higher in men than in women, more common in younger persons, more frequent in the gastric cardia or corpus than the antrum, and more common in postsurgical gastric remnants.

EBV-positive gastric carcinoma has a higher frequency of mutations in *PIK3CA*, *ARID1A*, *BCOR*, amplification of *JAK2*, *ERBB2*, *PD-L1*, and *PD-L2*, DNA hypermethylation (resulting in silencing of many genes), and a lower frequency of mutations in TP53 compared with EBV-negative gastric carcinoma.[81,161,716] Expression of p16, p27, E-cadherin, and p73 is reduced in EBV-positive gastric cancer, while expression of cyclin D1 and NF-κB are increased compared with EBV-negative cancer. Somatic mutations in EBV-positive gastric carcinoma have been associated with up-regulation of APOBEC in the tumors.[51] DNA methylation of CpG sequences in the promoters of tumor suppressor genes such as *PTEN* is induced by LMP2 by up-regulation of de novo methyltransferase 1. MHC class I is down-regulated in EBV-positive gastric carcinoma cells.

Gastric carcinoma cells are clonal or oligoclonal for EBV DNA. EBV-positive gastric carcinomas have an EBV type I latency pattern, with EBNA1 driven by the *Qp* promoter, expression of EBERs, BARTs, and variable expression of LMP2A.[201] EBNA1 expression in gastric carcinoma cells is associated with loss of PML bodies, impaired response to DNA damage, and reduced apoptosis.[640] BARF1 is also expressed in the tumors and like NPC, BART

miRNAs, but not BHRF1 miRNAs, are expressed in tissues from patients with EBV-positive gastric carcinoma.

EBV was not detected in preneoplastic (dysplasia and intestinal metaplasia) lesions in patients with EBV-positive gastric carcinomas, but only in the carcinomas.[767] This suggests that like NPC, EBV infection is a late event in the development of gastric carcinoma. EBV gastric carcinoma is associated with atrophic gastritis and lymphocytic infiltration.

Like NPC, levels of anti-EBV VCA IgA are higher in persons who subsequently develop EBV-positive gastric carcinoma than controls. Levels of anti-EBV VCA IgG and anti-EA IgG antibodies are higher in patients with EBV-positive gastric carcinoma than those with EBV-negative cancer.[277] EBV anti-VCA and anti-EBNA antibodies titers are higher in persons with dysplasia on gastric biopsy, suggesting that EBV reactivation could be related to an early phase of gastric carcinoma.

EBV-positive gastric carcinomas with a lymphoepithelial-like histology and large numbers of tumor infiltrating lymphocytes generally have a better prognosis than EBV-positive carcinomas with an adenocarcinoma histology and a patchy lymphocytic infiltrate. Patients with EBV-positive gastric carcinomas have a better survival rate than those with EBV-negative carcinomas.

Non-Hodgkin Lymphomas and Other Malignancies in Nonimmunocompromised Persons

EBV is present in about 6% of cases of non-Hodgkin lymphoma (NHL) in Europe.[629] This includes diffuse large B-cell lymphoma, lymphomatoid granulomatosis, pyothorax-associated lymphoma, peripheral T-cell lymphoma, and angioimmunoblastic T-cell lymphoma. In Asia, EBV is associated with NK/T-cell lymphoma and aggressive NK cell leukemia/lymphoma.[122]

Diffuse large B-cell lymphomas are EBV positive in 10% of nonimmunosuppressed persons; the rate of EBV positivity is higher in immunocompromised persons. EBV-positive diffuse large B-cell lymphomas have a poorer prognosis than EBV-negative lymphomas and are associated with increased age, extranodal disease, fever, and a poorer response to therapy. The most frequently mutated genes in EBV-positive DLBCL were *MYC*, *RHOA*, *PIM1*, *MEF2B*, *MYD88*, and *CD79B*.[760] About 40% of CD30+ anaplastic large B-cell lymphomas are EBV positive and express LMP1 with variable expression of EBNA2.[353] About 15% of large B-cell lymphomas in the oral cavity are EBV positive, while approximately 20% of T-cell-rich B-cell NHL is EBV positive.

Lymphomatoid granulomatosis usually presents with fever and masses in the lungs but also can involve the kidneys, skin, liver, and central nervous system.[449] Many patients with lymphomatoid granulomatosis have reduced numbers of CD8+ and CD4+ T cells; some patients have HIV, XLP1, or have received organ transplants. Pathology shows EBV in rare B cells, an exuberant T-cell response, and destruction of small blood vessels. Separate clonal lesions can arise at different sites. Lesions express EBV EBNA2 and LMP1, and EBV DNA levels in the blood are often not elevated. IFN-α is often effective in early stage disease, while late stage disease requires cytotoxic chemotherapy.

Pyothorax-associated lymphoma is an EBV-positive diffuse large B-cell lymphoma that

originates in the pleural cavity after a history of pyothorax. Tumors usually express EBNA1, EBNA2, and/or LMP.[19] The disease is probably due to chronic inflammation, persistent cytokine production, and reduced host immunosurveillance. Similar localized EBV-positive lymphomas, termed diffuse large B-cell lymphoma associated with chronic inflammation, can occur at sites of chronic osteomyelitis, cardiac myxomas, splenic cysts, skin ulcers, and near metallic prostheses.

EBV-positive mucocutaneous ulcers are more common in the elderly and they respond to reduction in immunosuppression or may spontaneously regress.

Peripheral T-cell lymphomas usually present with fever and lymphadenopathy and are often associated with HLH. The disease is more common in Asians and persons from South America. Macrophage activation is often present with elevated serum levels of TNF-α, IFN-γ, and other cytokines. Elevated levels of TNF-α in the serum are associated with a poorer prognosis. T-cell lymphomas have clonal EBV DNA and usually have type II EBV latency, although expression of LMP1 can be variable.[103] The lymphoma can involve α/β or γ/δ T cells.

Angioimmunoblastic T-cell lymphoma is a peripheral T-cell lymphoma that presents with fever, night sweats, weight loss, hepatosplenomegaly, lymphadenopathy, and hypergammaglobulinemia. The malignant T cells are usually clonal and patients may develop EBV-positive diffuse large B-cell lymphoma. Autoantibodies including immune complexes, cold agglutinins, rheumatoid factor, and antismooth muscle antibodies may be present. EBV is present in over 90% of cases, and the virus is present in the proliferating B cells that accompany the malignant T cells.[727] EBV-infected B cells can be polyclonal, oligoclonal, or clonal and are deficient in the immunoglobulin receptor. EBV DNA is elevated in the serum and parallels the clinical course.

Extranodal NK/T-cell lymphoma—nasal type (formally lethal midline granuloma) usually presents in nose, but can also involve the sinuses and palate. Other portions of the upper airway may be involved; much less commonly the gastrointestinal tract and skin are infected. Pathology shows invasion of blood vessels with necrosis. Most tumor cells are CD56+ and surface CD3− and express granzyme and perforin; however, in some cases, cells are CD56−, CD3+. These tumors are more common in Southeast Asia and Central and South America, especially in men. The disease may be associated with HLH. The tumors are nearly always EBV positive, clonal for EBV, and have type II EBV latency with variable expression of LMP1. Extranodal NK/T-cell lymphomas often have mutations in *STAT3*, *BCOR*, and *MLL2*, and *DDX3X*.[289,367] Some tumors have mutations in PD-L1/PD-L2. Tumor cells often show NF-κB and Akt activation and express TNF-α with dysregulation of STATs and Rel A. High levels of EBV DNA in the blood correlate with a poorer prognosis.

Aggressive NK leukemia/lymphoma presents with fever, night sweats, weight loss, pancytopenia, hepatosplenomegaly, and large granular lymphocytes in the blood and bone marrow. About 50% of cases are EBV positive and the disease is more common in Asians; some patients initially present with CAEBV. The level of EBV DNA in the plasma is elevated at onset of disease and parallels the course of the disease. Mutations in *STAT3*, *DDX3X*, *RAS-MAPK*, and histone modifier genes are often present.[163]

Inflammatory pseudotumor-like follicular dendritic cell sarcoma presents with fever and usually involves the spleen and liver. The tumors contain clonal EBV DNA with a type II pattern of EBV latency.

Breast cancer has been associated with EBV based on earlier reports, using PCR and

antibodies to EBV proteins that detected EBV in a small fraction of the tumor cells; however, more recent studies using *in situ* hybridization and immunochemistry have generally not supported an association of EBV with the disease.

EBV and HIV

Patients with late stage HIV often have higher levels of EBV-specific antibodies, lower levels of virus-specific CTLs, shed higher levels of virus from the throat, and have 10-fold higher levels of EBV in the peripheral blood than healthy persons.[50,84] Detectable EBV DNA in the blood was predictive of EBV lymphoma in patients with HIV.[482] In patients begun on highly active antiretroviral therapy, the EBV DNA load did not change, and there was a decline in BZLF-1-specific CD4+ and CD8+ T cells suggestive of less EBV reactivation. In contrast, there was an increase in EBNA1-specific CD4+ and CD8+ T cells to levels similar to those seen in healthy persons. A variant in the EBV BZLF1 promoter was increased in patients with HIV-associated lymphomas.[61]

A longitudinal study of EBV DNA loads and cellular immunity in HIV patients showed that patients who did not develop NHL had stable levels of EBV DNA and EBV-specific CTL precursors, while patients who developed NHL had increasing EBV loads and decreasing EBV-specific CTLs before the onset of lymphoma.[323] In another study, HIV patients who developed NHL had increasing EBV DNA levels in the blood and although they did not have a decline in the number of EBV-specific T cells, these cells lost their ability to produce IFN-γ in response to EBV peptides. Primary infection with EBV does not alter the HIV viral load or progression to AIDS.

The overall rate of EBV-positive lymphomas has declined with highly active antiretroviral therapy. However, this is highly dependent upon tumor type. Lymphomas that occur early in the course of HIV infection—BL and HL—have not declined in incidence with highly active antiretroviral therapy, while lymphomas that occur later when patients are very immunocompromised—immunoblastic and primary CNS lymphomas—have decreased.

Oral hairy leukoplakia is a nonmalignant disease that occurs in patients with late-stage AIDS and in some transplant recipients.[217] The disease presents with white corrugated “hairy” lesions on lateral aspect of the tongue or occasionally on the palate or buccal mucosa and is due to lytic EBV replication in the outer layer of epithelial cells, without evidence of latent infection in the basal layers. Pathology shows hyperkeratosis of the squamous epithelium with acanthosis and intranuclear inclusions, but no inflammatory cells. Biopsies show linear (replicating) EBV DNA and herpesvirus particles on EM. EBV lytic antigens BZLF1, EA, VCA, as well as EBNA1, EBNA2, and LMP1 are expressed in lytically infected epithelial cells. Multiple EBV strains have been detected in single lesions with EBV variants due to recombination in and adjacent to the EBNA2 gene between viruses. The disease responds to acyclovir, which inhibits EBV replication; however, relapses are common when acyclovir is stopped. Highly active antiretroviral therapy can resolve lesions.

Lymphoid interstitial pneumonitis is characterized by diffuse interstitial pulmonary infiltrates. The alveoli are infiltrated with EBV-positive B cells, immunoblasts, and plasma cells. The disease is more common in children with HIV, although it can occur in adults with autoimmune disease.

Burkitt lymphomas account for about 35% of cases of AIDS-associated lymphoma (Table 11.4). About 30% of BL in HIV are EBV positive. The disease occurs in patients with HIV usually before they develop severe immunodeficiency. These tumors usually have a type I EBV latency pattern, or less commonly a type II pattern, and have *c-myc* translocations.

Hodgkin lymphoma occurs early in the course of HIV and like patients without HIV, EBV is more often present in tumors of the lymphocyte depleted or mixed cellularity subtypes.

Non-Hodgkin lymphomas in patients with HIV are EBV positive in 50% of cases and are clonal for the viral genome.[85] EBV was detected more often in benign lymph nodes of HIV patients who subsequently or concurrently had NHL than in those without lymphoma. Patients with HIV progressing to NHL had loss of EBV-specific CD8+ T and CD4+ T cells, including EBNA1-specific CD4+ and CD8+ T-cell responses.

Diffuse large B-cell lymphomas include centroblastic and immunoblastic lymphomas. Centroblastic lymphoma involves the lymph nodes, accounts for 25% to 30% of HIV lymphomas, and 30% of the tumors are EBV positive. Immunoblastic lymphomas account for 10% of HIV lymphomas, 90% are EBV positive, and the tumors are extranodal. Diffuse large B-cell lymphomas often have type II or type III EBV latency, although variable expression of latent EBV genes has been reported.

CNS lymphomas in patients with AIDS are nearly always EBV positive, are immunoblastic lymphomas with type III EBV latency, and occur late in the course of AIDS when CD4+ T-cell counts are low[419] (Fig. 11.27). The cerebrospinal fluid is usually EBV positive. While studies before the era of highly active antiretroviral therapy found that detection of EBV in the cerebrospinal fluid of patients with mass lesions was highly predictive of CNS lymphoma, more recent studies suggest that the positive predictive value may be 30% or less. Increased metabolic activity on a PET scan along with EBV DNA in the CSF increases the likelihood of CNS lymphoma in these patients. HIV patients who subsequently developed CNS lymphomas lacked EBV-specific CD4+ T cells. Other immunoblastic lymphomas in patients with AIDS occur in the late stages of the disease and are usually EBV positive.

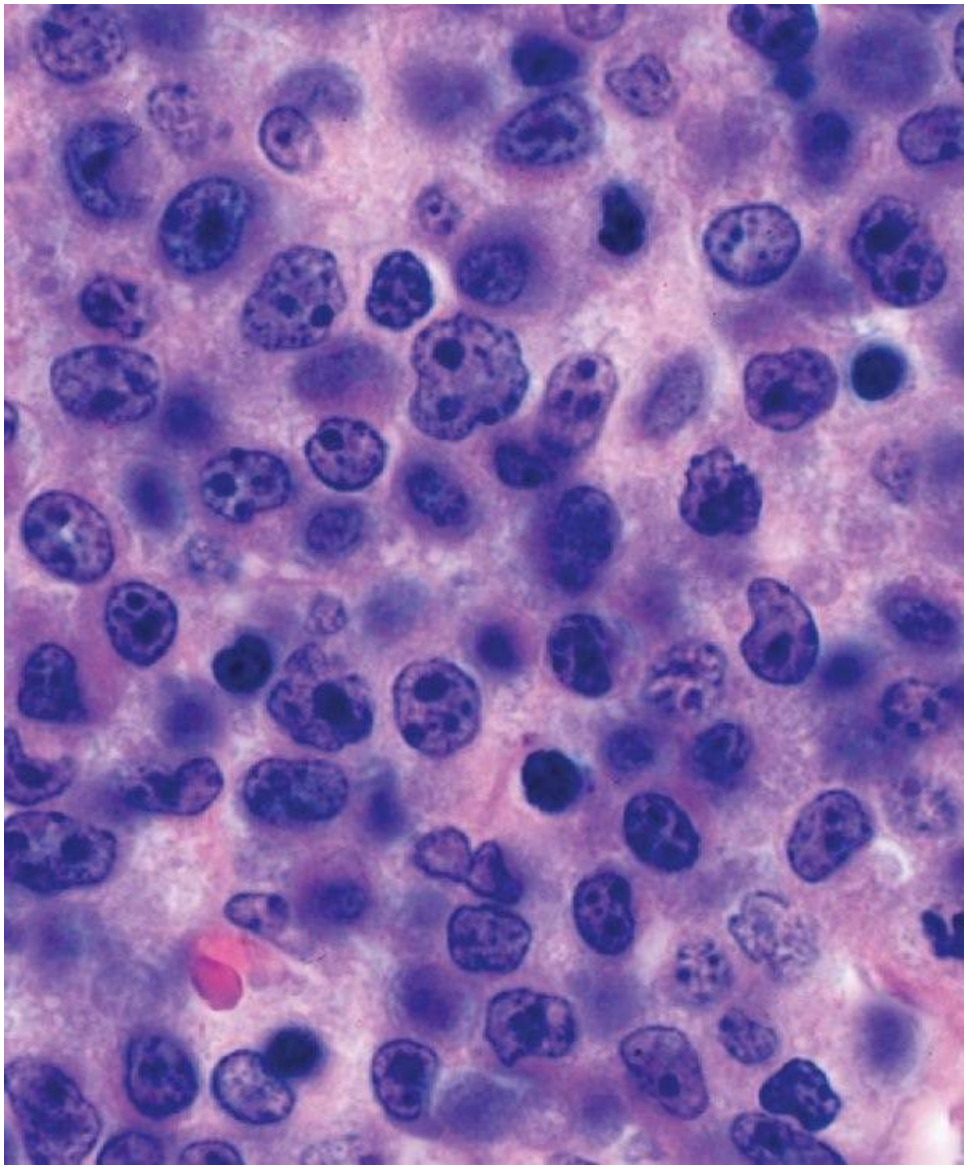

FIGURE 11.27 Biopsy from a patient with immunoblastic lymphoma of the central nervous system (Courtesy of Dr. Elaine Jaffe.)

Plasmablastic lymphomas are usually EBV positive and occur in the mouth or jaw of patients with HIV; less often they present in the sinus, gastrointestinal tract, or soft tissues. These tumors are EBER positive, have a type I latency pattern, and do not express CD20. They generally occur late in the course of HIV and have a poor prognosis.

Primary effusion lymphomas are located in the pleural, pericardial, or peritoneal cavity. The cells are positive for HHV-8 DNA and ≥90% of tumors contain EBV DNA. When positive for EBV, the EBV genome is required for cell proliferation. EBV inhibits HHV-8 lytic replication in primary effusion lymphoma cells. The tumor cells express EBNA1 and may express LMP1 and LMP2.

EBV-positive smooth muscle tumors, leiomyosarcomas, and leiomyomas occur in patients

with AIDS,[440] transplant recipients,[365] and in patients with congenital immunodeficiencies. These tumors usually present in the lungs or gastrointestinal tract but also can involve the liver, kidney, lymph nodes, central nervous system, and adrenal glands. The smooth muscle cells contain clonal or oligoclonal EBV DNA. Multiple tumors in the same patient may be from distinct EBV clones, indicating that they can arise independently. The disease usually occurs in the late stage of AIDS or at a mean of 3 years after organ transplant. Persons with primary EBV infection after transplant are at high risk.[669] Tumors can be either of donor or recipient origin in transplant patients. EBV gene expression varies; some tumors show type III EBV latency, while others express EBNA2, but not LMP1. In contrast, leiomyomas and leiomyosarcomas from immunocompetent persons do not contain EBV DNA.

Model for EBV Oncogenesis

While a large number of malignancies are associated with EBV, and new associations continue to be made, certain criteria have proved important for linking EBV to tumors. First, EBV should be in virtually every tumor cell. Second, the viral DNA should be clonal (or oligoclonal), indicating that the malignancy arose from an EBV-infected cell(s). Third, in the case of epithelial cell malignancies, viral DNA should be in dysplastic lesions, indicating that EBV infection occurred during oncogenesis. Fourth, at least one EBV-associated latency gene should be expressed, indicating that the virus has an active role in maintaining the tumor.

Some EBV-associated malignancies are strongly linked with the virus, which clearly is required for development of the tumor (Fig. 11.28). These malignancies have a short latency period between EBV infection or virus reactivation and development of malignancy and occur in highly immunosuppressed persons with little or no EBV-specific T-cell immunity. The tumor cells express most or all of the EBV-associated latency proteins and have few if any host gene mutations. Examples include EBV lymphoproliferative disease occurring early after transplantation or in patients with congenital immunodeficiencies. The low level of cellular immunity to EBV allows expression of the EBV transforming proteins, which rapidly results in transformation without the need for secondary cellular genetic changes.

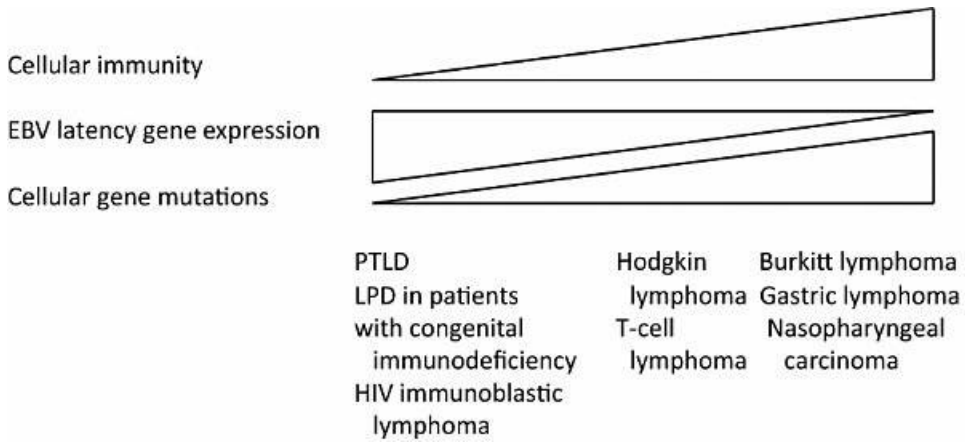

FIGURE 11.28 Model of EBV oncogenesis. EBV-associated malignancies in immunocompromised patients show full expression of EBV latency genes and few or no mutations or changes in cellular gene expression (left), while EBV-associated

malignancies in persons with otherwise normal immunity have limited expression of EBV latency genes and more mutations or changes in cellular gene expression (right).

In contrast, other malignances (e.g., HL) occur in otherwise healthy persons, have longer latency periods, and express an intermediate number of EBV latency genes. These patients have a degree of impaired T-cell immunity, but to much less an extent than those with EBV PTLD. Viral gene products can substitute for mutations in host cell genes that occur in the analogous EBV-negative tumors (e.g., crippled germinal center cells in HL).

A third class of EBV-associated malignancies (e.g., BL, NPC, gastric carcinoma) arise in patients who seem to be fully immunocompetent or challenged by another infection (e.g., malaria in the case of endemic BL) that may interfere with control of EBV infection. These tumors have mutations in cellular genes and more limited EBV latent gene expression. In EBV-associated epithelial cell malignancies (e.g., NPC, gastric carcinoma), genetic mutations are associated with inactivation of tumor suppressor genes and hyperplastic changes occur before EBV infection of the cells. In BL, EBV may initially drive proliferation of B cells resulting in chromosomal translocation and oncogene activation (e.g., *c-myc* in BL). In these diseases, EBV is clearly a cofactor and virus infection is one of several steps in development of the fully malignant phenotype. However, the presence of clonal EBV in every tumor cell, without loss of viral DNA after tumors are established, indicates that the fully malignant phenotype is dependent on EBV.

Other Diseases Associated With EBV

Chronic lymphocytic leukemia may have a subpopulation of cells infected with EBV and these cells express LMP1 and EBERs. EBV has been associated with transformation of chronic lymphocytic leukemia to diffuse large B-cell lymphoma. EBV has also been detected in T-cell prolymphocytic leukemia cells.

Rheumatoid arthritis patients often have elevated EBV DNA loads in the blood.[79] These patients have an increased risk of lymphomas (HL and diffuse large B-cell lymphoma), even in the absence of immunosuppressive therapy, and 24% of the lymphomas are EBV positive.

Multiple sclerosis (MS) has been associated with EBV in several studies.[36] Unlike the association of EBV with lymphoid and epithelial cell malignancies, the association of EBV with MS (and systemic lupus erythematosis) is primarily epidemiologic and EBV is likely to be a cofactor in these diseases. Primary infection with EBV is associated with an increased risk of MS[374]; persons who are EBV seronegative have a very low risk of MS. A meta-analysis showed a 2.2-fold increased risk of MS after IM. A case–control study showed that 83% of children with MS had evidence of EBV infection, compared with 43% of controls. A study of the prevalence of EBV-specific antibodies prior to the onset of MS found that serum antibodies to the EBNA complex in persons ≥25 years old were 2- to 3-fold higher in those who subsequently developed MS compared to those who did not.[375] The risk of MS was 36-fold higher in persons with high titers of anti-EBNA complex IgG antibodies and 8-fold higher in those with high EBNA1 titers than those with low titers titers.[484] Women in the highest quintile of EBNA1 IgG levels had a 3-fold higher risk of MS than the lowest quintile[483] Children of mothers with high VCA IgG during pregnancy had a 2.4-fold relative risk of MS.[483] A meta-analysis of several studies found an association between MS and anti-EBV VCA IgG, anti-EBNA IgG, and anti-EBNA1 antibody,

but not anti-EBV EA IgG, viral DNA in the serum, or DNA in CSF or brain.

Patients with MS have increased numbers and broadened specificity of CD4+ T cells to EBNA1. Patients with active MS have increased CD8+ T-cell responses to lytic EBV antigens.[18] CD107a+ CD8+ T cells recognizing lytic and latent EBV antigens were detected in the meninges or MS lesions of 11 of 12 patients.[625] Elevated levels of both antibodies and T cells to EBNA1 were associated with development of MS. EBNA1-specific T cells cross-reacted with myelin more frequently than autoantigens not associated with MS, and the myelin cross-reactive T cells produced IFN-γ and IL-2.

While most studies have not found EBV DNA or RNA in the brain, one study reported that nearly all postmortem brains from patients with MS showed EBV RNA (EBER) and BFRF1 protein in B-cell follicles, and LMP1 and EBNA2 in perivascular areas in white matter lesions. In contrast, EBV RNA was generally not detected in active plaques or in B cells in the CSF in another study. One study reported higher levels of antibodies to peptide sequences from EBV BRRF2 and EBNA1 in the serum and CSF from patients with MS compared with controls; antibodies to the viral proteins were present in oligoclonal CSF IgG. Increased levels of EBV antibody were detected in the serum and CSF of patients with MS; however, intrathecal synthesis of EBV antibody was uncommon, absent, or nonspecific in other studies. Of 10 patients with MS, treated with autologous EBNA1, LMP1, and LMP2A-specific T cells, 6 had both symptomatic and neurologic improvement and those who improved had T cells with high EBV reactivity.[536]

Systemic lupus erythematosus (SLE) is associated with elevated antibody titers to EBV; however, a prior history of IM is not associated with increased risk of SLE. In one study, 99% of children with SLE had evidence of prior infection with EBV compared with 70% of age matched controls.[283] EBV DNA was detected in the blood of 100% of patients with SLE, compared with 72% of controls. Patients with SLE often have higher EBV loads, increased numbers of latently infected B cells, and have certain EBV-specific antibodies that cross-react with SLE autoantigens. Patients with SLE more often have antibody to EBNA1 and produce antibody to more regions of EBNA1 than healthy persons. Antibody to 60 kDa Ro, which cross-reacts with EBNA1, was detected in some patients with SLE prior to the onset of disease; rabbits immunized with either a 60 kDa Ro or a cross-reacting EBNA1 peptide developed autoantibodies and SLE-like autoimmune disease. Increased levels of EBV VCA IgG and EA IgG were associated with a 1.3-fold or 1.4-fold risk of relatives of patients with SLE transitioning to SLE.[295] Meta-analyses showed a 2-fold higher risk of SLE for persons seropositivity to VCA IgG, a 8-fold higher risk for those who were EA IgG positive, and a 4-fold high risk for persons EBV DNA positive in blood.[381] Evaluation of transcription factors binding sites showed that almost half of GWAS loci associated with SLE are occupied by EBV EBNA2; similar GWAS loci for multiple sclerosis were also shared with EBNA2 sites.[234]

DIAGNOSIS

The diagnosis of IM in patients with typical symptoms is made by a positive heterophile antibody. In patients with atypical symptoms, or in those with typical symptoms and a negative

heterophile test, titers of EBV-specific antibodies are measured. Antibody to EBV VCA IgM antibody is the most useful test since the antibody is present only during the first 2 to 3 months of the illness (Fig. 11.17). EBV VCA IgG antibody is often elevated at the time of diagnosis, but since it persists for life, it is not useful for diagnosis of acute infection. Seroconversion to EBV EBNA positivity can be useful since antibodies take 3 to 6 weeks after the onset of illness to become positive and they persist for life. Antibody to EBNA2 is present early in IM, while antibody to EBNA1 is present later during convalescence.

Measurement of plasma EBV DNA is helpful when monitoring for EBV-associated tumors, which release DNA from apoptotic cells into the blood. Detection of EBV DNA in the blood can be useful for diagnosis of IM if serologic results are equivocal. Measurement of EBV DNA is also used to follow patients after transplant to predict the development of EBV PTLD or to follow patients with EBV PTLD, Hodgkin lymphoma, or NK/T-cell lymphoma after therapy.[212,330] Measurement of EBV DNA in whole blood (combined plasma and cells) is helpful for monitoring patients with EBV lymphoproliferative diseases associated with immune deficiencies and with CAEBV. The World Health Organization international standard for EBV has reduced the variability of whole-blood EBV DNA PCR results between laboratories.[624] Elevated levels of plasma EBV DNA is more specific than whole-blood EBV DNA for diagnosis of EBV diseases, but the latter is more sensitive to detect EBV in blood of immunocompromised persons.[306] Detection of cell-free EBV DNA in blood has been a useful marker to follow patients with NPC, NK/T-cell lymphoma, and Hodgkin lymphoma.[305]

Detection of EBV DNA in the cerebrospinal fluid of AIDS patients with lesions in the brain can be helpful for prediction of lymphoma. Culture of throat washings for EBV is not useful for diagnosis of IM since the virus persists for life in the throat of infected persons. PCR for the terminal repeats is used to determine if EBV is clonal in tissues, since individual clones have a fixed number of terminal repeats.

EBV is usually detected in tissue by *in situ* hybridization using a probe for EBER (Fig. 11.29) since this RNA is present at thousands of copies per cell. EBV latency proteins, including EBNA1, EBNA2, or LMP1, can also be detected in tissues. The characteristics of cells that EBV infects in blood can be determined by combined fluorescence *in situ* hybridrization and cell surface staining, or by staining for EBER and cell markers followed by flow cytometry.[129,195,331]

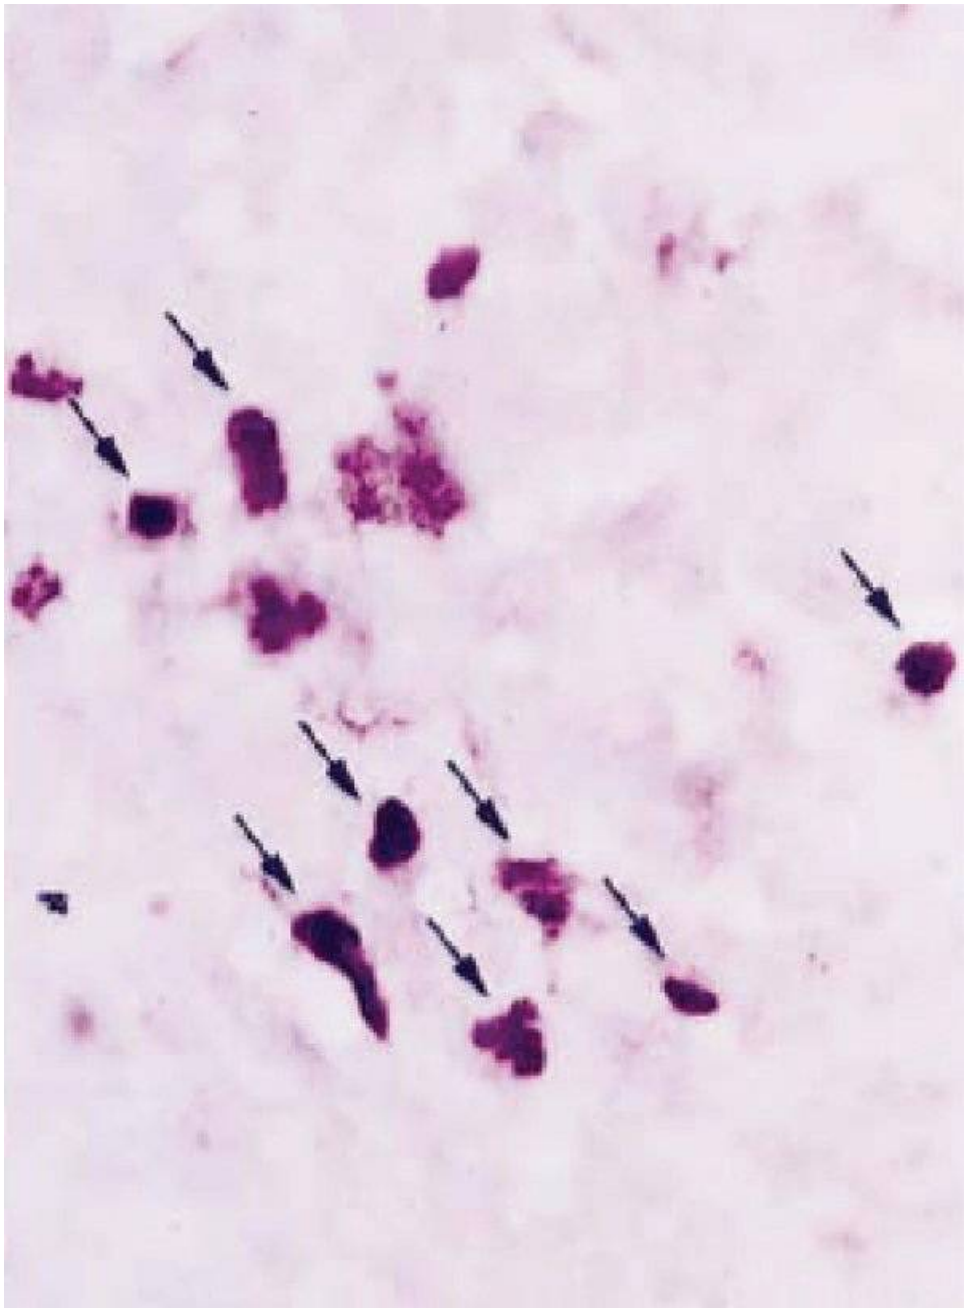

FIGURE 11.29 EBER staining from a biopsy showing EBV lymphoma. *Arrows* show cells that hybridize with the EBER probe. (From Cohen JI. Epstein-Barr virus infection. *N Engl J Med* 2000:343(7): 481–492. Copyright © 2000 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

INHIBITORS OF REPLICATION

Acyclovir and ganciclovir inhibit the viral DNA polymerase but do not inhibit latent infection.

Phosphorylation of acyclovir and ganciclovir is mediated by the EBV BGLF4 protein kinase, not the viral thymidine kinase (encoded by BXLF1). While treatment of chronic EBV carriers with acyclovir stops EBV shedding from the oropharynx, 1 month of therapy has no effect on the EBV viral load in the blood.[740] However, 1 year of antiviral therapy resulted in a modest reduction in the EBV viral load in the blood but did not affect the EBV DNA copy number per B cell.[257] Brincidofovir, a hexadecyloxypropyl ester of cidofovir, is greater than 100 times more potent as an inhibitor of EBV replication than acyclovir. Maribavir, an L-ribofuranoside benzimidazole, blocks phosphorylation of viral proteins by the EBV protein kinase and inhibits viral transcription, which results in reduced EBV replication.

TREATMENT

Infectious Mononucleosis

Treatment of IM is supportive. Contact sports should be avoided during the acute phase of the disease due to the risk of splenic rupture. While antiviral therapy reduces or eliminates virus replication and shedding from the oropharynx, it has no effect on symptoms. Corticosteroids reduce the duration of fever and sore throat; however, they may inhibit the development of cellular immunity to the virus and are not recommended for most cases of IM. The combination of corticosteroids and antiviral therapy did not reduce time off from work or school or the duration of the disease.[703] Corticosteroids are used for life-threatening complications such as upper airway obstruction due to tonsil enlargement, severe hemolytic anemia, and some cases of cardiac or central nervous system EBV disease.

EBV Posttransplant Lymphoproliferative Disease

Reduction in immunosuppression can allow an increase in EBV-specific T-cell activity against virus-infected B cells and in some cases, especially disease that occurs early after organ transplant, can cause tumor regression.[213] Rituximab, which depletes CD20-positive B cells, can be effective, especially in combination with chemotherapy. Surgery can be effective when PTLD lesions are confined to a single site. Cytotoxic chemotherapy (e.g., CHOP) is often effective early after transplant or in cases of rituximab failure. Radiation as well as high-dose methotrexate is often used for disease involving the central nervous system. Antiviral therapy has no effect once PTLD is established, since the EBV genome replicates in latently infected cells using the host, not viral, DNA polymerase.

Most tumors are of donor origin in hematopoietic stem transplant (HSCT) recipients. Thus, in these patients, infusion of donor lymphocytes has been successful although GVHD can occur.[524] EBV-specific T cells, either from stem cell donors[525] or HLA-matched donors from a donor bank,[561,704] have been used to treat EBV PTLD. Functional gene-marked CTLs persisted for up to 9 years. Immune escape from EBV-specific CTLs was reported in one bone marrow transplant recipient whose tumor cells mutated, deleting two EBNA3B epitopes, which resulted in a fatal outcome.

Most EBV PTLD in organ transplant patients is recipient in origin. In these patients,

reduction of immunosuppressive therapy can increase the level of EBV-specific T cells and may cure the disease. In some cases, EBV-specific CTLs have been expanded from organ transplant recipients and successfully treated the disease. Partially HLA-matched allogeneic T cells from a donor bank that covered 95% of common HLA haplotypes resulted in a complete remission in 42% of patients with PTLD (most of whom had undergone organ transplant) who had progressive disease despite conventional therapy.[231,561]

CTLs that recognize adenovirus, CMV, and EBV have been developed by incubating PBMCs with autologous EBV LCLs transducted with an adenovirus vector expressing a CMV gene; infusions of the CTLs into transplant recipients and their subsequent expansion in the blood were associated with lower levels of EBV DNA in the blood and resolution of EBV PTLD.[370] A rapid method of producing EBV-specific T cells involves stimulation of donor cells with EBV-specific peptides and antibody-mediated capture of cells expressing surface IFN-γ; this technique allowed isolation of EBV-specific T cells from donor blood in 36 hours and resulted in remissions in patients with early-stage PTLD.

While most EBV-specific T-cell therapies have focused on CD8+ T cells that recognize EBV antigen, some CD4+ T cells recognize EBV-transformed B cells not through viral antigens, but likely by cellular antigens that are induced by the virus. The latter may provide additional targets for T-cell therapy. Lymphokine-activated autologous killer cells have been effective in small numbers of organ transplant recipients with disease.

Hodgkin Lymphoma

Infusion of allogeneic EBV-specific CTLs into patients with refractory HL resulted in reduction in disease in some patients; however, the donor cells could not be detected in the recipients. CTLs were made to EBV-transformed B cells and infused into patients with EBV-positive HL; of 11 patients with measurable tumors, 2 had a complete response, 5 had stable disease, 1 had a partial response, and 3 had no response.[53] However, CTLs produced using dendritic cells transduced with LMP2 resulted in a higher frequency of LMP2-specific CTLs and induced a complete response in 4 of 6 patients with HL or NHL and relapsed disease, and maintained remissions in 9 of 10 patients. Infusion of EBV LMP1- and LMP2-specific CTLs into 21 patients with resistant or relapsed EBV-positive lymphomas resulted in 11 complete responses.[55]

Nasopharyngeal Carcinoma

A phase I trial showed that vaccination with a poxvirus (MVA) expressing the carboxyl terminal half of EBNA1 fused to LMP2 showed that the vaccine induced EBV-specific T-cell responses *in vivo*.[682] Dendritic cells from patients with NPC were pulsed with LMP2 peptides *in vitro*, and when injected into patients, they resulted in epitope-specific T-cell responses in the blood coincident with tumor regression in some patients.

Infusion of autologous EBV-specific T cells in patients with late-stage NPC resulted in control of disease in 6 of 10 patients; 3 of 4 patients with LMP2-specific immune responses after infusion had a clinical benefit. A second study by the same authors used higher doses of EBV-specific T cells after lymphodepletion by chemotherapy and reported control of disease in 6 of 11 patients.[622] In another trial, 10 patients with advanced NPC were treated with autologous EBV-specific CTLs; 4 patients who had been in remission remained disease free, and of 6 with

refractory disease before treatment, 2 had complete responses, 1 had a partial remission, 1 had stable disease, and 2 had no response.[668] A phase I/II study of 23 patients (including 10 patients reported previously[668] with recurrent or refractory NPC showed that infusion of autologous EBV-specific T cells resulted in disease-free outcomes in 62% of patients who had been in remission at the time of infusions, while 49% who had active disease at the time of the infusions had a complete or partial response. Patients with metastatic disease had a worse outcome than those with locoregional disease. A phase 1/2 trial of autologous EBV-specific CTLs in 21 patients with recurrent metastatic NPC yielded a median progression-free survival of only 2.2 months.[262] EBNA1-, LMP1-, and LMP2-specific T cells from patients with NPC were expanded ex vivo and infused into the patients resulting in an increased median overall survival compared with patients who did not receive the cells.[652]

Other Therapies

Other therapies to treat EBV diseases include the use of combined cytotoxic chemotherapeutic agents and ganciclovir to induce virus replication, express the viral protein kinase to phosphorylate ganciclovir (which is toxic to cells), and kill EBV-infected cells. Combined administration of ganciclovir and arginine butyrate (a HDAC inhibitor) resulted in EBV-positive tumor responses in 10 of 15 patients.[539] Romidepsin is the most effective of the FDA-approved HDAC inhibitors to induce lytic replication of EBV *in vitro*.[266]

HDAC inhibitors also increase the effectiveness of chemotherapeutic agents by inducing lytic replication in animal models of EBV lymphoma. Adenovirus expressing EBV IE genes reduced EBV tumor growth in mice. Demethylating agents such as 5-azacytadine also activate viral gene expression. Other approaches include low-dose hydroxyurea to reduce EBV episome copy number and rapamycin, which induces cell cycle arrest at the G1 phase in EBV-transformed B cells and inhibits growth of EBV lymphomas in SCID mice. Ritonavir, an HIV protease inhibitor, down-regulates survivin and cyclin D2, inhibits activation of NF-κB, and induces apoptosis in EBV-transformed B cells and inhibits growth of lymphoma cells in immunocompromised mice. Hsp90 inhibitors reduce EBNA1 expression and inhibit the growth EBV-transformed B cells in SCID mice. Ganetespib, an HSP90 inhibitor, improved survival in mice inoculated with transformed B cells and reduced the percentage of EBV-infected cells in the blood of a patient.[632] An HSP90 inhibitor reduced tumor formation with NPC cell xenografts in mice.[95] An HSP90 inhibitor reduced the growth of EBV-positive NK cell xenografts in mice.[488]

Bortezomib, a proteasome inhibitor, and Bay 11-7082 block NF-κB, induce apoptosis of EBV-transformed B cells, and enhance survival of mice injected with LCLs.[765] SAHA and bortezomib inhibit EBV lymphomas in a mouse model. Combined inhibitor of mTOR and PI3K/Akt inhibited EBV tumor growth in immunocompromised mice.[607] JQ1, an inhibitor of bromodomain and extra-terminal (BET) proteins, inhibited tumor growth in a mouse xenograft model.[237] Monoclonal antibody to CCR4 (mogamulizumab) inhibited the growth of EBV-positive NK cell lymphoma in mice.[307]

Based on the structure of EBNA1, benzoic acid–based inhibitors were designed that inhibit EBNA1 binding to DNA, block EBV transcription, and reduce growth of patient-derived tumors in mice[453]; one of these inhibitors has been tested in patients with EBV-positive nasopharyngeal

carcinoma. A computational designed inhibitor of the apoptosis inhibitor EBV BHRF1 induced apoptosis in tumor cells and prolonged survival of EBV-positive lymphomas in mice.[560] GAP31, a plant-derived protein, inhibited EBNA1 dimerization and EBV transformation of B cells and reduced growth of EBV-positive tumors in mice.[633]

PREVENTION AND VACCINES

Preemptive therapy for EBV lymphoproliferative disease has included antiviral therapy with acyclovir or ganciclovir. Results have been mixed, with more recent studies reporting a reduction in disease, while other studies showing no effect. Depletion of B cells from bone marrow used for transplantation reduces the risk of EBV PTLD, presumably due to removal of virus-infected cells. A single dose of rituximab (anti-CD20 antibody) given to allogeneic HSCT patients at high risk for EBV PTLD with rising viral loads reduced the rate of disease from 49% based on an historical cohort to 18% in the treated group and prevented death at 6 months.[176] However, relapses due to CD20-negative EBV-infected B cells have occurred that require other therapy. An alternative approach is to monitor patients with rising viral loads and to give rituximab or EBV-specific CTLs only when systemic symptoms occur. Infusion of EBV-specific T cells (directed again EBV latency-associated proteins) has been effective in reducing the EBV load in the blood and preventing EBV-associated PTLD in HSCT recipients.[213,248,590] A study of EBV-specific CTLs for prevention of EBV PTLD found that none of 101 patients who received CTLs developed the disease. Donor-derived EBV-specific CTLs have prevented disease in matched unrelated and haploidentical stem cell transplants. Prophylactic treatment with rituximab markedly reduced the risk of PTLD in haplo-cord blood transplant recipients.[707]

Reduction of immunosuppression is often effective early after transplantation when viral loads increase. In a study of 73 liver transplant recipients in which immunosuppression was tapered when EBV viral loads were elevated, one patient developed allograft rejection, but the incidence of PTLD declined from 16% to 2%. EBV-specific T cells prevented development of EBV-positive lymphomas when they were given as prophylaxis to T-cell depleted bone marrow transplant recipients with high EBV loads after transplant and at high risk of the disease; the cells can persist for at least 18 months.[248] Autologous EBV-specific T cells have also been used to prevent EBV lymphomas in solid organ transplants with high viral loads. Donor-derived LMP1-specific T cells reduced the rate of relapse after transplant for B-cell or T-cell EBV lymphoma or lymphoproliferative disease.[444]

Vaccination to prevent EBV infection or disease will be important in certain high-risk groups including transplant recipients, boys with mutations in SAP or XIAP, and areas where the frequency of NPC and BL are high.[121] Vaccination that reduces the rate of IM might reduce the frequency of EBV-positive HL, which is increased during the first 5 years after IM.

gp350 has been the major immunogen in vaccine studies; it is the major target for neutralizing antibody[65] and it is a target of CTLs. Infusion of immunodeficient mice, reconstituted with PBMCs from EBV negative persons, with monoclonal antibody to gp350 prevented development of EBV lymphomas after challenge with virus[230] and a monoclonal antibody to gH/gL reduced viremia in humanized mice challenged with EBV and monkeys

challenged with rhesus LCV.[637] Vaccination with soluble gp350 protected cottontop tamarins from lymphoma when challenged with EBV. While immunization of marmosets with gp350 reduced infection, protection did not always correlate with development of neutralizing antibody. Rhesus LCV is the homolog of EBV in rhesus macaques. Immunization of rhesus macaques with soluble rhesus LCV gp350 resulted in better protection from infection and reduced viral loads 2 years after infection in animals that became infected after challenge, when compared with virus-like replicon particles expressing rhesus LCV gp350, EBNA3A, and EBNA3B.[610]

A study of 19 seronegative children (1 to 3 years old) in China randomized to vaccination with vaccinia virus expressing gp350 or control found that at 16 months all 10 unvaccinated children were infected with EBV, while only 3 of 9 vaccinated children were infected. A study of 181 EBV-seronegative adults randomized to receive three doses of soluble gp350 in monophosphoryl lipid A/alum adjuvant or placebo showed that the vaccine reduced the rate of EBV IM by 78% but did not affect the rate of virus infection.[477,655] A phase I trial of children with chronic kidney disease using three injections of a lower dose of gp350 in alum showed that the vaccine induced neutralizing antibody in 33% of subjects receiving the highest dose of gp350 and immune responses declined rapidly; the authors concluded that a more prolonged vaccine schedule or an improved adjuvant was needed for these patients.

Vaccination of mice with a tetrameric form of gp350[139] or rabbits with trimeric gH/gL or trimeric gB[138] induced higher levels of antibody than the monomeric gp350. Vaccination of mice with gH/gL-EBNA1 and gB-LMP2 virus-like particles also induced high titer neutralizing antibody as well as virus-specific T-cell responses.[538] Vaccination of rabbits with gp350, gB, gp42, gH, and gL virus-like particles induced antibodies that protected B cells and epithelial cells from infection *in vitro*.[175] Presentation of gp350 on nanoparticles enhanced the levels of neutralizing antibody in monkeys compared with soluble gp350 and focused the immune response on the CR2 (receptor) binding site on gp350 in monkeys.[308] Vaccination of mice and nonhuman primates with nanoparticles displaying EBV glycoproteins (gH/gL/gp42) induced potent neutralizing antibody that protected B cells and epithelial cells from infection and blocked EBV glycoprotein-mediated cell fusion.[65]

An alternative or complementary strategy is to induce potent T-cell responses to control primary infection so as to reduce the viral load after infection and potentially reduce the risk of EBV-associated malignancy. A study of 14 HLA B*0801 EBV-seronegative adults randomized to receive an HLA B*0801 EBV EBNA3A peptide (FLRGRAYGL) and tetanus toxoid in a water in oil adjuvant showed that 8 of the 9 volunteers developed epitope-specific T-cell responses.[168] At 2 to 12 years after follow-up, 1 of 2 placebo recipients developed IM, while 4/4 vaccinees that became infected with EBV did not develop IM. Virus-like particles expressing nearly all the EBV genes except for BZLF1, EBNA2, 3A, 3B, 3C, and LMP1 and the terminal repeats induced neutralizing antibody and T-cell responses in mice. Vaccination of mice with virus-like and light particles that contain lytic and latent EBV antigens resulted in virus-specific T cells that controlled outgrowth of EBV, and particles containing EBNA1 protected mice from wild-type EBV in humanized mice.[768] Vaccination of transgenic mice with adenovirus expressing EBNA1, following by boosting with MVA expressing EBNA1, resulted in protection both as a prophylactic and therapeutic vaccine to prevent or treat EBV lymphoma.[593]

PERSPECTIVE

While we have learned much about EBV, many important questions remain. The precise mechanisms by which EBV is associated with malignancies, and how these relate to the establishment and reactivation from latency, are still being uncovered. Much remains to be learned about EBV gene regulation in newly infected and latently infected cells, including how long-range DNA interactions and epigenetic pathways control EBV programs. Knowledge remains incomplete of how EBV causes these cells to differentiate into memory B cells, and whether these reservoir cells differ from uninfected memory B cells. Many EBV lytic gene products remain poorly studied, and roles for miRNAs and circular RNAs remain to be fully characterized. It is not fully apparent why EBV IM is primarily a disease of adolescents and young adults, though humanized mouse models and human studies will continue to provide new insights. The types of immune responses needed to prevent EBV infection, EBV mononucleosis, or virus-associated malignancies are uncertain. The role of EBV in multiple sclerosis and other autoimmune diseases is still unclear. While EBV-specific CTLs have often been effective in the treatment of EBV posttransplant lymphoma, these cells have been less effective in the treatment of NPC and EBV-associated lymphomas, and improved virus-specific therapies are needed. Newer therapies to block EBV immune evasion mechanisms or to alter EBV genome programs to allow latently infected cells to be better recognized and killed by the immune system are needed. Finally, while small scale trials have shown that an EBV vaccine can reduce the incidence of IM but not the rate of infection, larger trials with more effective vaccines are needed to prevent EBV infection and/or disease. EBV continues to teach us about B-cell biology, and studies of immune deficiencies that predispose to severe EBV infections inform us about how the immune system controls virus infections. Thus, the study of EBV continues to enrich our knowledge of human biology and virology and further progress should help to reduce the burden of EBV-associated cancer.

ACKNOWLEDGMENTS

The authors acknowledge the mentorship of Elliott Kieff, with whom all of us trained and who has greatly influenced our understanding of EBV. We also acknowledge Alan Rickinson, who along with Elliott Kieff wrote earlier versions of this chapter, and who have shaped our knowledge about EBV. We thank Nancy Raab-Traub and Alan Rickinson for reviewing this chapter and for valuable suggestions. We acknowledge the assistance of our colleagues, in particular Dr. Rui Guo. J.I.C. is supported by the Intramural Research Program of NIAID. R.L. is the Dan and Bertha Spear Research Professor and is supported by grants from the NIAID and NINDS. B.E.G. is supported by grants from NIAID, NCI, and a Burroughs Wellcome Career Award in Medical Sciences. Additional references can be found in the prior edition of this chapter in Fields Virology.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is a genus of herpesvirus in the subfamily of β-*Herpesvirinae*. CMV is the prototypical β-herpesvirus and has a protracted replication cycle characteristic of its subfamily. The name CMV (from the Greek cyto-, "cell," and megalo-, "large") comes from the fact that this virus causes enlargement of the infected cell with nuclear and cytoplasmic inclusions. Humans, monkeys, and other mammals serve as natural hosts. CMVs co-speciated with their host at least 90 million years ago. Co-speciation resulted in these viruses being highly restricted to their natural host species.

Human CMV (HCMV) infects between 40% and 99% of the population worldwide depending on geographical region and socioeconomic factors. Primary infection with CMV most commonly results in subclinical infection and long-term (months to years) virus shedding. Like all herpesviruses, HCMV infection is never completely cleared. The virus persists in the host indefinitely by establishing a latent infection—the maintenance of viral genomes in the absence of virus replication—punctuated by sporadic, frequent, and, in healthy hosts, asymptomatic reactivation events that result in subclinical virus shedding.

While reactivation of CMV in healthy individuals is typically asymptomatic, HCMV is an important opportunistic pathogen in immunocompromised individuals, such as following solid organ transplantation (SOT) and hematopoietic cell transplantation (HCT), patients undergoing immunosuppressive therapies, and persons affected by genetic or acquired immunodeficiency. Despite available antiviral therapies that can provide benefit in the control of CMV disease, the virus remains a significant cause of morbidity and mortality in individuals with inadequate cellular immunity. There are currently no approved vaccines, and more effective, safe and orally bioavailable antiviral drugs are needed.

HCMV is the most significant infectious cause of intrauterine infection and a leading cause of disease in the new born. Transplacental transmission of CMV to the fetus during pregnancy, which occurs rarely with other herpesviruses, leads to a congenital (present at birth) infection in approximately 1% of pregnancies worldwide regardless of the maternal CMV serostatus prior to conception. Congenital cCMV infection results in clinically significant neurodevelopmental abnormalities in 10% to 15% of congenitally infected newborns, the most common being sensorineural hearing loss. The frequency of congenital infections caused by CMV and the associated damage to the developing nervous system further underscores the importance of CMV as a human pathogen.

The virion of HCMV (~200 nm) is composed of an enveloped icosahedral capsid encasing a 236-kilobase pair double-stranded DNA genome (Fig. 12.1). CMV genomes have exceptionally

large protein-coding capacities, much greater than other herpesviruses (>170 proteins). HCMV proteins with known functions are summarized in Supplementary e-Table 12.1. The viral genome also encodes microRNAs (miRNAs, Supplementary e-Table 12.2) and long RNAs thought to be noncoding (lncRNAs), although there is some evidence for coding potential discussed in later sections. The protein content of CMV particles is large and complex due to the tegument (viral and host proteins and RNAs packaged between the envelope and the capsid). Despite the restricted species host range, within the host HCMV causes systemic infection and replicates in diverse cell types, including but not limited to epithelial cells, endothelial cells, fibroblasts, and hematopoietic cells. HCMV may also enter and remain quiescent such that outcomes of infection are dictated by cell type and differentiation status, and include productive, chronic/persistent, and latent patterns. In the following sections, we review the biology and pathogenesis of HCMV infection. While a historical perspective is provided, older editions of this chapter should be consulted for the literature supporting findings that predate the year 2000 due to space constraints.

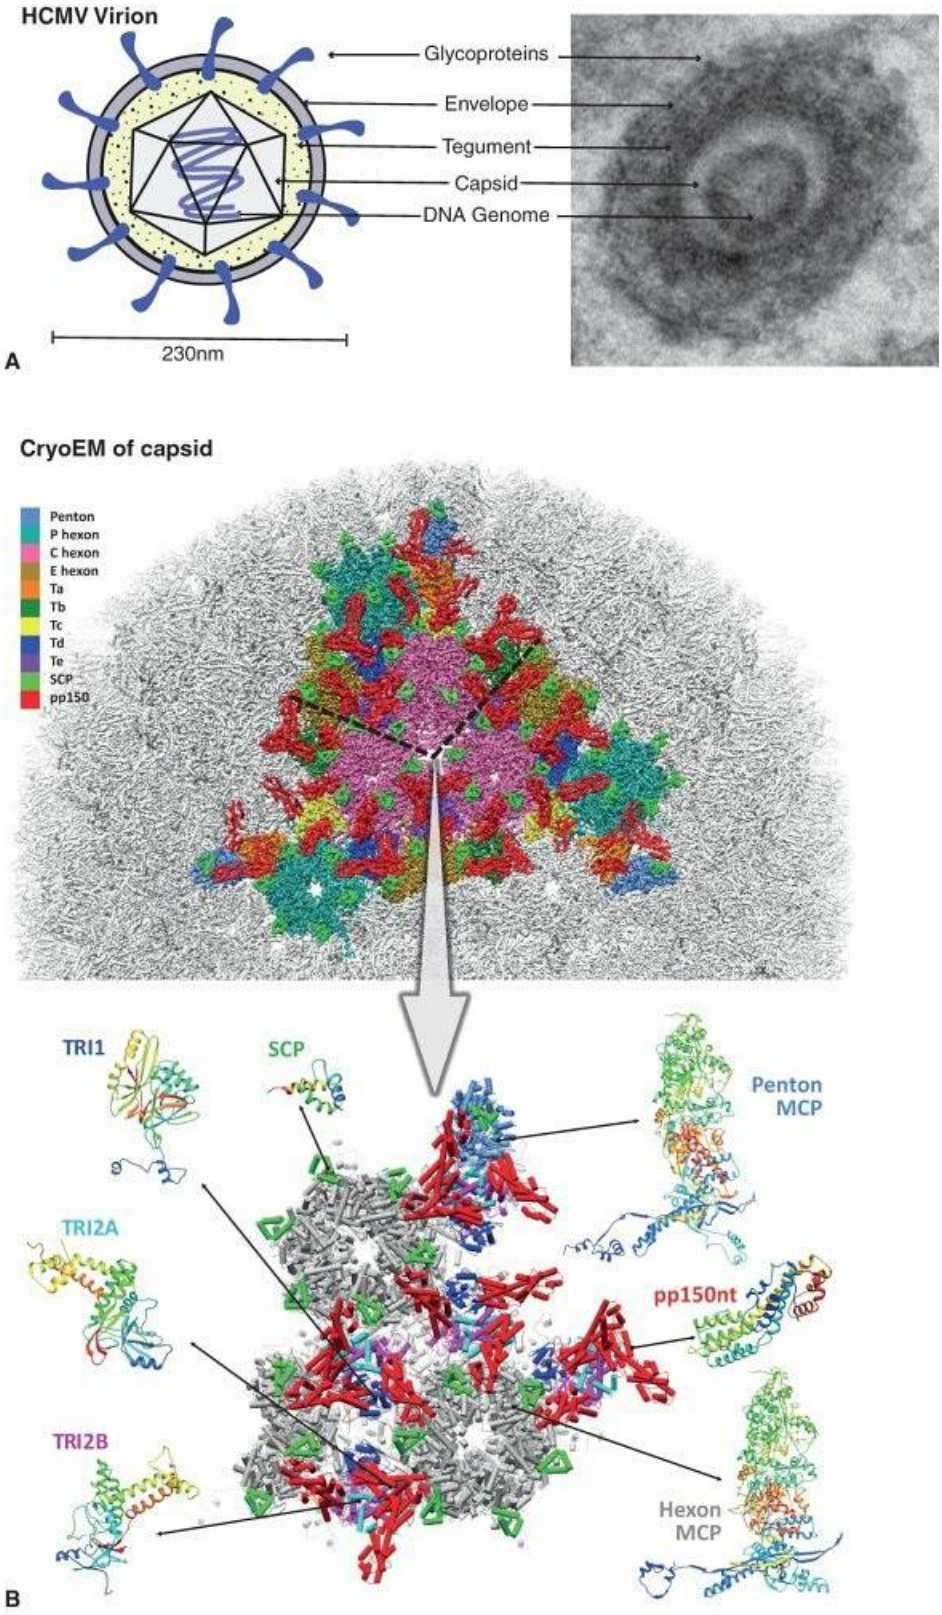

FIGURE 12.1 Virus structure. A: Schematic and electron micrograph of HCMV virion. The double-stranded DNA genome core, capsid, tegument, envelope (cell-

derived lipid bilayer) and glycoproteins are indicated. There are numerous glycoprotein complexes on the surface of the virion and these are represented in Figure 12.6. **B:** Cryo-EM showing nucleocapsid structure from within a virion (strain AD169) showing capsomeres. The capsid proteins smallest capsid protein (SCP), pentons and hexons of major capsid protein (MCP) and Triplex (TRI2A, TRI2B, and TRI1) and the pp150 tegument protein are indicated. Peripentonal (P), center (C) and edge (E) hexons are also shown. Each asymmetric unit contains a C hexon, P hexon, one-half of an E hexon, and one-fifth of a penton plus 16 copies of SCP that sit atop each MCP, five and one-third heterotrimeric triplexes (indicated with different colors). (Panel B—courtesy of Dr. Hong Zhou, University of California, Los Angeles, California.)

HISTORY

HCMV has been recognized as an opportunistic pathogen and an important infectious cause of birth defects for well over half a century. Nearly 100 years ago, histopathology provided the first evidence of this filterable infectious disease agent associated with congenital disease together with type A intranuclear inclusions typical of herpesvirus-infected cells. Infected cells present in tissues of immunocompromised adults or congenitally infected newborns have unmistakable large cell, “owl’s eye” cytopathology, or cytomegaly.[246] By the early 1950’s, diagnosis of HCMV disease was facilitated by the identification of inclusion-bearing cells in urine along with the demonstration of virus-like particles by electron microscopy. Human salivary gland virus was isolated from the urine of newborns with characteristic clinical and histopathological findings that was termed cytomegalic inclusion disease (CID), now known to be caused by HCMV. By the early 1970s, diagnosis of CMV infection in newborns and transplant recipients by virus isolation was established as a gold standard.

Surrogate animal models using related viruses infecting mice, rats, and guinea pigs play important roles defining the pathogenesis. Rat CMV (RCMV) and murine CMV (MCMV) (classified as *Muromegaloviruses*) replicate and produce a similar cytopathology to HCMV but only on fibroblasts from the homologous species. More recent studies using rhesus CMV (RhCMV) have been possible due to isolation of specific pathogen-free rhesus macaques.[492] Species specificity is recognized as a key characteristic of all CMVs.

Given the low frequency of the clinically apparent or symptomatic congenital CMV infection, the high, worldwide seroprevalence of CMV was unexpected. CMV is recognized as a common asymptomatic virus infection. In 1975 it was reported that transplantation of kidneys from seropositive individual results in a seroconversion in 83% previously seronegative recipients. This finding was confirmed for any transplanted organ—indicating the existence of a latent infection given the lack of detectable virus.

The CMV genome was first sequenced in 1990, revealing the largest human viral genome sequence known. The genome was originally annotated as open reading frames (ORFs) of 100 or more contiguous codons and that did not overlap other ORFs by more than 60%. This led to the identification of 189 putative unique genes. Since this seminal work, our appreciation of the HCMV coding potential has expanded with the identification of additional sequences, many

smaller ORFs, noncanonical initiation codons and products from spliced genes. The first HCMV isolate (Toledo strain) to be sequenced prior to extensive passage in cultured fibroblasts revealed a 15-kilobase sequence in the unique long (U_L) region of the genome, referred to as the *b'* region that happened to be inverted but naturally present in all clinical isolates (Fig. 12.2). This region is often lost during serial passage in cultured fibroblasts. The *b'* region encodes 19 to 22 genes with functions related to the broad cellular tropism of HCMV, immune modulation, and latency (Fig. 12.3).[96] Further, reevaluation of the coding potential and RNAs associated with ribosomes during infection has also expanded HCMVs actual potential well beyond 200 unique genes.[161,425,427,597]

Genetic variation within the DNA genome of HCMV strains was first appreciated around the turn of 21st century.[142,213,495] The genetic instability of HCMV genomes propagated in fibroblasts led to cloning a number of low-passage clinical strains as bacterial artificial chromosomes.[410,690] This not only resulted in genomes that could be stably propagated but permitted the use of techniques in prokaryotic molecular biology to introduce mutations to target genes and define gene function.

Beyond congenitally infected infants, the most severe manifestations of uncontrolled HCMV replication have occurred in AIDS patients. During the emergence of the HIV epidemic and before the introduction of highly active antiretroviral therapies, CMV disease occurred in 21% to 44% of AIDS patients late in their disease when CMV retinitis was prevalent. Currently, the most significant setting for CMV disease is associated with immunosuppressive therapy and allograft rejection following SOT and HCT, particularly evident in developed countries. CMV is the single most important cause of infectious disease after organ transplantation and affects 75% of transplant recipients with high morbidity and mortality within the first year following transplantation.

The most important antiviral with clinically demonstrable activity against HCMV, ganciclovir and its oral form, valganciclovir, are derivatives of an aciclovir nucleoside that targets the viral DNA polymerase. These antivirals were initially used to treat end-organ disease associated with CMV infection in AIDS. It is now common practice to use these antivirals for prophylaxis or for preemptive therapy in the setting of SOT or HCT. Although typically beneficial, treatment with these antiviral drugs is sometimes ineffective in controlling virus levels or altering the clinical outcomes in the settings of transplantation as well as congenital disease. Antiviral prophylaxis with a recently available drug, letermovir, targeting the viral terminase can prevent CMV disease particularly in the HCT setting. Importantly, no existing antiviral therapies target the latent virus reservoir.

CMV was declared a priority for vaccine development byt the US Academy of Medicine in 2004. While CMV vaccines reached Phase I or II trials, there currently is no approved vaccine against CMV. A number of challenges exist to development of an effective vaccine against CMV due to its exquisite ability to evade clearance by a natural immune response and the inability of the natural immune response to prevent superinfection by additional CMV strains. Comprehensively defining the complex immune response to CMV is key to understanding viral persistence and pathology and critical to CMV vaccine development. Major advances in the 21st century have provided insights into the strikingly unique immune response associated with CMV persistence and viral genes required for reactivation, which hold exciting promise for future development of tailored vaccine vectors to target historically intractable pathogens and

cancers.[90,235–238]

CLASSIFICATION

CMV is a genus of viruses in the order *Herpesvirales*, in the family *Herpesviridae*, and in the β-*Herpesvirinae* subfamily. HCMV carries the official ICTV designation as human herpesvirus 5. The betaherpesvirus subfamily exhibits a greater level of evolutionarily and genetic divergence than either the α- or γ-herpesvirus subfamilies. Higher order primate CMV species including chimpanzee CMV (ChCMV), which infects chimpanzees and orangutans; simian (SCMV); and RhCMV that infect macaques resemble HCMV and serve as promising animal models. One hundred sixty-three of the predicted 168 ChCMV genes are homologous and colinear with HCMV.[150] While RhCMV is a more tractable model than ChCMV, only 111 genes share homology with HCMV.[527] The relatedness between HCMV and *muromegaloviruses* (MCMV and RCMV) that were previously classified as CMVs, falls off dramatically such that less than 80 genes exhibiting sequence homology. Nonetheless, MCMV and HCMV exhibit many common biological attributes in infection, pathogenesis, immune modulation, and latency. CMVs achieve these ends via divergent mechanisms and distinct gene products. For the purposes of this chapter, CMV is used to collectively refer to the entire genus or when referencing clinical disease (e.g., CMV disease in the immunocompromised host or congenital CMV). The chapter is focused on HCMV, and research findings that rely on other species of CMV are specified. Due to constraints inherent in studying CMV pathogenesis in humans, many key observations are referenced from the study of animal models.

VIRION STRUCTURE

Capsid

The HCMV virion ranges from 200 to 300 nM in diameter and consists of three structurally definable regions, the innermost DNA containing capsid, a structurally less well-defined tegument layer, and the outermost lipid-containing envelope (Fig. 12.1A). Of these, the capsid of HCMV shows relatedness to capsids of other herpesviruses, including the most well studied herpesvirus, herpes simplex virus-1 (HSV-1). The HCMV capsid is approximately 130 nM in diameter. Due to the size of the HCMV genome, viral DNA within the HCMV nucleocapsid is likely near the limit of viral DNA that can be packaged.[692] Because of a predicted high internal pressure of the HCMV nucleocapsid secondary to the charged and tightly packed genomic DNA, several unique structural properties of the capsid have been proposed to facilitate packaging of the viral genome and subsequent stabilization of the nucleocapsid. Major capsid protein (MCP, encoded by UL86), minor capsid protein (MnCP or Triplex 1, TRI1, encoded by UL85), minor capsid binding protein (MnCBP or Triplex 2, TRI2, encoded by UL46), smalllest capsid protein (SCP, encoded by UL48.5), and the portal proteinn (encoded by UL104). Assemblin, encoded by UL80.5, is cleared from the mature capsid prior to genome packaging, significant quantities it its

cleavage product is associated with the mature particle.[526,640] In addition to mature nucleocapsids associated with infectious virions, capsids lacking genomes may be enveloped producing noninfectious enveloped particles (NIEPs) (Fig. 12.2A). Furthermore, infection results in noninfectious particles that lack both viral DNA and capsids that are termed dense bodies (DB), based on their appearance in electron micrographs. Characteristically, DB are larger than virions and more heterogeneous in their protein composition than virions, and their relative abundance is viral strain dependent. Both NIEPs and DBs are produced and released from infected cells, particularly in culture. The mature capsid of the infectious virion contains five virus-encoded proteins.

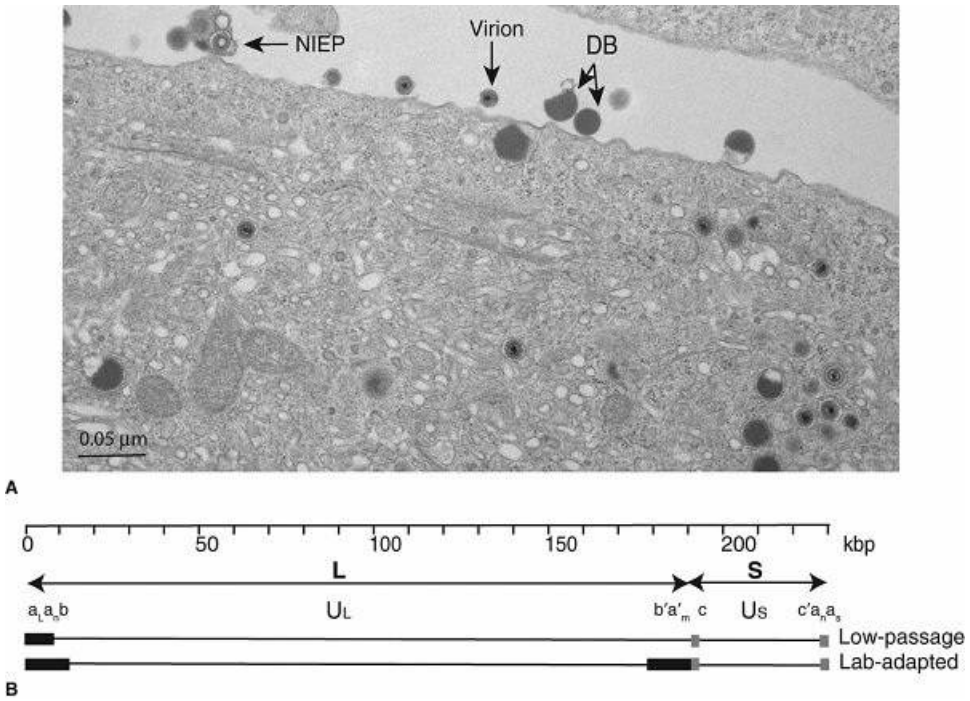

FIGURE 12.2 HCMV infection and genome structure. A: Electron micrograph of infected human fibroblasts with intracellular and extracellular HCMV virions, noninfectious enveloped particles (NIEP) and dense bodies (DB). Scale bar, 5 mM. **B:** HCMV genome structure. The size scale (*top line*) is in kilobase pairs (1 kbp = 1,000 base pairs). The long (L) and short (S) segments of the genome are shown with arrows. Schematics for common lab-adapted (e.g., AD169) and low-passage (e.g., TB40/E, Merlin, Toledo, etc.) strains are shown. The L-terminus is composed of the *a* sequence repeat (a_L) where zero to several copies of the *a* sequence may exist (a_n). The *b* sequence repeats at the opposite end of the U_L region near the L–S junction of the unique long (U_L) coding region in AD169. However, the *b* sequence inverted repeat is replaced by additional U_L sequence in the low-passage strains, referred to as $U_L b'$. This is followed by one to several additional copies of the *a* sequence inverted repeats (a_m') at the L–S junction. The S segment of coding sequences is bordered by the c′ inverted repeat at the L–S junction and the c sequence inverted repeat and an *a* sequence repeat (a_S) with a variable number of additional copies of the *a* sequence (a_n).

Using cryo-electron microscopy, the structure of the HCMV capsid was solved at an average resolution of 3.9 Å[692] (Fig. 12.1B). Several key protein structures and protein–protein interactions have been defined that, in turn, have provided explanations for the stability of DNA containing nucleocapsid.[692] The icosahedral structure of the HCMV capsid consists of 12 pentons, 150 hexons, and 320 triplexes with a triangulation number of 16.[144,692] A single SCP molecule associates with each MCP and a single pp150 (*UL32*) tegument protein is present on each MCP/SCP heterodimer.[692] Unique to the structure of the MCP is the presence of a Johnson-fold, a motif homologous to a structural feature in all herpesviruses and some bacteriophages that stabilizes the capsid.[692] In addition, favorable charge interactions between the HCMV DNA and hexons provide a mechanism for packing of the viral DNA as well as stabilizing the nucleocapsid.[692] These features support remarkable stability of the capsid structure. Lastly, the tegument protein pp150 interaction with MCP/SCP heterodimers as well as with triplexes creates a net or a skein-like structure to further maintain the structural integrity of the nucleocapsid, a feature unique to primate CMVs.[692,693] For more detailed discussion of capsid assembly, see section *Capsid assembly, DNA encapsidation, and nuclear egress*.

Tegument

The virion tegument layer resides between the envelope and the capsid and remains the least well-characterized region of the virion both in terms of composition and organization. The tegument consists of dozens of proteins, many of which carry out critical functions in the replicative cycle and in the modification of host responses to infection. Over 50% of the total number of virus-encoded proteins are located in the tegument[526,640]; however, only a small fraction contribute directly to the structural integrity of the virion. A majority of tegument proteins contribute to HCMV genome replication, efficient cytoplasmic assembly of infectious progeny, and modulation of host innate and adaptive immune responses. Most tegument proteins are phosphorylated, and phosphorylation may regulate tegument protein function.[214] Ultrastructural studies of the HCMV capsid have localized pp150 to the innermost layer of the tegument through its interaction with the SCP.[144] Beyond pp150, our understanding of the order of tegument protein remains rudimentary.

Although there is little evidence that individual virus-encoded proteins are required to maintain the structural integrity of tegument, deletion of individual tegument proteins can dramatically impact the assembly of infectious virions.[111] It is difficult to discern whether the loss of an single tegument protein has a direct impact on virion instability or alternatively, impacts stability by altering the incorporation of other tegument proteins important for early steps in infection, as has been described for the role of pp65 (*UL83*) in the incorporation of UL69 and UL97 proteins into the virion.[111] Tegument proteins also impact CMV replication by contributing to viral modulation of host intrinsic and innate immune responses. Functions that have been assigned to individual tegument proteins in the replication of HCMV do not provide clues to their location in the tegument. As an example, tegument proteins such as pp150 that function in both stabilization of the nucleocapsid and potentially in the transport of the nucleocapsid to sites of virion assembly presumably must belocalized to the inner tegument layer.[144,263,612,692] Finally, proteomic studies have also identified a substantial number of host cell proteins as well as virus-encoded RNAs within the tegument of extracellular virions,[526,620,640] even though these do not play any obvious a role in infection.

Envelope

The tegumented nucleocapsid is surrounded by a lipid bilayer envelope derived from the endoplasmic reticulum–Golgi intermediate compartment and contains a large number of virus-encoded proteins. The envelope exhibits a unique lipid content including very long chain fatty acids and cholesterol that distinguishes it from membranes of uninfected cells.[222,319] The lipid composition of the HCMV virion envelope is similar to that of synaptic vesicles and exocytic vesicles produced by exocrine cells.[367] It is perhaps not surprising that the lipid composition of the HCMV virion envelope differs from that of intracellular membranes in uninfected cells given the major alterations in host cell lipid metabolism and extensive spatial reorganization of intracellular membranes that accompanies generation of the membranous virus assembly compartment in the late phase of virus replication.[201,330,545] Interestingly, the cholesterol content of the infected cell increases significantly during infection and may contribute to the fusogenic activity of the envelope.[222,474] The membrane lipids incorporated into the virion envelope may also be derived from inhibition of lipid transport from the infected cells.[544,694,695] Thus, the characteristic spatial reorganization of host cell membranes in virus infected cells is accompanied by increased lipid production as well as inhibition of fatty acid oxidation and changes in intermediary metabolism to support increased lipogenesis required for virus membrane production and additional sources of carbon for ATP production.[563,647,694]

The HCMV envelope contains orthologs of core herpesvirus glycoproteins, glycoprotein B (gB), gH, gL, gM, and gN. In addition, glycoproteins unique to HCMV, including gO together with UL128, UL130, and UL131A proteins, contribute to early events of virus infection including virion attachment, fusion, and penetration of the target cell, contributing to the broad cellular tropism.[224,385,671,702] Each of these proteins is present within functional glycoprotein complexes in the virion. For more detailed discussion of glycoprotein complexes and function, see section *Attachment and Entry*. HCMV envelope protein complexes likely provide a level of regulation of the entry process into the host cell. Complex formation may also ensure functional activity of individual glycoproteins regardless of the overall stoichiometry of individual glycoproteins in the virion envelope. This possibility is consistent with findings that the composition of the envelope, including the relative amounts of individual core envelope protein complexes, can vary depending on the level of expression of nonenvelope viral proteins as well as the cell type in which the virus is propagated.[336,350,353,557] Most of the core envelope glycoproteins are involved in entry, with the exception of gM, which has been implicated in assembly and release of virions and noninfectious viral particles.[224,247,267,325] Beyond gB, gH, gL, gM, gN, gO and the UL128, UL130, and UL131A gene products, as many as 50 to 70 glycoproteins are encoded by HCMV. Many of these glycoproteins traffic to sites of virion assembly and can be incorporated into the envelope of HCMV; however, none of these has been shown to be required for virion envelopment, attachment, entry, or maturation and release arguing that they likely do not play a direct role in assembly or function of the virion envelope. Yet these viral proteins are likely required for efficient *in vivo* replication, immune modulation, and persistence of HCMV. Examples of these functions include incorporation of the viral G protein–coupled receptor (GPCR), US28, which modifies the cellular responses to HCMV infection.[47,395]

GENOME STRUCTURE AND ORGANIZATION

Genome Organization

The HCMV genome is one of the largest and most complex of any characterized herpesvirus. Initial DNA sequence analysis and conventional annotation of the 236 kb strain AD169 genome, together with follow-up investigation[142,161] established the presence of 40 conserved core protein-coding genes common to all subfamilies of mammalian herpesviruses along with a larger subset (~70) conserved across the β-herpesviruses with some of these encoding late transcription machinery that is also preserved in γ-herpesviruses (Supplementary e-Table 12.1 and Figs. 12.2 and 12.3). Taxonomy of herpesviruses is based on common virion structure together with the level of conservation of predicted protein coding genes.[148,149] β-herpesviruses are the most diverse herpesvirus subfamily such that even primate relatives show remarkable differences in genetic content. Despite this, HCMV and nonhuman primate β-herpesviruses exhibit a colinear genome organization where genes encoding different HCMV temporal classes of protein-coding and noncoding RNAs are interspersed as with other herpesvirus subfamilies. In addition, betaherpesviruses have characteristic gene families that are not observed in either alphaherpesviruses or gammaherpesviruses.

TABLE 12.1 Clinical and laboratory findings in infants with symptomatic congenital HCMV infections[a]

Clinical Findings	Frequency
Hepatosplenomegaly	17%
Petechiae	55%
Jaundice	40%
Microcephaly	35%
Seizures	1%
Intrauterine growth restriction	27%
Laboratory Findings	
Elevated transaminases (liver)	55%
Decreased platelets	38%
Elevated bilirubin (direct)	46%
Cranial imaging abnormalities	71%

[a]Finding in 78 infants with symptomatic congenital HCMV infection identified by screening enrollment in natural history study

of cCMV infections.[162]

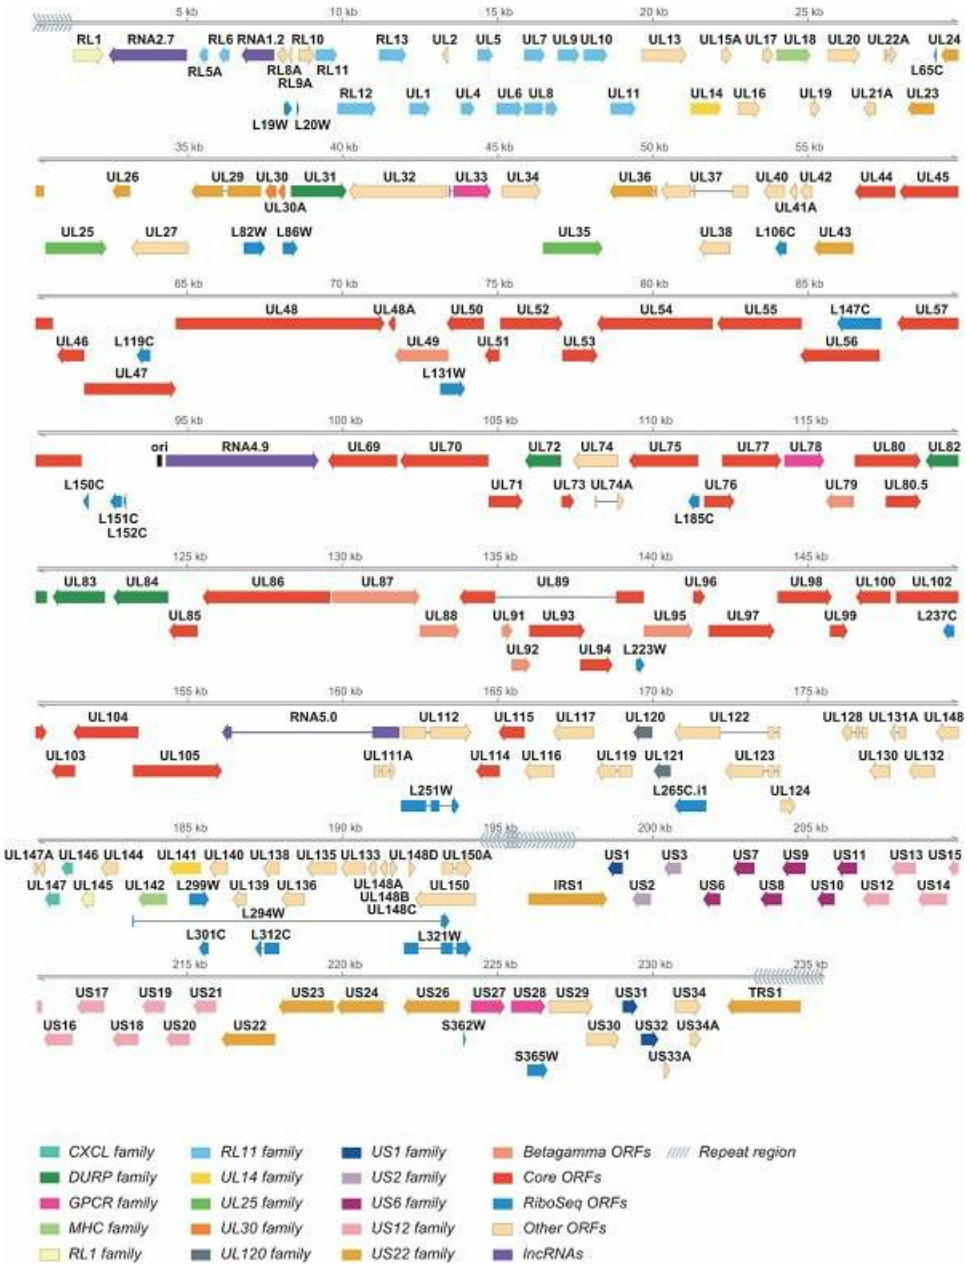

FIGURE 12.3 Genome schematic. Genome map of HCMV based on low-passage strain Merlin. The inverted repeats (RL, IRS, and TRS) are shown by the arrow fletching bordering the unique regions (U_L and U_S). Protein-coding ORFs (previously annotated or validated from ribosome profiling) and lncRNAs are indicated by colored arrows grouped according to the key shown at the foot, with gene nomenclature. Introns connecting protein-coding regions or exons in noncoding RNA5.0 are shown as a line. The colors of ORFs indicate conservation among members of the family *Herpesviridae* (core ORFs) or the subfamilies *β-herpesvirinae* and *δ-herpesvirinae* (betagamma ORFs), with subsets of the remaining noncore ORFs grouped into gene

families. UL72 is both a core ORF and a member of the DURP gene family. (Courtesy of Noam Stern-Ginossar and Yaara Finkel, Weizmann Institute, Israel.)

The genomes of HCMV and closely related chimpanzee CMV share high identity,[150] and both retain a class E genome arrangement with unique long (U_L) and unique short (U_S) regions flanked by terminal and internal repeats in an arrangement first described for HSV-1 (*ab*-U_L-*b'a'c'*-U_S-*ca*), shown in Figure 12.2 and summarized.[147,148] This arrangement of terminal and internal inverted *a* sequences, which contain the genome cleavage/packaging signals, promotes intramolecular recombination (genome inversion) during replication such that virus stocks are composed of four equimolar and independently infectious isomers with regard to the orientation of the short (S) and long (L) genome components. As with HSV1, genome inversion is dispensable for replication in cell culture[551] although likely provides some fitness advantage. The *c'* and *c* repeats (also called IRS and TRS) flanking the S genome component have a partially duplicated IE gene set (IRS1 and TRS1). In contrast, the large *b* and *b'* repeats (also called TRL and IRL) flanking the L genome component in viral strains that underwent extensive propagation are absent low-passage strains.[149] The RhCMV and cynomolgus monkey CMV genomes show a simpler structure with direct terminal repeats without internal repeats or genome isomerization. Directly repeated *a* sequences of variable length and copy number are found at genome termini and include two herpesvirus-conserved DNA cleavage and encapsidation (packaging) signals, called *pac1* and *pac2* near the cleavage site that dictate the position of the genome termini.[656] These elements are recognized by the machinery that is conserved in herpesviruses to cleave and feed the DNA into a capsid as well as to cut a second time once a genome length is packaged, leaving single overhanging 3′-nucleotides.

The viral genome origin of DNA synthesis (*ori*Lyt) controls genome replication during productive infection from a location between the divergent *UL57* and *UL69* genes in the middle of the U_L region. This position of *ori*Lyt is conserved in all characterized betaherpesviruses, apparently along with a lncRNA (RNA4.9 in HCMV) that is transcribed from the *ori*Lyt region and localizes to the nuclear replication compartment (RC) where it is required for efficient expression of *UL57* and DNA replication.[611] The *ori*Lyt in CMVs is large (~1,500 bp) and structurally complex, and in HCMV, includes a pyrimidine-rich sequence, reiterated elements, direct and inverted repeat sequences, and transcription factor–binding sites.

Early on, AD169 and Towne strains were selected for research purposes. Both were readily propagated in fibroblasts owing to adaptation through serial passage that had also attenuated virulence and supported testing as live attenuated vaccines. Both were overattenuated, leading to alternative, ongoing live attenuated vaccine strategies.[6,7] Both of these so-called laboratory-adapted strains are available from ATCC as a mixture of variants with varying degrees of gene loss.[59,140,161,225] The substantial gene loss in clonal derivatives of common strains first came to light through comparison to cosmid cloned DNA of strain Toledo,[96] a low-passage strain that exhibited virulence compared to Towne[495] and because Towne-Toledo chimeras were being evaluated as vaccine candidates.[7,605] Toledo carried a larger number of genes than higher passage strains, but its genome carries substantial mutations and alterations compared to clinical isolates,[495] most markedly lacking a functional gH/gL pentamer complex[224,641] that is critical for epithelial and endothelial cell attachment and other clinically relevant activities.[536,600,653,654]

It is now very clear that HCMV rapidly develops a pattern of specific as well as more random mutations that generally subvert restrictions on cell-to-cell spread and/or cell-free release during propagation on susceptible cell substrates, including fibroblasts and epithelial cells, as well as endothelial cells and myeloid cells.[669] Although several low-passage virus strains, such as TB40/E, VR1814 and TR and their respective bacmid cloned derivatives (TB40E-BAC4, FIX-BAC, and TR-BAC) have been employed as more representative of HCMV clinical virus because they support entry and replication in all known susceptible cell types as well as human tissue explants or tissue implants (in mice), these strains represent mixtures of variants with accumulated mutations in a variety of genes and, once converted to a bacmid allows only a single clonal derivative to be the focus of study. Even though HCMV strains are most readily isolated on fibroblasts, propagation on epithelial cells or endothelial cells preserves gH/gL pentamer function, at least for the Merlin strain, for entry and the ability to infect a broader range of cell types in culture than strains propagated on fibroblast.[432]

Most recently, the Merlin strain has been presented as a potential prototype strain for detailed evaluation of HCMV biology.[198,587,669] Genome sequence analysis starting with nonpropagated clinical material provided exemplary information on genome changes that accompany propagation of HCMV strains in cell culture.[145] Such alterations are known to be relevant to other HCMV strains.[336,430_432,460,556,644,669] HCMV in clinical material remains highly cell associated, revealing remarkable levels of instability when propagated in cell culture, indicating strong selective pressure for accumulation of both cell type–common and cell type–specific mutations during passage. Based on evaluation of Merlin[145] and information from other cultured strains, RL13, encoding a virus-encoded IgG Fc receptor, appears to be a very unstable viral gene independent of cell type. In fibroblasts, gH/gL pentamer components (UL128, UL130, and UL131A proteins, also known as the *UL128* locus) show dramatic instability. Merlin strain was harnessed to conditionally express the principal viral genes (RL13 and the UL128 locus) otherwise lost upon passage, allowing studies with a fully competent strain with a full complement of viral genes approximating prototypic HCMV[587]. Resulting observations help address broad concerns about unrecognized chance mutations accumulating in cultured viral stocks.[336,431,432,669] While some strains have been propagated with either intact RL13 or intact UL128 locus, these studies brought to light how RL13 and pentamer function together contribute to restriction of cell-free virus production during infection. It is becoming clear that characteristic cell-to-cell spread possibly proceeds independent of the gH/gL/gO glycoprotein complex,[556] but dependent on long-suspected and recently described gH/gL/gB complexes that predominate on virions.[635] The presence of an apparently intact RL13 in low-passage strains (e.g., TR) where gH/gL pentamer levels are distinctly low, but not absent, suggests that reduced expression may also occur during propagation.[431,556] Thus, strong selective pressure drives genomic modification to overcome restriction and facilitate efficient replication, production of cell-free virus and improved spread from cell to cell. Curiously, this selective pressure to mutate RL13 and UL128 locus may be negated by clinical strain isolation in the presence of pooled human gammaglobulin, presumably owing to the effects of anti-CMV antibodies that themselves limit cell-free spread of this virus in fibroblasts.[460] There are a wide range of additional unstable genes that have been noted but where the mechanism of restriction is less well established. In addition to the variation observed upon propagation in cell culture, recent deep DNA sequence evaluation of HCMV genomes directly in clinical materials has revealed an apparent abundance of variation in natural infections that have been ascribed to error-prone replication, substantial recombination,

and/or mixed infections with multiple strains.[139,518–520,606,607] As this area matures with more incisive methods of analysis, it is likely to have tremendous impact on many aspects of HCMV biology, immunology, therapy, and immune prophylaxis.

Coding Potential and Variation

Remarkable efforts in sequence analysis, comparative genomics, annotation of predicted protein-coding regions and study of both strain variants and additional primate CMVs has since revealed remarkable levels of genome evolution, recombination, and diversity as a variety of HCMV strains have been dissected.[84] HCMV genome annotation continues to be provisional with canonical protein-coding regions shorter than about 80 codons, use of unusual translation initiation codons and overlap with larger ORFs not included without substantial verification of their biological significance. The refinement of HCMV annotation has included many methods, including comparisons to HCMV that have not been propagated, as well as comparison to chimpanzee CMV. In addition, alternative bioinformatic algorithms and relating protein composition continues to be applied to the challenge of estimating coding capacity. Initial genome annotation methods gave a reasonable estimate of 170 protein-coding genes that formed a foundation for purposes of functional dissection of genome organization. Except for a few outliers, the order of ORFs has been depicted as RL1-to-RL13-UL1-to-150-IRS1-US1-to-US34-TRS1 (Table 12.1 and Figs. 12.2 and 12.3). Emphasis has therefore been on a uniform nomenclature where genes are numbered in sequential order and the gene product is either identified by the same name or includes a prefix. In addition to these genes, HCMV encodes four lncRNAs, two short embedded oriLyt RNAs and as many as 26 miRNA genes.[482] Recent transcript mapping,[198] ribosomal profiling,[265,595,597] mass spectrometry,[443,660] and further characterization of abundantly expressed lncRNAs[595] have revealed a growing complexity associated with HCMV genome annotation and functional organization. HCMV benefitted from being selected for evaluation in the first application of ribosomal profiling to a mammalian system.[597] Ribosomal profiling identified many previously unidentified ORFs, internal ORFs lying within known ORFs, ORFs in alternative reading frames, upstream ORFs, and ORFs encoded antisense to canonical ORFs.[597] Strikingly, these studies also identified a number of polypeptides initiating at noncononical codons and eight novel ORFs within the β2.7 RNA that has been designated as a lncRNA; two of these proteins were identified in infected fibroblasts and are recognized by CD4+ and CD8+ T cells.[265,597] When transcribed lncRNAs, miRNAs and mRNAs are considered,[265,482,597] HCMV may encode as many as 800 gene products, a complexity that is supported by remarkable parallels in roseolaviruses HHV6A and HHV6B.[183]

Accurately estimating the true functional organization of the HCMV genome has been compromised by shortcomings in annotation methods that have overlooked the existence of multi-cistronic transcripts, as well as small, multiple and overlapping ORFs that employ translation initiation codons other than canonical AUG. RNA polymerase II initiation of viral transcription is promiscuous with transcriptional start sites clustering within a 20-basepair interval,[468,597] indicating that HCMV may have regions to initiate transcription, rather than precise transcriptional start sites.[468] The over 7,000 transcriptional start sites detected during lytic replication are in vast excess of the number of ORFs that have been predicted. Alternative transcriptional starts generate overlapping or nested ORFs that produce multiple variants of a protein.[94,501,502,586] Well characterized examples in HCMV include *UL44* and *UL136*, which

each give rise to overlapping transcripts with unique 5′ ends and co-terminal 3′ ends. Alternative *UL44* transcripts arise from a noncanonical TATA element.[271] At least five nested UL136 proteins with distinct localization and roles in replication are synthesized from alternative transcriptional starts.[93,94] *UL93-UL99* is also well appreciated to be a complex transcriptional unit encoding several polycistronic transcripts and overlapping 3′ coterminal transcripts that encode the UL99/pp28 protein. Some of alternative transcription start sites may result in alternative 5′ untranslated regions for differential regulation of translation, affecting ribosome initiation and progression.[418] As an example, the 5′ UTR of major immediate early transcripts is inhibitory to translation in transient reporter assays, but critical for IE protein accumulation in the context of infection, suggesting the existence of important translation regulatory sequences in the UTR.[25]

HCMV-encoded genes (~70) that contribute to productive replication in cultured fibroblasts are more likely to have more accurate functional assignments than viral genes that modulate the cellular or organismal immune environment, particularly when the species specificity of HCMV is factored in. The challenges to investigators seeking biological function of viral gene products that modulate infected cells or the host response to infection is to choose an appropriate strain variant and cell type that maximizes the expectation that accurate insights will emerge. This issue remains daunting as, for example, the *UL36*-encoded viral inhibitor of caspase-8 activation (vICA), originally characterized as a suppressor of extrinsic cell death, is commonly mutated in laboratory strain variants,[572] including a single amino acid substitution (C131R) that ablates cell death suppression. This unnoticed mutation is carried by widely studied variants of strain AD169 distributed by the ATCC (AD169*var*ATCC), as well as clonal derivatives (e.g., AD169-BAC or BADwt) used for experimental mutagenesis[691] and vaccine development.[194] This loss-of-function mutation is found in by other AD169 variants (e.g., AD169*var*UC and AD169*var*UK) as well as other viral strains (e.g., Towne*var*RIT); however, gene function has been preserved in other variants (e.g., AD169*var*DE and Towne*var*ATCC) in use around the world.[60,161,572] This diversity allowed initial characterization of mutant phenotype in monocyte lineage cells.[405] Such a pattern implied vICA function, though not obvious, was deleterious in fibroblasts dependent on additional factors as virus was passaged. Any phenotypic evaluation of *UL36*-mutant viruses requires a *UL36* competent strain for comparison.[163,405,572] The consequences of inapparent mutations is broad as a great many single gene mutants, including many implicated in cell death, have been studies in an UL36-deficient parental background without acknowledging the potential impact of caspase-8 activity, one of the most aggressive signaling systems present in all mammalian cells[419] but one that is normally completely suppressed by vICA during infection.[572] This issue has also impacted characterization of nonhuman primate CMVs. The *UL36* homolog is nonfunctional in RhCMV strain 68-1 and fails to suppress apoptosis unless repaired.[406] Unexpectedly, this defect does not undermine the ability of RhCMV 68-1 to replicate in fetal macaques.[102] Somewhat mysteriously, the repair of UL36 function had no impact on replication or vaccine vector efficacy in macaques but unveiled a significant contribution of this cell death suppressor to replication and immunogenicity in adult cynomolgus monkeys.[81] These examples illustrate the substantial challenges to fully account for underlying inapparent or unnoticed mutations that are likely to accumulate with cell culture passage of CMV variants chosen for study.

The analysis of HCMV gene function has generally followed one of two strategies. Viral genes may yield insights into biological activity when studied in isolation, when mutated in the

virus or through a combination of both. This applies to studies in cultured cells, organoid cultures or human tissue–implanted mice because humans are the only available host for HCMV. A wider variety of viral gene products have been studied in isolation than have been studied in the context of viral infection, particularly in the context of engineered fully competent strains of virus,[336,431,432,587] leaving opportunities to investigate viral gene products that modulate the host response to infection. Some viral genes have revealed aspects of their function through specific phenotypes affecting replication, cell function, immune parameters, and latency. Directed or random mutagenesis of viral genomes has yielded phenotypes that help define biological function. The virus strain, host cell type, precision of the mutagenesis, and approaches for evaluation may all impact the physiological relevance of the data that are generated by these approaches. The genome complexity of HCMV, together with the range of settings where this virus interfaces with host cell and host defense pathways for replication, persistence, pathogenesis, and latency provides opportunities for investigation and discovery.

STAGES OF REPLICATION

CMV is a slow replicating virus that produces low viral yields in comparison to other viruses (10- to 100-fold less compared to HSV-1). While CMV infects and replicates in a wide variety of cells in the host organism, the replicative cycle has largely been studied in fibroblasts. Fibroblasts, a stromal cell present in all tissues, has been the model of choice because of their relative ease of isolation from a variety of discarded tissues and ready propagation in culture, as well as their capacity to support viral gene expression and progeny virus production. Figure 12.4 summarizes the replicative cycle and compares it to the latent state.

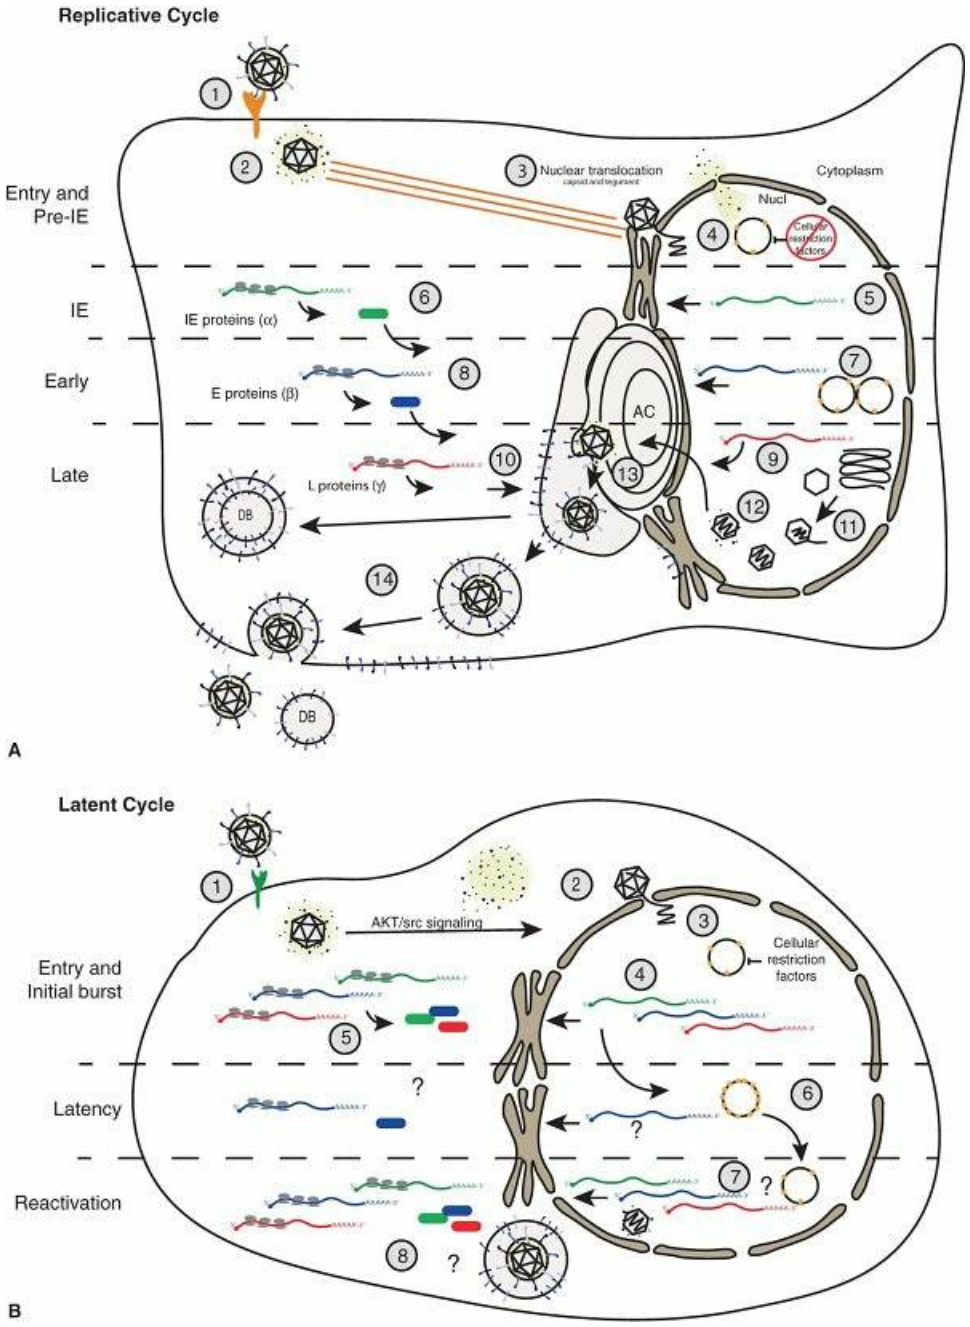

FIGURE 12.4 Overview of infection: replicative and latent states. A: The HCMV replicative cycle has been most thoroughly characterized in primary human fibroblasts. (*1*) HCMV attaches to the cell surface and binds cellular receptors to trigger (*2*) entry by endocytosis or fusion at the plasma membrane (detailed in Fig. 12.5). (*3*) The virion has been proposed to translocate along microtubules to the nuclear pore and following docking, extrudes the viral genome into the nucleus. (*4*) The genome is circularized and chromatinized by cellular histones. Viral tegument proteins (*yellow stipples*) are also translocated to the nucleus where they function to block cellular restrictions to viral gene expression and replication, including genome silencing. (*5*) Immediate early gene expression (*green*) begins and does not require,

although maybe enhanced by, other viral factors, such as tegument proteins. (*6*) IE proteins are synthesized in the cytoplasm and then transported back into the nucleus where they stimulate early gene expression. (*7–8*) Early transcripts (*blue*) will be synthesized and translated and the early proteins stimulate viral genome synthesis. (*9*) Following the onset of viral DNA synthesis, late transcripts accumulate (*red*), and late proteins are synthesized. (10) Late structural proteins will be transported into the nucleus for assembly of capsids (detailed in Figs. 12.9 and 12.10). (*11*) Concatemeric genomes will be resolved and encapsidated. (*12*) Nucleocapsids receive the first layer of tegument and then egress by budding through the nuclear envelope, where they become enveloped and then de-enveloped. (*13*) Capsids will be further tegumented and enveloped within the viral assembly compartment (detailed in Figs. 12.12 and 12.13). (*14*) Mature virus particles and dense bodies (vesicles of viral tegument protein) egress via exocytic mechanisms that remain poorly characterized. **B: Latency** is studied in primary and cell line hematopoietic progenitor and myeloid lineage systems. (*1*) The virus enters through pentamer–cellular receptor interactions and endocytosis. (*2*) The capsid is translocated to the nucleus with delayed kinetics relative to fibroblasts and tegument proteins are retained in the cytoplasm. (*3*) The genome is extruded into the nucleus where it is circularized. (*4*) Broad, low-level viral gene expression from across the genome is detected and (*5*) viral proteins are synthesized. (*6*) The viral genome is further silenced, as indicated by limited viral gene expression (e.g., IE and *UL135* among others). Some genes such as *UL138* and Luna remain detectable by assays for RNA or protein expression. It is not known how the genome is maintained in latently infected cells, but viral proteins and miRNAs have been shown to be important for latency, maintenance of the genome and reactivation. (*7*) Cellular triggers such as differentiation or inflammation will trigger reexpression of viral genes and reactivation of replication. (*8*) The cascade of events from reexpression of genes to egress of virions following reactivation are poorly characterized.

Attachment and Entry

Entry occurs in seven distinct steps (1): viral glycoprotein attachment to heparan sulfate glycosaminoglycans, (2) viral glycoprotein-mediated binding to specific cell surface receptors, (3) entry via (3a) endocytosis/micropinocytosis or (3b) gB-mediated fusion at the plasma membrane, (4) release of the capsid into the cytoplasm following fusion with the (4a) endosomal membrane or (3b) the plasma membrane, (5) microtubule (MT)-mediated transport of the capsid towards the nucleus, (6) likely docking at the nuclear pore, and (7) extrusion of the viral genome through the portal and into the nucleus (Fig. 12.5).

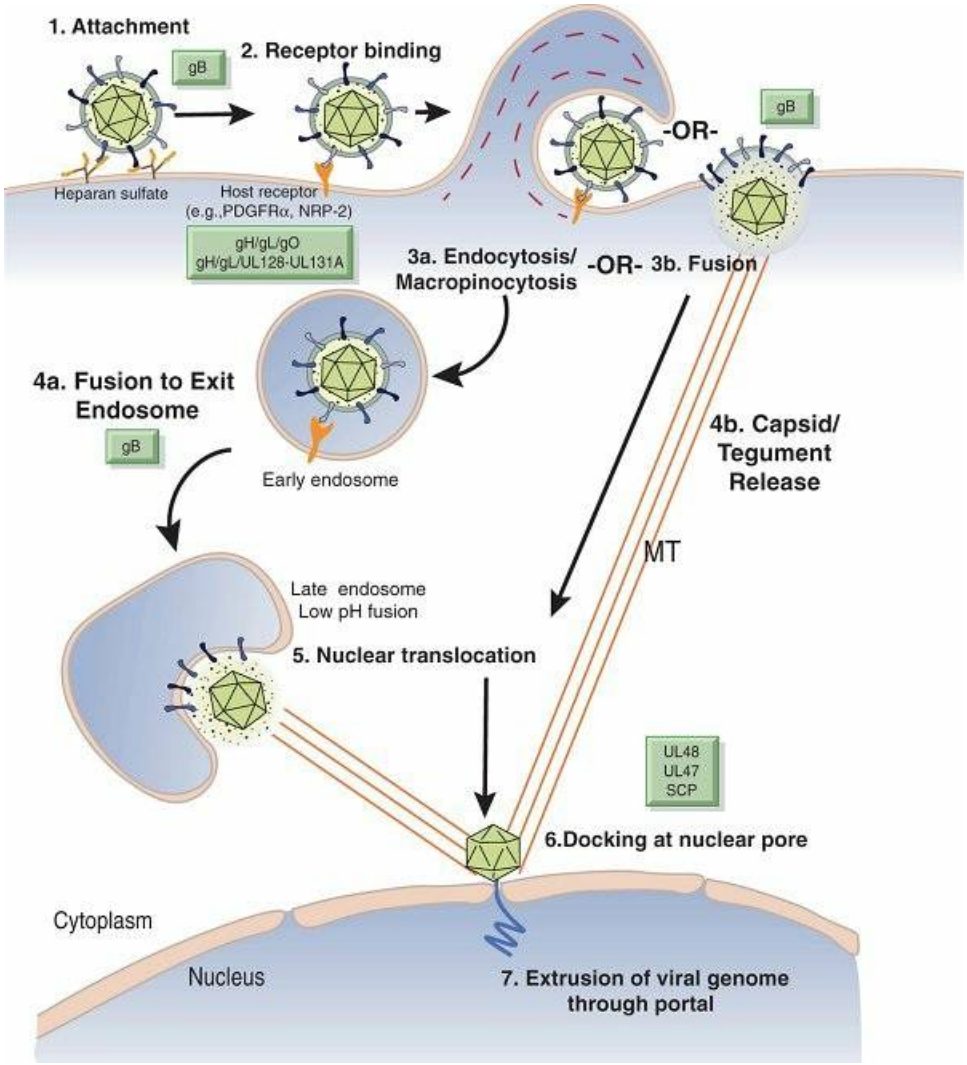

FIGURE 12.5 HCMV entry and translocation to the nucleus. (*1*) HCMV attaches to cells through an interaction of gB with heparan sulfate. (*2*) CMV trimer (gH/gL/gO) and pentamer (gH/gL/UL128/UL130/UL131A) will engage receptors on the cell surface, including PDGFRα and NRP-2, respectively. (*3a*) HCMV will enter the cells by endocytosis/macropinocytosis or (*3b*) through direct fusion with the plasma membrane. (*4a*) The endocytosed capsid and tegument (stippled) enters the cytoplasm by gB-mediated fusion of between the viral envelope and the endocytic membrane, possibly requiring low pH for gB-mediated fusion or (*4b*) tegument and capsid are released into the cytoplasm following fusion at the plasma membrane. (*5*) The capsid is translocated by microtubules to the nuclear membrane. (*6*) The capsid interacts with the nuclear pore. (*7*) The genome is translocated into the nucleus where it will associate with ND10. The UL47 and UL48 tegument proteins and SCP facilitate this process. Viral transcription and genome synthesis will begin at ND10s, forming viral replication compartments (detailed in Fig. 12.9). (Adapted from David Johnson, Oregon Health and Science University, Portland, Oregon.)

As in all herpesviruses, virion envelope glycoproteins are essential for virus attachment and

entry and are also important targets of the host humoral immune response.[116,682] A number of different glycoprotein complexes support attachment and entry into different cells types, underlying, in part, the broad tropism of HCMV for many cell types.[440,550] Initial contact with cells is mediated by gB and the gM/gN complex binding to heparan sulfate glycosaminoglycans, as is common to many herpesviruses. Heparan sulfate proteoglycans are diverse in structure and expressed on the surface of all cells. gB is synthesized as a 160-kDa precursor that is cleaved by furin in the Golgi body to produce 116-kDa and 55-kDa fragments that remain disulfide linked, and both full-length and cleaved forms are present on infected cells.[67] Soluble gB binds cells with or without heparan sulfate and high concentration of soluble gB blocks HCMV entry. gM/gN is the most abundant glycoprotein complex on virions,[324,640] although with the exception of heparan sulfate binding, a role for this glycoprotein complex during entry has not been observed.[386]

Critical to HCMV entry is the specific binding between cell surface receptors and gH/gL complexes on the virus particle (Fig. 12.6). gH/gL on the virion surface forms complexes with either gO to form the "trimer" or UL128-UL131 to form the "pentamer" entry complexes.[5,115,224,653,654] There is little evidence for the presence of free gH/gL complexes on the virion.[703] gO functions to incorporate gH/gL into the virion envelope[671] and the gH/gL/gO trimer and the gH/gL/UL128-UL131 pentamer form mutually exclusive complexes for entry mediated by disulfide bonds between gL Cys^{144} and gO Cys^{351} or UL128 Cys^{162}, respectively.[101,115] The trimer is required for entry into all cell types but is not required for cell-to-cell spread.[671] A approximately 2.8 Å cryo-EM structure of the trimer reveals that gH, gL, and gO interact in a linear orientation to assemble into a boot-like structure.[329] gH/gL has been recently shown to form a complex with gB, although a role for this complex in entry has not been defined.[635] Given the evidence that gH/gL complexes with only a small proportion of gB and only in the pre-fusion conformation, gH/gL may stabilize the pre-fusion conformation of gB until receptor binding triggers fusion.[567]

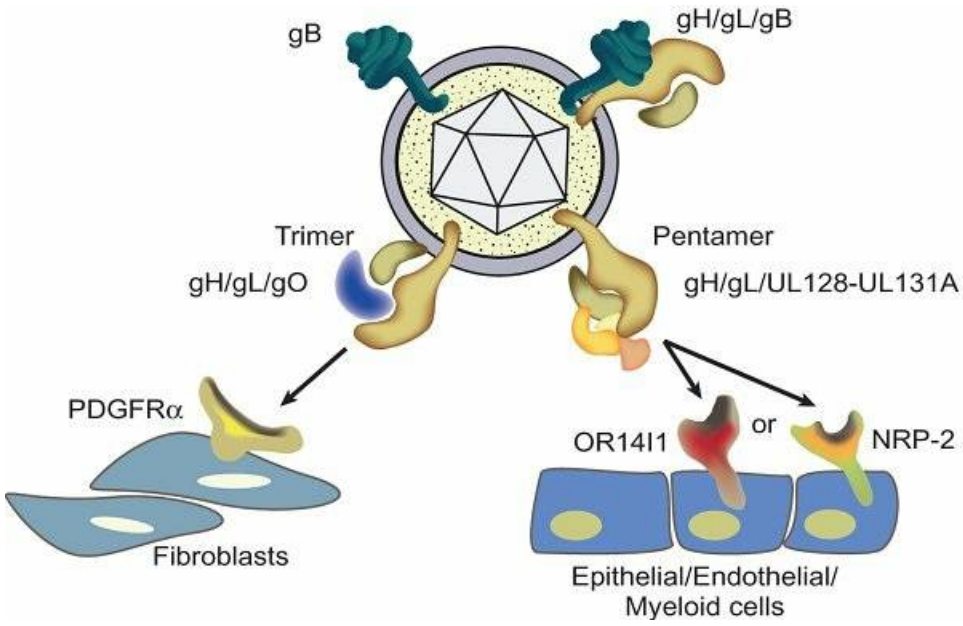

FIGURE 12.6 HCMV glycoproteins and cellular receptors/coreceptors. Glycoprotein B (gB) mediates the initial attachment to cells by binding heparan sulfate. gH and gL form a number of additional complexes that interact with specific receptors to mediate entry into a variety of cell types. gH/gL/gO forms the trimer to mediate entry into fibroblasts through its interaction with PDGFRα. Additional unknown trimer receptors likely exist for entry into epithelial and endothelial cells. gH/gL/UL128/UL130/UL131A forms the pentamer to mediate entry into epithelial, endothelial and hematopoietic cells and interacts with neuropilin-2 (NRP-2) or the OR14I1 coreceptor to mediate entry. Both the trimer and the pentamer likely bind other cellular coreceptors or mediators for entry, perhaps depending on the cell type. A complex gH/gL/gB has recently been discovered, but its role in entry has not been defined. [Courtesy of David Johnson, Oregon Health and Science University, Portland, Oregon.]

The gH/gL pentamer contributes to HCMV tropism for epithelial, endothelial, and hematopoietic cells, but is dispensable for entry into fibroblasts.[536,600,653,654] The *UL128-UL131* locus is unstable during passage in fibroblasts and accumulates mutations that restricts viral tropism for endothelial, epithelial, and myeloid cells,[224,431,432,536,654] largely explaining the reticence of these cells to infection by laboratory-adapted virus strains. Additionally, the loss of any one of the these components (UL128, UL130, and UL131A) results in failure to assemble pentamer and compromises replication in epithelial and endothelial cells.[523,535,537,653] 3.0 and 5.9 Å X-ray crystal structures of the pentamer bound to neutralizing antibodies demonstrate that gL forms a three-helix bundle and beta hairpin that acts as a docking site for UL128/UL130/UL131A.[101] Beyond its importance to tropism, the pentamer increases the cell association of progeny virus and facilitates cell-to-cell spread.[5] Recent evidence indicates that entry into fibroblasts is mediated via trimer–host receptor interaction and occurs through a rapid form of clathrin-independent, pH-independent macropinocytosis.[243,638] However, entry into epithelial cells, requires the pentamer in addition to the trimer and entry occurs through an abnormal macropinocytosis followed by low pH-dependent fusion at the endosome.[638,654]

The majority of BAC clones of low-passage HCMV strains (the exception being the Merlin strain[703]) express high levels of gH/gL/gO trimer and lower levels of gH/gL/pUL128-UL131A pentamer. The *UL148* gene, encoded within the UL*b*' region typically absent in fibroblast-adapted strains, increases levels of trimer complexes on virions, while not affecting levels of pentamer.[353] UL148 protein dampens ER-associated degradation (ERAD) of gO, possibly through an interaction with SEL1L or other elements of the ER quality control machinery.[441,447] US16 interacts with and facilitates incorporation of pentamer into the virion by unknown mechanisms and its deletion results in a defect in entry into epithelial and endothelial cells.[379]

The ability of the various glycoprotein complexes formed on the HCMV virion to engage with multiple host surface receptors and coreceptors underlies the broad cellular tropism of HCMV. The criteria for establishing a cellular protein as a receptor for CMV entry relies on (a) defining an interaction between the receptor and a virion protein, (b) the ability of antibodies or peptides that interfere with the interaction to block infection, and (c) correlating cellular permissivity to infection with receptor expression. Cellular receptors, coreceptors, or mediators for HCMV entry include platelet-derived growth factors alpha (PDGFRα),[287,399,581,591,679,681]

transforming growth factor beta receptor 3 (TGFβR3),[329,398] epidermal growth factor receptor (EGFR),[657,658] integrins,[180,181,657] paxillin,[448] neuropilin-2,[399] and OR14I1.[683] PDGFRα was identified as the cellular receptor for the gH/gL/gO trimer, interacting with gO, to directly mediate entry into fibroblasts,[287,581,591,681] but not epithelial and endothelial cells.[287,591,638] While the ectodomain of PDGFRα is required, its signaling activity is dispensable for entry and spread in fibroblast cultures.[679,681] Indeed, trimer engagement with PDGFRa competes directly with PDGF binding and interferes with PDGFRα signaling.[329] Neuropilin-2 (NRP-2) was identified as a receptor for the HCMV pentamer using a high-throughput avidity-based extracellular interaction screen to define interactions between single pass transmembrane proteins and trimer or pentamer.[399] NRP-2 binds soluble pentamer and silencing of NRP-2 or soluble NRP-2 reduces entry into cells. This study identified a number of other candidates, including TGFβR3, which interacts with the trimer independently of PDGFRα.[329] A CRISPR/cas9 screen identified the multi-pass membrane-associated, olfactory receptor, OR14I1, as a receptor for the pentamer (in addition to NRP-2 and a coreceptor, CD147). OR14I1 and its induction of AC/PK/AKT signaling is required for endocytic entry into epithelial cells; silencing OR14I1 or synthetic N-terminal peptides of OR14I1 reduces entry[683]; however, interaction with the pentameric complex has not been observed.

While strong structural data support PDGFRα/TGFβR3 and NRP-2 as bona fide cellular receptors required for HCMV entry, many other cellular proteins function as coreceptors or mediators of entry. Mediators of HCMV entry promote or enhance entry by a variety of mechanisms, including the clustering or processing of other proteins important to attachment or entry. EGFR facilitates entry,[657,658] and EGFR signaling is important to entry and virus trafficking to the nucleus,[98,303,657] but its role as a receptor remains controversial.[268,638] There is yet no evidence for an interaction between EGFR and HCMV glycoprotein complexes, and no direct interaction with the pentamer has been detected.[287] Integrins α2β, α6β1, and αvβ3 interact with a highly conserved disintegrin domain on gB to mediate entry.[180,181,657] Pentamer-mediated stimulation of EGFR and integrin signaling and their downstream stimulation of paxillin, a regulator of actin rearrangement, is important for entry into monocytes, as well as virus-stimulated motility.[448,449] CD90/Thy-1 interacts with gB and αvβ3 integrins and recruits paxillin, which act as gH-dependent coreceptors.[356,657] CD90/Thy-1 stimulates EGFR and PI3K signaling important for entry, suggesting the EGFR, integrins, paxillin, and CD90/Thy-1 form a signalosome necessary for HCMV entry.[356,657] CD147 is another important mediator of entry that specifically increases pentamer-mediated entry and cell–cell fusion in epithelial and endothelial cells, although soluble CD147 does not block entry and it does not bind pentamer directly.[636] Other factors mediating entry include US16, which mediates efficient viral infection of endothelial and epithelial cells when the pentamer complex is absent.[70] More recently, a novel complex between gH and gpUL116 (gH/UL116) has been reported in the virion that forms independently of gL and does not appear to form a complex with other gH containing complexes (gH/gL/gO; pentamer).[85] From this collective work, it is clear that HCMV enters cells through interactions between viral glycoproteins and constituents of the plasma membrane; however, much remains to be understood about the details of the processes involved in entry.[440,550]

gB functions as a membrane fusogen and is critical for cell-to-cell spread in addition to virus entry.[267,672] gB associates with gH/gL complexes following its synthesis and gH/gL regulates gB-mediated cell–cell fusion.[567,635,637] In the prefusion form, the gB fusion loops are thought to

be tucked close to the viral envelope and out of reach of the target membrane. A 3.6 Å resolution crystal structure of gB in its prefusion form reveals a tripod structure where the fusion loops are sequestered In the prefusion form, the gB fusion loops are sequestered by interactions with internal domains of the protein closer to the viral envelope.[372] Two 3.6 Å resolution crystal structures of the postfusion form of the gB ectodomain establish it as a class III viral fusogen, resembling that of HSV-1 and EBV.[80,100] gB is thought to mediate entry by rapid, low pH–independent fusion of the virus at the plasma membrane, at least in fibroblasts. While gB is reported to interact with cellular receptors such as PDGFRα,[581] EGFR,[658] and integrins,[180,181] it is not clear what role, if any, these interactions play in entry given the fusogenic nature of gB.[672] gB may also mediate low pH–dependent fusion events in the endosome for entry of low-passage strains into epithelial and endothelial cells.[536] Most recently, gB-mediated fusion at the plasma membrane of fibroblasts has been shown to be associated with a single amino acid substitution (D275Y), resulting in a highly fusogenic gB variant in the AD169 laboratory strain and activation of caspase 2 and aberrant mitosis.[613] This finding suggests that highly fusogenic properties of laboratory-adapted virus strains may represent an adaptation that arose during passage in cell culture, although this has yet to be investigated.

Intracellular Trafficking and Genome Release

Tegument proteins are released upon entry into the cytoplasm and traffic to sites where they function in modulating the initial host response to infection and modulate transcription of IE genes[34,61] to either initiate or delay virus gene expression to ensure successful infection. As one well-characterized example, pp71 tegument protein targets the host factors that otherwise silence gene expression from the viral genome, including hDaxx[539] and BclAF1.[349] Exogenously expressed pp71 is used experimentally to enhance the infectivity of and replication from transfected viral genomes.[34] This theme is discussed further in section *Pre-IE events and Intrinsic Responses to Infection*.

Cytoplasmic microtubules facilitate translocation of the capsid to the nucleus where viral DNA is released[457] (Fig. 12.5). While genome uncoating and nuclear translocation are poorly defined in CMV infection, the capsid is thought to release viral DNA at the nuclear pore by extrusion of the genome through the same portal composed of UL104 proteins that was employed for packaging.[158] Although few viral proteins have been defined as required for this process, UL47 and UL48 tegument proteins are required for steps following entry at the plasma membrane but preceding IE gene expression.[38] The deubiquitinase activity of UL48 (cleaves K11, K48, and K63 linkages) is autocatalytic regulating its own stability and is important for virion stability such that disruption of *UL48* reduces levels of intracellular genomes following infection.[301,309,655] While the HCMV genome traffics to the nucleus and expresses IE proteins within 30 minutes in infected fibroblasts, the process of nuclear translocation is delayed in hematopoietic cells (≥4 hours in CD34+ progenitor cells and ≥3 days in CD14+ monocytes). In these settings of delayed expression, a distinct early endosome to trans-Golgi network route requires pentamer-induced integrin-Src signaling.[303,304] Upon entry into the nucleus, the linear genome is predicted to circularize by mechanisms that are yet to be investigated for any herpesvirus.

Replicative Program

During a replicative infection *in vitro*, viral genes are expressed in a temporal cascade of three phases: immediate-early, early, and late genes. These phases of gene expression have been classically defined through the use of metabolic inhibitors. Immediate early RNAs can be detected new protein synthesis is inhibited (e.g., cycloheximide) because their expression does not require *de novo* synthesis of viral proteins, whereas all early and late viral gene expression is restricted under such conditions due to the requirement for IE proteins to control activation. Further, late gene expression is blocked by inhibitors of viral DNA synthesis (e.g., phosphonoacetate or phosphonoformate) whereas early gene expression is unaffected. A fourth class of genes includes early-late genes, which accumulate to low levels in the early phase and more robustly at late times, and are partially reduced by inhibitors of viral DNA synthesis. Global analysis of viral protein accumulation indicates greater complexity in the accumulation of viral proteins, with five distinct temporal protein clusters.[660] This analysis reveals HCMV proteins that accumulate with delayed early kinetics (beginning at 24 hpi and peaking at 48 to 72 hpi) and that are either sustained or reduced at later times (72 to 96 hpi), indicating greater complexity in the regulation of viral gene expression than previously characterized.

Pre-IE Events and Intrinsic Responses to Infection

Upon delivery of the viral genome to the nucleus, viral genomes reside at the periphery of the nucleus and colocalize with RNA polymerase II transcription factors, TATA-binding protein, and transcription factor IIB.[270] The viral genome localizes to promyelocytic leukemia (PML) nuclear domains (ND10 or PML bodies), which sequester growth promoting or pathogen restricting factors. ND10-associated proteins serve to cooperatively repress viral transcription[203] and contribute to the silencing of viral gene expression for latency.[143,648] Yet, ND10s serve as sites where nuclear viral RCs initiate.[12,13] Therefore, viruses, including HCMV, target ND10-associated restriction factors, as well as others not associated with ND10, for dispersion or destruction to promote viral gene expression.[616] Host factors restrictive to IE gene expression and the replicative cycle include histone deacetylase 1 (HDAC1),[43] Daxx,[539,540,676] ATRX,[380] IFI16,[136] SPOC1,[514] and SAMHD1.[82,151,302] Tegument protein pp71 (encoded by *UL82*) is a virion transactivator that traffics to the nucleus where it targets the host transcriptional repressor Daxx for proteasomal degradation[89,136,248,539,540,676] and redistributes ATRX,[380] leading to the activation of IE genes. *UL82*-mutant viruses are growth defective at low multiplicities of infection, and this defect is overcome by Daxx knockdown.[61] The importance of pp71 in preventing silencing of viral gene expression is further reflected in that overexpression of *UL82* enhances infectivity of HCMV genomes.[34] In addition to targeting Daxx, pp71 promotes HCMV replication by enhancing transcription from cellular promoters alone or in cooperation with cellular transcription factors.[104,251,366] Another tegument protein, pp65 (encoded by *UL83*) interacts with and targets IFI16 to the major immediate early promoter (MIEP), where it drives IE2 gene expression and limits interferon (IFN) responses.[136] The UL97 serine/threonine-specific kinase is delivered to infected cells as part of the tegument and is expressed *de novo* at approximately 5 hpi.[633] It functions to support replication and maturation and is the kinase that activates ganciclovir.[364] Unique phosphorylation of HDAC1 by UL97 decreases its association with Daxx and the HCMV MIEP sequences to maintain the chromatin around the MIEP in an active conformation for MIE gene expression.[43] Infection with UV-inactivated HCMV, which enters but cannot express viral genes, retains the ability to stimulate SAMHD1 phosphorylation,

indicating a role for either UL97 in the viral tegument or a host kinase.[82,302] The UL97 HCMV kinase, as well as other conserved β- and γ-herpesvirus kinases, phosphorylate and inactivate SAMHD1 in primary human fibroblasts and macrophages to unarm this host defense,[82,155,302,698] although cyclin dependent kinase 2 (CDK2) also regulates the phosphorylation of SAMHD1 in HCMV infection.[151] SAMHD1 also is targeted for proteasomal degradation during HCMV infection by a mechanism dependent on Cullin-RING-E3 ligases.[82,262] While some studies have shown an NFκB-dependent, dNTPase-independent SAMHD1-mediated down-regulation of MIE gene expression that may contribute to the establishment of quiescence,[302] other studies find no effects on MIE gene expression[151] and others have shown effects on late gene expression.[262] Taken together, tegument proteins function, at least in part, to reduce cellular restrictions, priming the cell for replication, effectively kickstarting viral gene expression and the productive replication cycle. As viral gene expression begins, the IE proteins, IE1-86 kDa and IE2-72 kDa proteins, both localize to ND10s and IE1 disrupts ND10 by stimulating proteasome-independent loss of SUMOylated PML.[11,317,685] Other CMV proteins that contribute to ND10 remodeling include US25, UL29/UL30, UL69, UL76, UL98, and TLR9.[543]

HCMV-mediated alteration of cell cycle progression is also important for initiation of productive replication. pp71 and UL69 drives cells infected in G0 or G1 to the G1/S boundary and pp71 blocks their further progression into S phase by targeting the retinoblastoma growth suppressor (pRb) for degradation.[160,291] The UL97 kinase also acts as a viral cyclin-dependent kinase and phosphorylates and inactivates pRb, thereby inducing E2F transactivation.[258] IE2-86 kDa restricts progression into S phase.[668] When HCMV infects cells in S phase, initiation of the replication cycle is delayed until the cell enters G1/G0[187] whereas infection in mitosis results in mitotic catastrophe and an abortive infection.[242,661] A chromatin-tethering domain in a minor variant of IE1, IE1-19 kDa, tethers viral genomes to chromatin either directly or indirectly and is important for maintaining genomes during mitosis when cells are infected during S phase.[384]

The pp150 tegument protein is a substrate of cyclin A2/CDK and its phosphorylation in cyclin A2 expressing cells restricts IE gene expression, representing a mechanism by which the virus has evolved to control the timing of its gene expression.[49] Viral gene expression will initiate as cyclin A2 is degraded when cells enter G1. Much remains to be understood about how tegument proteins and their host interactions control the initial events of infection to impact the commitment to productive replication or alternatively, the establishment of latency.

The HCMV genome associates with host histones upon its translocation to the nucleus. Chromatinization occurs in a nonrandom and predictable manner based on intrinsic DNA sequence, but as infection progresses, nucleosome occupancy drops precipitously in a manner dependent on IE1 gene function.[697] One mechanism by which the IE1-72 kDa protein facilitates virus replication is by antagonizing deacetylation of histones associated with the viral genome and histone deacetylase inhibitors rescue IE-mutant virus replication defects.[439] IE1 was shown to interact with HDAC3, presumably to inhibit its activity.

Regulation of Major Immediate Early Gene Expression

Immediate early genes are expressed in the first few hours of infection, and although they may be enhanced by other viral factors, IE gene expression does not require them. IE gene expression arises from five loci across the HCMV genome: *UL123* (IE1) and *UL122* (IE2), *UL36* and *UL37*,

TRS1/IRS1, and *US3*. The MIEP is located between *UL124* and *UL128* and drives the expression of *UL123* and *UL122*. The MIEP is a complex promoter, consisting of an enhancer (−520 to −65 nucleotides, nt), a unique region (−780 to −610 nt), and a modulator (−1,145 to −750 nt) in addition to the core promoter (−65 to +3 nt) (Fig. 12.7). While the promoter is sufficient for transcription of IE genes, the enhancer element increases the rate of transcription. The modulator has context dependent roles, repressive to MIEP activity in undifferentiated cells, but actively drives the MIEP in permissive fibroblasts. The MIEP is initially activated by host transcription factors and gives rise to a common RNA precursor that is alternatively spliced,[125,366,592] which encodes two major phosphoproteins known as IE1-72 kDa and IE2-86 kDa and several minor proteins (Fig. 12.8). IE1-72 kDa is encoded by exons 1 to 4, and IE2-86 kDa is produced by an exon skipping event and is encoded by exons 1 to 3 and 5. Preferential splicing results in early accumulation of IE1, which switches at later times to favor IE2.[362,456,546] The host cyclin A2 and ubiquitin-dependent segregase VCP/p97 differentially regulates alternative splicing of IE2.[362,456] Other splice variants including portions of exon 4 (IE1) or exon 5 (IE2) identified include: IE1-9 kDa, IE1-17.5 kDa, IE1-19 kDa, IE2-18 kDa, and IE2-55 kDa.[30,564,592] The MIEP is negatively regulated by the 14-basepair palindromic cis repression site at −13 to −1 relative to the MIEP transcriptional start site.[110] The strength of the MIEP in driving gene expression is best demonstrated by its broad use in driving transgene expression in viral and plasmid vectors.

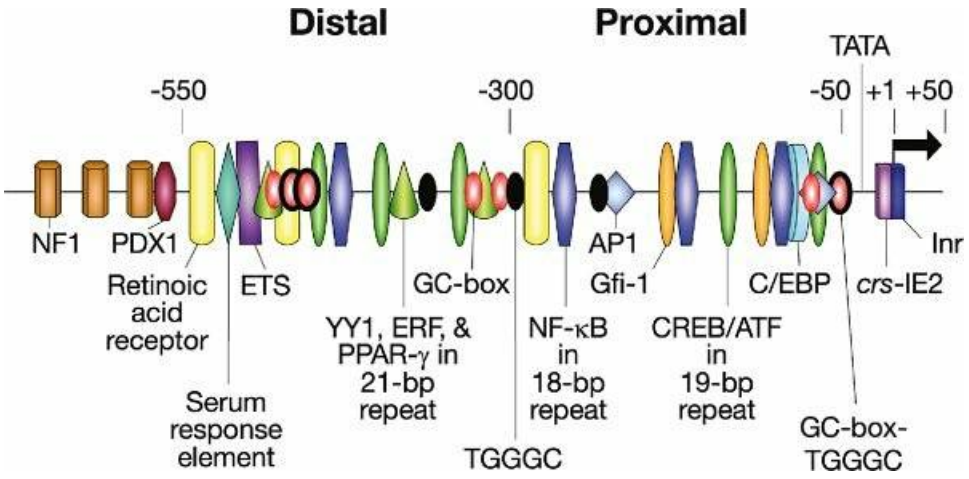

FIGURE 12.7 The major immediate early promoter. The major immediate early promoter (MIEP) consists of the core promoter (−65 to +3 nt), enhancer (−520 to −65 nt), unique region (−780 to −610 nt), and modulator (−1,145 to −750). The schematic diagrams the distal and proximal promoter/enhancer and the relative locations of binging sites for both activating and repressing transcription factors. (Courtesy of Jeffery Meier, University of Iowa, Iowa City, Iowa.)

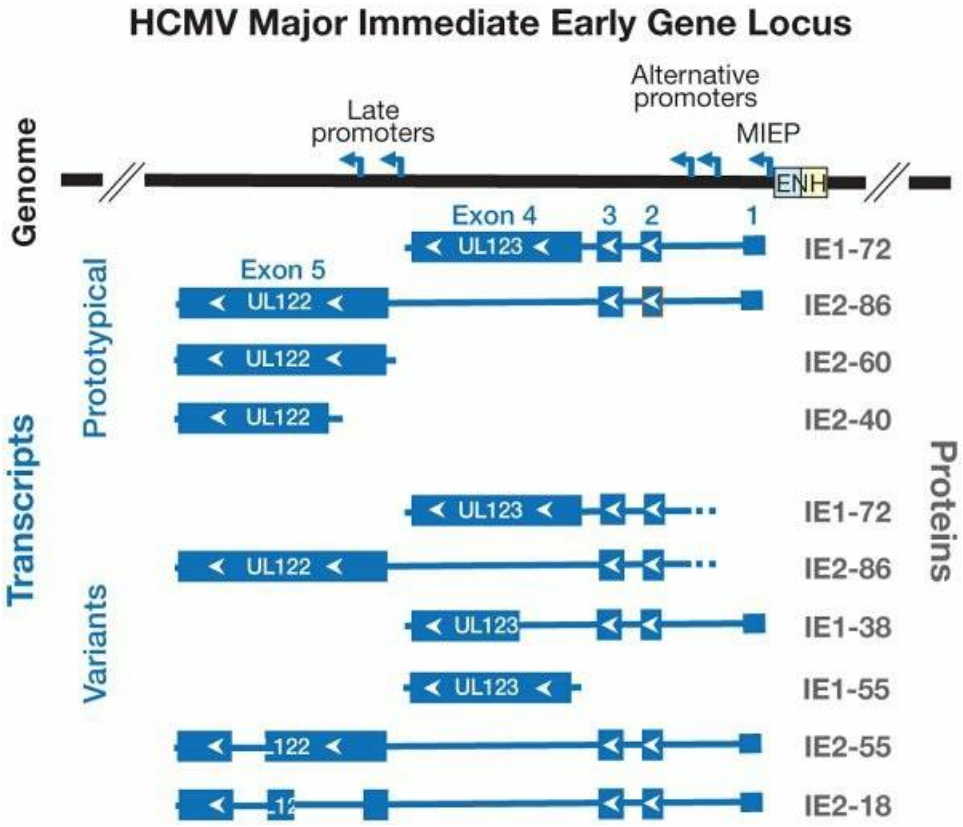

FIGURE 12.8 Transcripts and proteins originating from the major immediate early transcription unit. The major immediate transcription unit gives rise to ten distinct transcripts through alternative splicing and alternative transcription initiation site usage. The primary transactivators for virus replication and most well studied are the IE1-72 kDa and IE2-86 kDa proteins. Roles for other IE gene products have yet to be fully defined. (Courtesy of Jeffery Meier, University of Iowa, Iowa City, Iowa.)

The MIEP-enhancer regulatory region is composed of a dense assembly of transcription factor binding sites (Fig. 12.7), indicative of its complex landscape of regulation. The regulatory region extends beyond the region required to regulate IE gene expression, suggesting an additional role in persistence or latency. MIEP-driven transcription is strongly regulated by host factors that bind to the modulator (e.g., ETS-1 repressive factor, ERF, and YY1), unique (e.g., nuclear factor 1), and enhancer regions (e.g., NFκB/rel, CREB/ATF, Sp-1, retinoic acid, AP1, serum response factor (SRF)/Elk, and γ-IFN activating sequence (GAS) as reviewed.[125] The enhancer region also contains sequences for binding repressive YY1 and methylated DNA-binding protein (MDBP). Further, SPOC1 (also known as PHF13) is a regulator of chromatin structure induced by infection that binds to the MIEP, that recruits heterochromatin promoting factors, such as KAP1 and histone 3 lysine 9 methyltransferases to suppress expression and replication.[514] The MIEP is also regulated by viral proteins, including TRS1, UL83, pp71, IE1-72 kDa, and IE2-86 kDa.[61,89]

At late times in infection (coincident with or following viral genome synthesis), IE2-86 kDA along with intermediate and late IE2 gene products bind to a cis repression site (crs) within the

MIEP and represses its activity through a self-cooperative transcriptional negative-feedback loop.[110,365,387,483,618] While this autoregulation does not prevent basal transcription factors from binding the MIEP, RNA polymerase II recruitment to the MIEP is reduced. Repression of the MIEP at late times is also mediated by recruitment of deacetylases and methyltransferases that silence the promoter.[348,507] Following DNA synthesis and cis-repression of the MIEP, transcripts driven from alternative promoters within intron A of the MIE locus accumulate to support a second phase of IE1-72 kDa and IE2-86 kDa protein synthesis.[26,129] Transcripts initiating from these intronic promoters differ in their 5′ untranslated region but support the synthesis of full length IE1-72 kDa and IE2-86 kDa proteins because exon 1 of the MIE locus is noncoding. CTCF binding within intron A of the MIE locus negatively regulates MIE gene expression.[398] The 5′ UTR of MIE transcripts have been shown to be a critical determinant of IE protein accumulation and may allow for context-dependent regulation of IE protein translation.[25]

Immediate Early Proteins

IE1-72 kDa activates transcription and regulates intrinsic and innate responses to infection. IE1-72 kDa is required for replication at lower multiplicities of infection and its role as a transcriptional activator was first appreciated through its ability to stimulate its own promoter, through its association with host transcription factors, and its sequestration of histone deacetylases.[127,439] IE1-72 kDa also indirectly affects gene expression as IE1-72 kDa stimulates expression of LUNA latency antigen not through direct interaction with the LUNA promoter, but rather through blocking Daxx-mediated suppression of LUNA.[509] Further, IE1-72 kDa binds condensed chromatin through a chromatin tethering domain and interacts with histones H2A and H2B,[175] inhibiting the deposition of histones onto the viral genome,[439,697] although this role is dispensable during replication in fibroblasts. Related to its ability to maintain active chromatin, IE1-72 kDa disrupts ND10s to antagonize intrinsic antiviral defenses and genome silencing.[10,346,670] PML-mediated sumoylation of IE1-72 kDa[522,585] functions to sustain accumulation of IE2-86 kDa to promote viral gene expression and replication.[438,639] While IE1 does not stimulate the turnover of PML like HSV-1 ICP0, it inhibits the sumoylation of PML to inhibit a type I IFN response, and induces the ubiquitination of Sp100, another ND10 component.[308,371] In addition to SP100, the ubiquitination of HES1, a neural progenitor cell regulator of Notch signaling, is stimulated by IE1-72 kDa.[371] The acidic domain of IE1 is required to down-regulate the IFN response to viral infection.[320,475] While IE1 does not disrupt the transcription of IFN, it associates with STAT1 and 2 transcription factors to inhibit the IFN-stimulated gene factor 3 complex (ISGF3: STAT1, STAT2, and IRF9) from binding DNA and inducing a JAK/STAT-mediated IFN response.[256,320] IE1-72 kDa also binds to and traps STAT3 in the nucleus and represses IL6-induced/STAT3-responsive gene expression, which rewires IL6 signaling to downstream proinflammatory IFNγ-like signaling (repressing STAT3 and activating STAT1) and tempers HCMV replication.[239,313,516]

IE2-86 kDa is a potent transcription factor that stimulates activation of viral and host promoters. IE2-86 kDa regulates viral gene expression and productive infection.[163,393,690] In addition to its role in directly transactivating the MIEP, the IE2-86 kDa protein interacts with p300/CBP associated factor (P/CAF),[72] HDAC1, and some methyltransferase,[507] suggesting a mechanism by which HCMV differentially regulates acetylation of histone tails associated with the MIEP depending on the timing in infection. Further, IE2 may indirectly facilitate E2F-

mediated activation of the MIEP through its interaction with and inhibition of the retinoblastoma protein (pRB).[223] By contrast to its role as a transactivator, IE2-86 kDa represses the transcription and induces the degradation of immature interleukin 1β (IL-1β) following activation of the AIM2 inflammasome.[56] Importantly, at later points in infection, homomultimers (6 to 8 monomers) of IE2-86 kDa bind to the cis-repression element in the MIEP to repress its own expression, and this negative feedback contributes to localization of incoming viral genomes to ND10s, transcriptional strength, and viral fitness.[199,618] During early and late phases of infection, IE2 p60 and p40 variants are expressed and repress IE gene expression.[30]

The complexity of MIE locus structure and transcription through the MIE region is just one example of the complexity of transcription across the genome that includes differential transcriptional starts, exon skipping, alternative splicing, and differential polyadenylation. Despite decades of intense work on the MIEP and MIE gene products, more remains to be learned about how IE proteins impact early gene expression and the role of IE1 and IE2 protein variants and context-dependent regulation of transcription and translation.

US3, *UL36-38*, and *TRS1/IRS1*, expressed with IE kinetics, are critical for viral gene expression and regulate key host responses to infection. Similar to IE2, *US3* expression is regulated by *crs* upstream of its transcriptional start.[99,339] US3 postranslationally impedes the trafficking and peptide loading of MHCI to evade cytotoxic T-cell activation.[14,285,469] While CMV encodes a number of related proteins to disrupt MHC–peptide presentation, *US3* is the first expressed. UL37 exon 1 (UL37x1, also known as vMIA) potently inhibits mitochondrial-mediated cell death by sequestering Bax and Bak in the outer mitochondrial membrane to prevent cytochrome *c* release.[204] *UL36* is a *US22* family member and also inhibits cell death by blocking caspase 8 activation initially observed in macrophages.[405] IRS1 and TRS1 are highly homologous *US22* family members with identical amino termini and unique carboxy termini that share 50% identity. Both TRS1 and IRS1 inhibit the IFN-based induction of protein kinase R (PKR), and both are required for virus replication.[112,397,405] The proteins encoded by IRS1 and TRS1 both contain RNA binding domains in their amino termini and PKR binding domains in their carboxy termini.[226,227] TRS1 stimulates translation of transcripts, particularly those with HCMV 5′ UTRs, prevents stress granule formation resulting from PKR-mediated phosphorylation of eIF2α.[705] Independent of its role in inhibiting PKR-mediated phosphorylation of eIF2α, TRS1 blocks macroautophagy through an interaction with Beclin1 with the amino terminal end of TRS1.[105] Without the modulation of these host responses during IE times, infection would be terminated.

Early/Delayed Early Genes

Following peak expression of IE genes between 8 and 12 hpi, delayed early or early genes are transcriptionally activated. Most of the 65 early phase proteins and miRNAs (Supplementary e-Tables 12.1 and 12.2) accumulate gradually until the onset of viral DNA synthesis. Early genes have important roles in the regulation of IE and late transcription, the synthesis of viral genomes, encapsidation of viral genomes, the regulation of the cell cycle, and the evasion of adaptive immune responses. Many early proteins, as well as IE proteins, localize to nuclear RCs where viral DNA and RNA accumulates as both are synthesized. Disruption of early genes typically results significant defects DNA synthesis, late gene expression, and virus production.[163,690]

The promoter region of three early genes, *UL112-113*, *UL54* (DNA polymerase), and *UL4* illustrate the complexity of HCMV transcriptional control and provide insight into the dependence of early gene expression on IE gene expression as well as the differential regulation of gene expression by host and viral functions as infection proceeds. *UL112-113* transcripts[666] are detected beginning at 8 hpi and remain constant through late times. The transcripts are differentially spliced to yield four unique proteins (pp34, pp43, pp50, pp84). At late times, the transcriptional start sites are altered but the mRNA splicing pattern and polyadenylation remain the same throughout infection. The UL112-113 pp84 isoform is proposed to interact with and target the UL44 DNA processivity factor to RCs and the oriLyt for viral DNA synthesis.[307,310,470,555] Promoter-proximal ATF/CREB and IE2-86 kDa binding sites are important for sustained transcription of *UL112-113*, but most important during late times of infection.[337,529] The HCMV DNA polymerase, UL54, is also detected by 8 hpi and continues through late times of infection, relying on a single transcriptional start but two polyadenylation sites. Host transcription factors regulated by IE2-86 kDa control expression of *UL54*. *UL4* encodes a minor virion glycoprotein (gp48) that is transcribed early and continues late and is dependent on Elk1 and IE2-86 kDa binding to its promoter and the TATA element is stimulated by MAPK signaling.[107,108] *UL4* expression is regulated at the translational level by a short 22 amino acid upstream ORF, uORF2, within the *UL4* leader sequence[16] that induces ribosome stalling.[41,538,673] Much remains to be understood about the cellular and viral factors controlling early gene activation, transcriptional start site selection and switching, and protein isoforms.

Early gene products regulate viral gene expression broadly. *UL34* is encoded by transcripts with alternate transcriptional start sites that result in two proteins that differ by 21 amino terminal amino acids. The UL34 proteins localize to RCs, bind multiple sites across the HCMV genome, and are required broadly for viral gene expression and viral replication.[503] UL34 represses some genes, including *US3* and *US9* expression, acting on a novel cis repression site.[352,373] UL21A enhances viral genome synthesis and the expression of IE genes in the later phases of infection necessary for maximal virus replication.[179] The UL21A protein interacts with the multiple subunits of the anaphase promoting complex (APC) E3 ubiquitin ligase and with cyclin A2, resulting in its proteasomal degradation.[83,117,170] This may function to relieve the early restrictions imposed on viral gene expression by cyclin A2 in S/G2 cells.[49] Targeting cyclin A2 and APC neutralizes the cyclin A2 restriction to virus replication and halts cell cycle progression in infected cells into or through mitosis. UL21a–cyclin A2 interaction is important for viral genome synthesis and maintaining chromosome stability in infected cells.[170] Further, UL38 and UL28-29 proteins interact with protein complexes containing histone deacetylate 1 (HDAC1) and recruit the nucleosome remodeling and deacetylase complex (NuRD) to maintain derepression of MIE gene expression throughout infection.[417,619] These examples highlight examples of early genes targeting host pathways to ensure viral gene expression and successful viral genome synthesis.

UL97, a serine/threonine kinase, is the only conventional protein kinase encoded by HCMV. Defining a kinase and its physiologically relevant substrates requires demonstrating that the purified kinase is sufficient to phosphorylate the substrate *in vitro* on specific residues and that the phosphorylation matters by mutation of phosphorylation sites or phenotype due to loss of the kinase. It is important at all stages of viral gene expression and replication and, as such, is a major target for antiviral drug development. Depending on the state of the cells, mutational or pharmacological inactivation of the kinase results in a minimal or as much as a tenfold reduction

in viral genome accumulation and an approximately 10- to 1,000-fold reduction in virus progeny yield, with defects beginning prior to viral genome synthesis and extending through late phase virion maturation.[46,326,498,515,675] The loss of UL97 results in a more severe replication defect during infection with low-passage strains that contain the ULb' region of the genome, and specifically *UL135*, compared to laboratory-adapted strains.[354,652] UL97 has a number of cellular substrates including histone deacetylate 1 (HDAC1), the retinoblastoma tumor suppressor (pRb), elongation factor delta, and lamin A/C.[43,229,258,296,414,497] Tegument-derived UL97-mediated phosphorylation of HDAC1 is important to maintain the MIEP in a de-repressed state for optimal IE gene expression.[43] UL97 phosphorylation of viral proteins inhibits the aggregation of PML nuclear bodies.[326,333,493,497,625] UL97 is a functional orthologue of human cyclin dependent kinases (CDKs) with overlapping contributions to infection.[242] Like CDK1, UL97 phosphorylation and inactivation of growth suppressor, pRB, and the related proteins, p107 and p130, activates E2F-responsive genes to stimulate the cell cycle. However, unlike CDK1, UL97 is not susceptible to p21 inhibition.[258,273] The role of UL97 in activating E2F transcription of cellular genes, late viral genes, and in viral genome synthesis can be complemented by the human papilloma virus E7 oncoprotein,[293] indicating conservation in the importance of modulating these host pathways for DNA virus infection. UL97 promotes KAT5/Tip60 histone acetyltransferase (HAT) phosphorylation to increase expression, while UL27 inhibits KAT5/Tip60 HAT to decrease expression of CDKs.[517] This dual pronged regulation indicates to importance of regulating CDK activity during infection. Further, the putative processivity factor, UL44, is heavily phosphorylated by UL97 and cellular kinases (candidates include CDK1 and CK2).[327] The role of UL97 phosphorylation of UL44 is not clear, but phosphorylation by host kinases near its nuclear localization signal is critical for viral DNA synthesis and replication.[568] Finally, UL97 phosphorylation of the nuclear lamina component, lamin A/C, promotes disassembly of the nuclear lamina and thus nuclear egress of newly formed capsids. How this happens is a subject of debate where one group finds the viral nuclear egress complex (NEC) recruits UL97 for this purpose and that dominant negative laminA/C can complement the loss of UL97,[561,562] while another group reports that lamin-associated protein p32 recruits UL97.[229] UL97 is also important for formation of the cytoplasmic viral assembly compartment and infectious virus particle maturation.[31]

HCMV encodes polyadenylated long RNAs, RNA2.7, RNA1.2, RNA4.9, and RNA5.0 (number indicating length in kilobases) transcripts that are expressed early and dominate the HCMV transcriptome, but have poorly ascribed functions. While these have been thought to be noncoding, RNA2.7, RNA1.2, and RNA4.9 are detected on polyribosomes, protein products from these RNAs have been confirmed and are proteins are recognized as antigens in humans based on CD4 and CD8 responses.[265,597] The β2.7 RNA stabilizes mitochondrial membrane potential through its interaction with mitochondrial enzyme complex 1 to prevent apoptosis.[512] The 4.9-kb RNA localizes to nuclear RCs, forming an RNA–DNA hybrid at the origin of lytic replication (*oriLyt*). RNA4.9 transcription or the RNA–DNA hybrid formation stimulate viral genome synthesis, perhaps by stimulating *oriLyt* unwinding.[611] RNA4.9 has also been shown to interact with the viral genome and the polycomb repressive complex 2 (PRC2),[533] and may regulate gene expression for latency.

DNA Synthesis

HCMV DNA synthesis occurs in the nucleus of infected fibroblasts, starting at 14 to 16 hours post infection *in vitro*. Upon delivery to the nucleus, the linear double-stranded genome circularizes and localizes to PML bodies or ND10s by unknown mechanisms.[12,13] These sites constitute prereplication foci where viral transcription and genome synthesis are initiated to form RCs. The formation of RCs depends on polarization of the inner nuclear membrane SUN1 proteins to reorganize actin filaments to spatially segregate viral DNA from inactive histones and host DNA.[500] As discussed further below, the compartmentalization and the concentration of viral and cellular DNA synthesis, transcription, and RNA processing factors at RCs are important for efficient *de novo* synthesis of viral genomes.

Initiation of HCMV genome replication occurs from a complex, bidirectional *oriLyt* encompassing at least 1,500 bp between *UL57* and *UL69* genes, an origin of replication considerably larger and more complex than other beta-herpesviruses and other herpesviruses.[466] In contrast to α- and β-herpesvirus genomes, HCMV contains only one *oriLyt* since deletion of minimal or complete *oriLyt* sequences abolishes virus replication.[55] The *oriLyt* can be divided into essential region I containing a bidirectional UL84-IE2-86 kDa-responsive promoter and a pyridine-rich Y block and essential region II containing a RNA-DNA hybrid (R loop) formed via G-C rich DNA. When R loops interact with UL84, IE2 and/or UL112-113 gene products, initiation of DNA replication proceeds.[122,290,305] UL34 protein binds to the *oriLyt* to facilitate replication protentially through interactions with IE2-86 kDa, UL44, and UL84.[574]

The core replication fork is composed of six proteins conserved among herpesviruses, the DNA polymerase (UL54), the DNA processivity factor (UL44), a single stranded DNA binding protein (UL57), and the heterotrimeric helicase–primase complex (UL105, UL102, UL70) (Fig. 12.9). Additional proteins, including UL36-38, IRS1/TRS1, and IE1/2, UL84, and UL112-113 regulate *oriLyt* activity.[467,549] CMV lacks an origin-binding protein with enzymatic activity such as found in α-herpesviruses or in γ-herpevirsues (latent origin), and likely initiates productive DAN replication in a manner similar to gammaherpesvirus oriLyt. UL84 is expressed early and multimers of the UL84 protein binds IE2-86 kDa protein through leucine zipper motifs.[123] The UL84-IE2 interaction is only important for *oriLyt*-dependent DNA replication in certain viral strains[123] and antagonizes IE2 transactivating activity, but not *crs* functions.[199] However, UL84 is not essential in all HCMV strains, and differences in IE2 or other viral functions compensate and function in its place.[583] The UL112-113 gene expresses four phosphoproteins p34, p43, p50, and p84, which are all expressed early and accumulate at nuclear RCs. While p34 and p50 are dispensable for replication, p43 and p84 isoforms are required for replication[555] and the interaction between p84 and UL54 and UL44 proteins is specifically required for genome replication.[307] UL114 interacts with UL54–UL44 complex and is important for maintaining genome integrity, excising uracil that is misincorporated into the genome or that results from spontaneous deamination of cytosine,[494] and it is important for late phase amplification of viral genomes.[132]

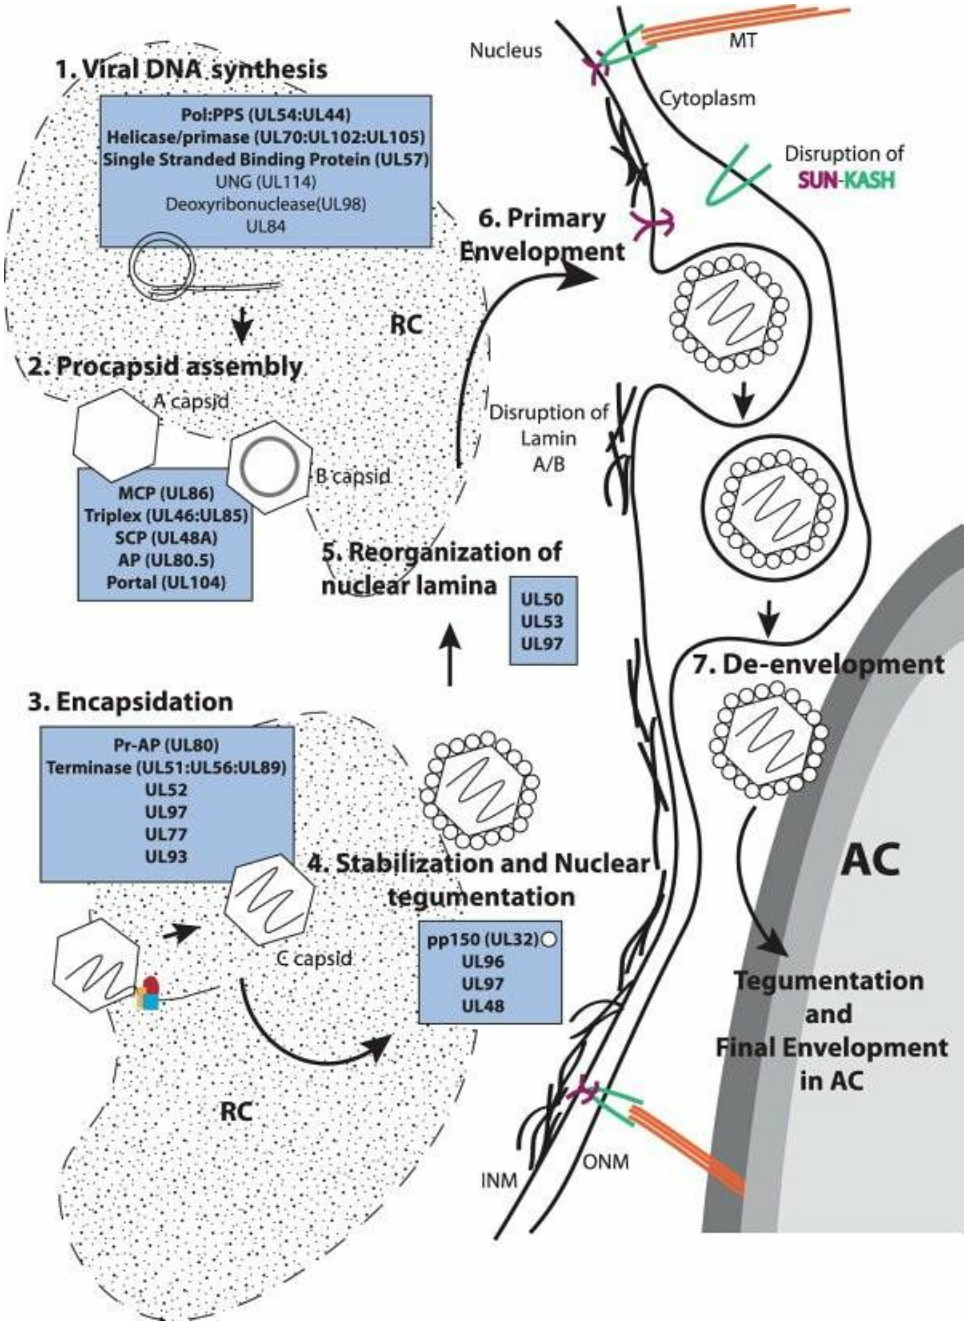

FIGURE 12.9 Schematic of viral genome replication to nucleocapsid nuclear egress. (*1*) The 230-kb ds-DNA genome is synthesized in viral replication compartments (RC, *stippled areas*) by a rolling circle mechanism. Six proteins make up the core replication machinery, including the DNA polymerase (Pol, UL54), the putative DNA processivity factor (PPS, UL44), the helicase/primase complex (UL70, UL102, UL105), and the single stranded DNA-binding protein (UL57). Other proteins important to genome synthesis includes the uracil–DNA deglycosylase (UNG, UL114), the deoxyribonuclease (UL98), and pUL84 (function unknown). (*2*) Procapsid assembly requires the MCP, the Triplex, SCP (UL48A), pAP (UL80.5), and the portal protein (UL104). From these proteins, A and B type capsids are formed. (*3*)

Encapsidation of genome length viral DNA results in the formation of C type capsids and requires the maturational protease (Pr-AP), the terminase complex (UL51, UL56, and UL89) and UL52 (supports the terminase, required for concatemer cleavage). Other proteins important to encapsidation include UL97 (viral protein kinase) and UL77 and UL93 (links capsid triplex and terminase). (*4*) Nucleocapsids acquire pp150 tegument in the nucleus, which functions to stabilize the nucleocapsid with UL96 and UL48 (*5*) The nuclear egress complex composed of UL50 and UL53 proteins, which recruit the UL97 viral kinase to activate UL50 and UL53 and phosphorylate lamin A/B for breakdown. (*6*) Capsids egress out of the nucleus by budding through the inner nuclear membrane (INM) into the perinuclear space and then (*7*) de-envelop and enter the cytoplasm through fusion with the outer nuclear membrane (ONM). Egress of nucleocapsids into the perinuclear space requires the dissociation of SUN and KASH proteins, which tether the INM and ONM to the cytoskeleton/microtubules (MT). Once in the cytoplasm, virion maturation will continue through the viral assembly compartment (detailed in Fig. 12.12).

A growing list of host transcription factors, DNA damage factors, and other regulators are known to be relocalized to viral RCs during virus replication to regulate genome synthesis and gene expression. The C-EBPα transcription factor localizes to RCs through its interaction with UL84.[289] The nucleolar host protein nucleolin associates with UL44, and this interaction is required for the localization of UL84 and UL44 within nuclear RCs.[39,599] Some DNA damage factors, including γH2AX and ATM, are recruited to RCs where they may contribute to replication.[381,684] The altered localization of p53 and DNA damage response factors may facilitate replication, recombination or repair of viral genomes at the expense of the host genome.[188,454,684] While much remains to be understood about the presence of these host factors in RCs, virus replication is compromised in ataxia telangiectasia-mutated (ATM) protein kinase–deficient cells due to the failure to up-regulate γH2AX-mediated stabilization of the MRE11–RAD50–NSB1 (MRN) complex.[684]

Components of the ubiquitin proteasome systems assemble into domains at the periphery of HCMV RCs and ongoing proteasome activity is required for viral gene expression, particularly in early and late phases of infection.[188] Further, UL35 associates with the ubiquitin-specific protease (USP) 7 and components of the Cullin 4A (DCAF1, DDB1, and DDA1) E3 ubiquitin ligase complex, localizing these proteins to nuclear foci.[542] Together, with tegument-derived pp71 (UL82), UL35 directs the degradation of BclAF1, which restricts HCMV gene expression and replication. UL35 also induces γH2AX and p53 binding protein 1 (53BP1) foci, suggesting activation of a DNA damage response, and activates a G2 cell cycle checkpoint.[542] UL76 recruits and concentrates the polyubiquitinated protein receptor S5a by binding its von Willebrand factory type A domain and K48- and K63-linked polyubiquitinated proteins in nuclear foci juxtaposed with RCs, which is important for the formation of the RCs and the ubiquitin proteasomal factor aggresome.[361] Together these findings indicate the importance of host processes in viral genome synthesis and RNA processing that have yet to be fully understood.

UL44 stably associates with the C-terminus of the viral DNA polymerase UL54 and stimulates its activity in a DNA-dependent, sequence-independent manner, similar to the role of cellular processivity factor PCNA or the processivity factors encoded by other

herpesviruses.[22,376,377] UL44 forms a C clamp–shaped dimer that binds DNA and is important for *oriLyt*-dependent replication, which represents a mechanism distinct from both the trimeric PCNA ring and the monomeric HSV UL42 processivity factor.[23,314,570] UL44 is phosphorylated by UL97, CDK1/cyclin B, CK1, and CK2 to generate a number of phosphorylated isoforms.[17,18,568] Substitution of UL97-phosphorylation sites on UL44, remarkably, does not reduce the efficiency of viral DNA synthesis in fibroblasts. C-terminal sequences containing a nuclear localization signal and CK2 phosphorylation sites are critical for UL44 interaction with importin α/β and nuclear import of UL44.[17] Intriguingly, a role for UL44 in suppressing IRF3 and NF-κB transcription suggests links between DNA replication and repair and the innate immune response.[195]

Herpesvirus DNA synthesis is thought to start as a theta form before switching to rolling circle. The mode of HCMV genome replication is largely inferred because the structure is consistent with head-to-tail concatemeric genomes thought to be produced by rolling circle during HSV replication. Genomes will accumulate to several thousand genome copies per cell by the time progeny is released from fibroblasts.[466,626] In epithelial and astrocytoma cells, replication is more subdued and viral genome levels do not exceed 1,000 copies per cell. In cells supporting high levels of replication, the accumulation of viral genomes may ultimately result in several compartments coalescing to a single compartment that fills the nucleus.[598,599]

Late Genes

Late gene expression is maximal after the onset of viral DNA replication, and this class of genes is largely comprised of genes with structural roles in virion assembly and maturation. For example, all capsid proteins are encoded by late genes, and their expression is inhibited if viral DNA synthesis is blocked. By contrast, while many tegument proteins are encoded by genes expressed with late kinetics, about half of the tegument-encoding genes are expressed with immediate-early, early, or early-late kinetics, suggesting nonstructural roles.[660] Expression of early-late or leaky late subsets of late genes are those that are expressed prior to the onset or without requirement for the onset of viral DNA synthesis, but that may not achieve maximal expression until after the onset of viral DNA synthesis. Late genes are controlled by simple promoters defined by regions surrounding the TATA or TATT motif, although some have multiple transcriptional start sites. Late mRNAs conserved among β- and γ-herpesviruses are spliced and arise from symmetric transcription from both DNA strands.[198]

HCMV encodes six viral transcription factors, *UL49*, *UL79*, *UL87* (viral TATA-binding protein, preferring TATT), *UL91*, *UL92*, and *UL95*, that are essential for late phase expression of *UL44* and other true late genes.[272,458,459,480] For example, transcription of true late genes requires UL92 function, which is conserved with γ-herpesviruses, but strikingly different from that of α-herpesviruses.[459] UL79 interacts with host RNA polymerase II, UL87, and UL95, as well as components of the DNA replication complex and stimulates RNA pol II processivity and prevents stalling on the viral genomes.[479] Further, IE2 strengthens the expression of 16 early-late or late genes, including *UL83* and *UL146*, by increasing RNA polymerase II initiation of transcription independent of TATT sequences or the late viral transcription factors.[355]

The late viral transcription factors also stimulate expression of separate promoters controlling IE2-60 kDa and IE2-40 kDa at late times in infection. IE2-40 kDa synergizes with

IE2-86 kDa in transactivation of early and late promoters, and both recognize the cis repression signal (crs) of the MIEP.[548,665] The roles of MIE variants (Fig. 12.8) in contexts beyond productive infection in fibroblasts have been less thoroughly investigated.

Capsid Assembly, DNA Encapsidation, and Nuclear Egress

The process of capsid formation, encapsidation of DNA and virus maturation is conserved across herpesviruses.[202] As an overview, three HCMV capsid forms accumulate in the nucleus, denoted as A, B, and C capsids (Figs. 12.9 and 12.11). A-type capsids lack scaffold and viral DNA. B-type capsids contain the scaffold of UL80 proteins but lack viral DNA. Both A and B capsids are thought to be terminal structures, although B capsids may be enveloped as NIEPs. C capsids have both scaffold and DNA and represent true nucleocapsids assumed to be in the process of maturing. The capsid is composed of MCP, MnCP/TRI1, MnCBP/TRI2, SCP, and the portal protein. Proteins of the capsid are organized into 162 capsomers (150 hexamers plus 12 pentamers) and 320 triplexes located between capsomers (discussed in detail, see Virion Structure). Capsomers are composed of six copies of the MCP per hexon and five copies of the MnCP per penton. Hexons and pentons associate in the cytoplasm before being transported into the nucleus to assemble into capsids (Fig. 12.10). One of the 12 pentons in each capsid is composed of entirely of portal protein, which self-assembles into a homododecamer complex for controlling viral DNA encapsidation.[249] SCP is present as 1 molecule attached to the tip of each MCP of the hexon and penton.[144,692]

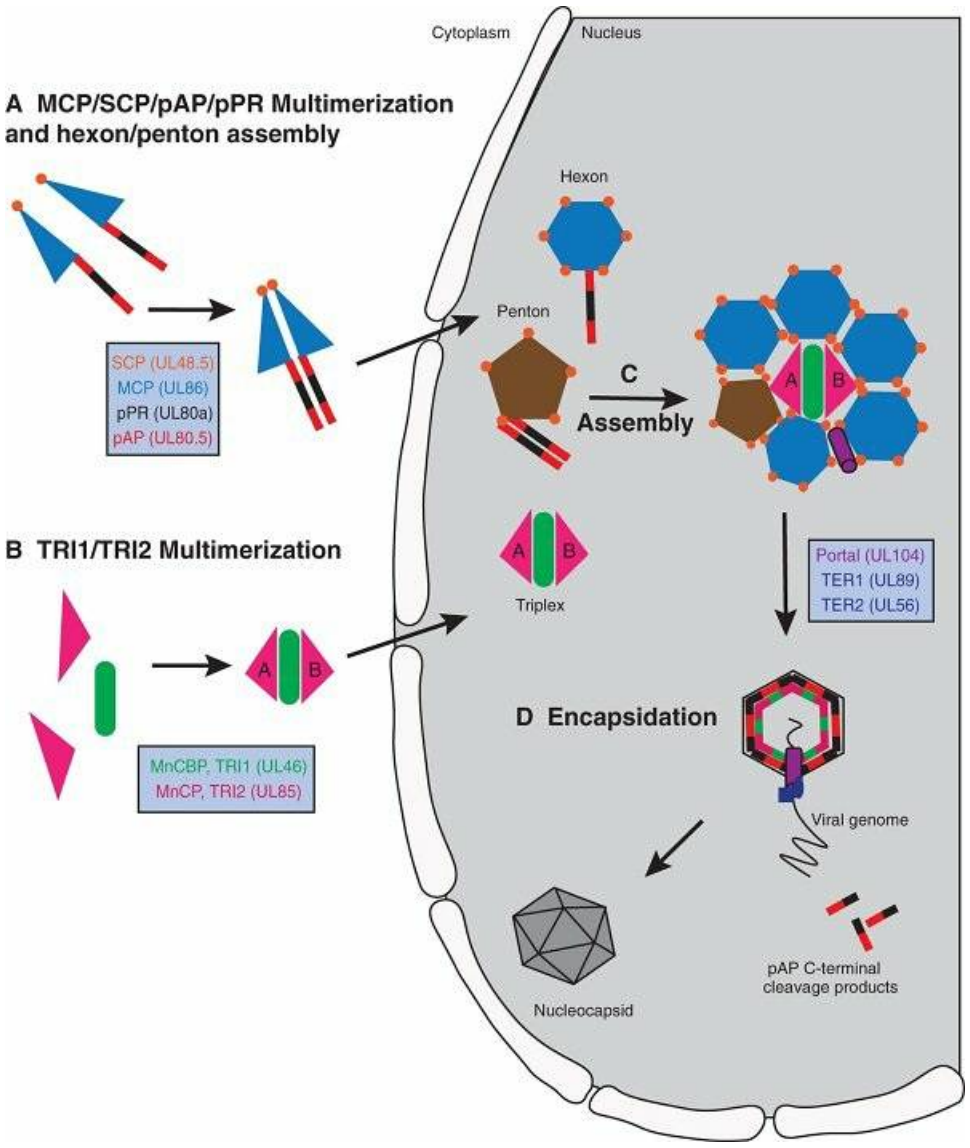

FIGURE 12.10 HCMV nucleocapsid assembly. A: Initial interactions between MCP protein and SCP, the assembly protein pAP and the protease precursor pPR take place in the cytoplasm resulting in the formation of multimers following interactions between conserved domains in the amino and carboxyl domains of pAP and pPR depicted as red boxes. The expression of a nuclear localization signal (NLS) by pAP and pPR permits translocation of MCP-containing multimers into the nucleus. **B:** Similarly, a triplex consisting of two molecules of MnCP/TRI2 and one molecule of MnCBP/TRI1 takes place in the cytoplasm prior to translocation into the nucleus secondary to an NLS present in MnCBP. **C:** Once in the nucleus, multimerization leads to self-assembly of hexons and pentons followed by assembly of the procapsid that also incorporates a dodecamer of the portal protein UL104 in an asymmetric vertex. **D:** Packaging of the concatemeric viral DNA is accompanied by cleavage of the pAP and pPR by the protease activity present in pPR, thus allowing sufficient volume within the procapsid for packaging of full length HCMV DNA.

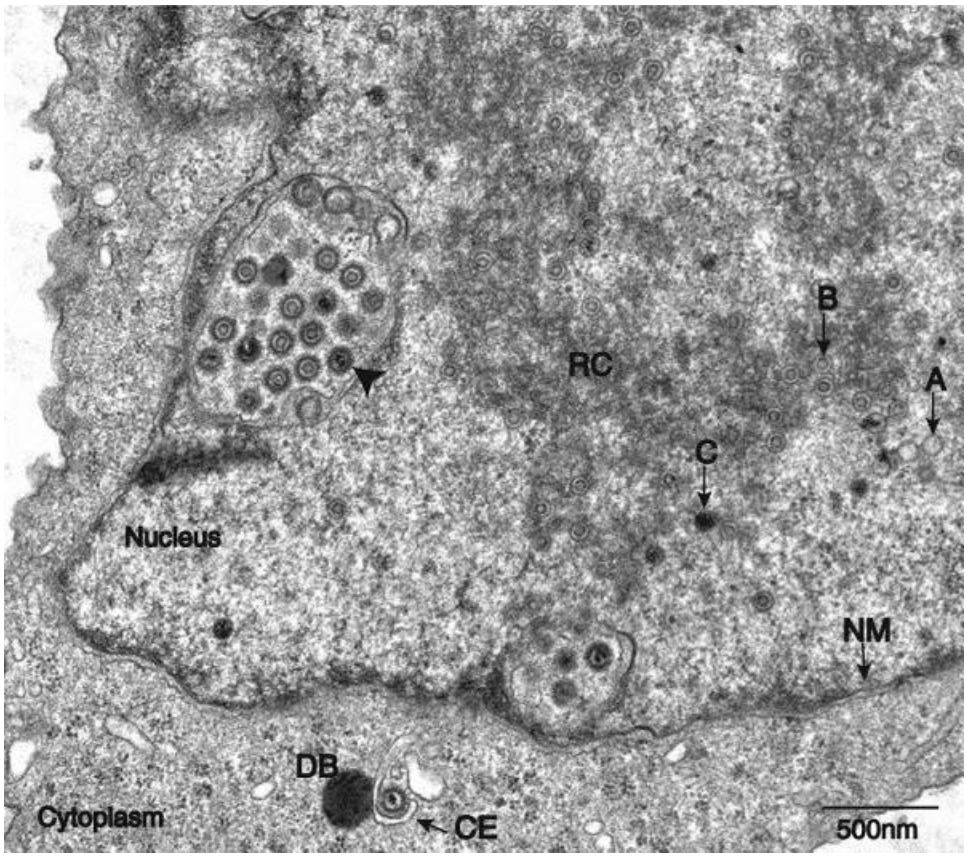

FIGURE 12.11 Nucleocapsids and nuclear egress in infected fibroblast. Transmission electron micrograph of HCMV-infected fibroblast. Replication compartments (RC) marked by accumulation of viral nucleic acids mark the site of genome encapsidation. Type A (lack scaffold and DNA), B (contain scaffold, but not DNA) and C (viral genome containing) capsids are marked with arrows. Nucleocapsid with initial layer of tegument is marked by an arrowhead. CE, capsid undergoing cytoplasmic envelopment; DB, dense body; NM, nuclear membrane.

UL80 encodes four in-frame, carboxy co-terminal proteins: the UL80a encodes the protease precursor (pPR, 74-kDa), UL80.5, the assembly protein precursor (pAP, 38-kDa), as well as two additional proteins. The process of capsid maturation begins when the MCP associates with protease precursor complex (pPR-pAP:pAP) and is transported into the nucleus where proteolytic processing results in assembly of procapsid shells (Fig. 12.10).[202,378,442] SCP interacts with MCP and presumably translocates to the nucleus with MCP/pPR/pAP.[335,692] Heterotrimeric complexes between the two dimer-forming TRI2 conformers of the MnCP and one TRI1 protein assemble in the cytoplasm and are translocated to the nucleus (Fig. 12.10).[202] Where the triplex stabilizes hexons and pentons, completing the capsid floor between capsomers.[692]

Capsid assembly is coordinated by the pAP, and the pPR, PR, self-cleaves to produce pAP (Fig. 12.9). Precise protease cleavage steps releases MCP, inactivates the protease, and orchestrates the replacement of the scaffold in procapsids with viral DNA. PR, AP, and pAP are removed from nucleocapsids into which DNA has been packaged. Properly formed capsids (C

capsids) mature more efficiently than defective nucleocapsids, such as the NIEPs lacking DNA.

Encapsidation of unit length genomes depends on the terminase proteins, encoded by UL51, UL56 (encoding TER2), and UL89 (encoding TER1) and interactions with the portal protein complex.[622,623] The terminase is a target for the antiviral drug letermovir.[206,357] The portal protein forms a multimeric ring thought to consist of a self-generated dodecameric oligomer for entry of the DNA into the capsid.[249] Terminase machinery (the ATPase encoded by UL56 and the nuclease encoded by UL89) recognizes free genomic ends, cleaves viral genomes at the portal leaving a single-base 3′ extensions at both genomic ends, and powers a single genome length of DNA through the portal and into the capsid by ATP hydrolysis.[260,623] A 129-bp region contains both cis-acting, AT-rich *pac* elements, which are sufficient for cleavage and packaging.[656] UL89 encodes a curvilinear monomer with single amino acids known to be important for DNA binding (R544) and nuclease (D463) activity through mutagenesis.[621] The portal protein interacts with the UL56 protein subunit of the terminase complex, linking the production of unit-length genomes with packaging.[159] The terminase complex dissociates after cleavage and is not part of the mature virion. UL93 and UL77 proteins associate with capsids and have roles in retaining viral DNA in the nucleocapsid.[54,316]

Tegumentation begins with association of SCP on hexons and pentons with pp150 in the nucleus.[692] As intact C capsids cannot be isolated from the nuclei of infected cells, the net-like pp150 tegument is thought to stabilize DNA-containing capsids against the high pressure exerted by encapsidation of the large genome.[144,692] Although the CMV and HSV-1 capsids are similar in size, the CMV packages about 50% more viral DNA, providing an explanation for the significant differences in the structure of the capsids between the two herpesviruses.[692] Tegumentation continues in the cytoplasm in conjunction with envelopment within the viral assembly compartment.[91,144,693]

The passage of the approximately 100 nm CMV nucleocapsid from the nucleus to the cytoplasm for continued maturation requires the capsids to move through the nuclear lamina and inner and outer nuclear membranes (Fig.12.9, UL80). In HCMV, the viral UL50- and UL53-encoded proteins form the core of the NEC, and structures of truncated forms of the NEC and subunits have been solved.[383,650] Heterodimers recruit the UL97-encoded viral kinase and thin and disperse nuclear lamina.[562] Nucleocapsids dock at lamina-depleted areas on the inner nuclear membrane and interact with NEC components at budding sites.[413,643] The viral protein kinase phosphorylates both NEC components, UL50 (Ser 216) and UL53 (Ser 19)[561] and phosphorylates the lamina A/C (Ser 22) on th same site that is targeted by the cellular Cdc2/cyclin-dependent kinase (CDK)1 for breakdown of the nuclear lamina during mitosis.[229] Acetylation of lamin B1 impedes disruption of lamin structure and the nuclear egress of virions.[429] Host proteins, including the inner nuclear membrane protein emerin, also associate with the NEC and emerin knockdown results in defects in all classes of viral gene expression, virus maturation, and infectious progeny production.[412] UL97 is important for viral genome synthesis and accumulation of capsids in the cytoplasm (nuclear egress).[326]

Nucleocapsids reach the cytoplasm by acquiring a temporary envelope from the inner nuclear membrane as the nucleocapsid buds into the perinuclear space (Figs. 12.9 and 12.11). To accommodate this process, the nuclear periphery juxtaposed to the virus-induced, membranous cytoplasmic AC is altered, indicated by enlargement of the perinuclear space as the result of

decreased SUN domain proteins, which tether inner and outer nuclear membranes through their interaction with KASH domain proteins in the outer nuclear membrane.[73] This envelope is lost by a process of de-envelopment that involves fusion with the outer nuclear membrane as the capsid enters the cytoplasm. Once in the cytoplasm, pp150pAP associated with the nucleocapsid interacts with the ER chaperone, BiP/GRP78, and the dynein-associated motor protein, bicaudal D1, resulting in translocation to the AC for further tegumentation and final envelopment.[73,263] UL47, UL48, and UL88 are required for accumulation and tegumentation of virions within the AC.[91,332]

Envelopment and Egress

Envelopment of HCMV is proposed to occur following budding of tegumented particles into viral glycoprotein studded membrane bound vacuoles, a process that is believed to occur within the AC.[19,146,545] The AC was initially described as an isolable membranous compartment that contained virion envelope and tegument proteins.[545] The AC represents an extensive, sequential remodeling of secretory membranes, including the Golgi and trans-Golgi, endocytic membranes, and is surrounded in what appeared to be concentric layers of membranes from the ER-Golgi intermediate compartment (ERGIC) and ER (Fig. 12.12A and B).[19,146,252,506,545] Components of the late endocytic compartment are also associated with the AC, including SNARE family members[95,328] and the ER chaperone, BiP.[74,75] BiP depletion results in disintegration of the AC and diminishes infectious progeny production, suggesting the importance of host proteins in maintaining the AC and for virus production.[74] A number of activated signaling proteins are relocalized and sequestered in the AC, including mTOR and EGFR, although their role in the function of the AC is less clear.[77,118] Transferrin, β-catenin, and components of ESCRT also localize to the AC[21,146,328] (Fig. 12.13A–D).

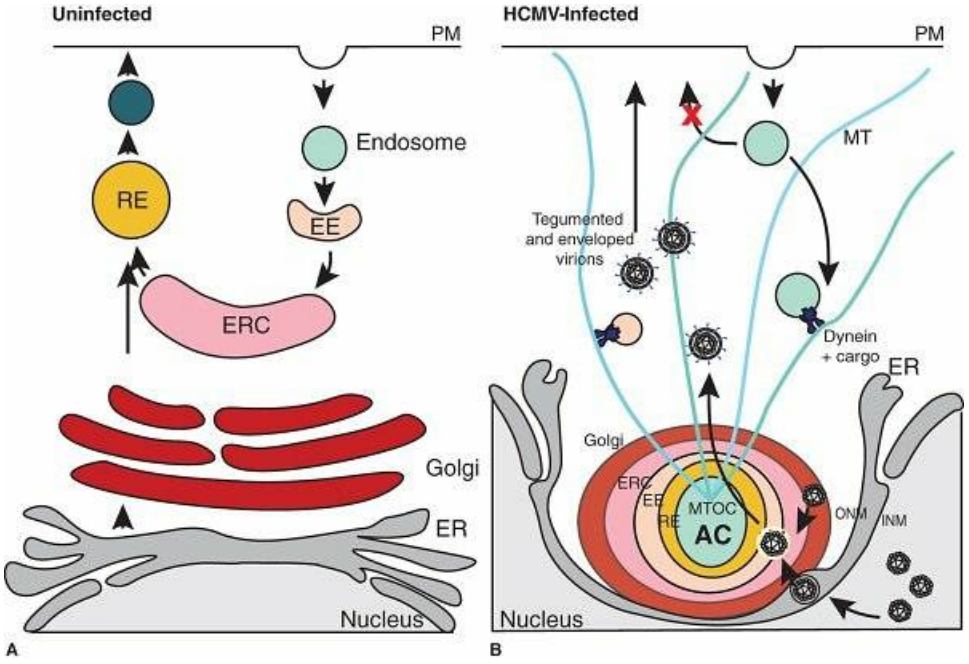

FIGURE 12.12 Cytoplasmic virus maturation. A: Uninfected cell with components

of the secretory pathway (ER and Golgi complex) and endocytic pathway (early endosomes [EE]; endocytic recycling compartment [ERC]; recycling endosome [RE]). **B:** Productively infected cell with concentration of components of secretory (Golgi) and endocytic pathway (ERC, RE, EE) into a juxtanuclear compartment designated the virion assembly compartment (AC). The AC colocalizes and is formed from a Golgi-derived microtubule organizing center (MTOC) in the infected cells. Dynein motor proteins traffic endocytic vesicles and cell surface cargo to the AC, but recycling to the plasma membrane is largely blocked late in infection. The topology of the assembly compartment has been depicted as concentric rings or spheres of the different components of the secretory pathway on the outside and components of the endocytic pathway inside of AC. Virion structural proteins are concentrated in the AC by virus-induced trafficking of proteins in the secretory pathway to the AC and by the inhibition of recycling of endocytosed proteins by viral microRNAs. The tegumented capsids are enveloped by budding of particles into virion glycoprotein–containing membranous vesicles in the AC. The inhibition of AC morphogenesis has been shown to both decrease the yield of infectious virus and increase the number of defective particles released from the infected cell arguing that a major role of the AC is to facilitate virion maturation: the acquisition of tegument and envelope through the budding into or envelopment of tegumented particles by cytoplasmic vesicles containing essential virion envelope proteins (Fig. 12.13E).[253,264,506] The accumulation of membrane-bound viral glycoproteins in the AC (Fig. 12.13C and D) results from a combination of viral miRNA-mediated inhibition of vesicular trafficking from the secretory pathway and the endocytic recycling pathway while sustaining anterograde traffic in the secretory pathway and endocytosis[253] (Fig. 12.12). HCMV-induced membrane reorganization in infected cells is not seen in other herpesviruses and allows concentration of the large number of virus-encoded glycoproteins, providing coordinated genesis of the HCMV envelope at a single cellular location and the maturation infectious progeny. Transport of the tegumented particle to sites of envelopment is thought to be microtubule dependent as inhibition of microtubule nucleation and function decreases the assembly of infectious virus.[263,499] Further, the formation of the AC depends on the motor protein, dynein, and a dynein-interacting protein, bicaudal D1.[73,263] Forces exerted by dynein contribute to the deformation of the nucleus into the kidney bean shape characteristic of cells in the late stages of CMV infection (Fig. 12.13D).[73,499] The AC acts as a Golgi-based microtubule organizing center (MTOC) by enhancing Golgi-based microtubule nucleation, a process requiring microtubule acetylation driven specifically by plus end binding protein EB3 (or MAPRE3) and resulting in nuclear rotation.[499] These microtubule-mediated changes also serve to create polarity in the nucleus for virus-induced compartmentalization.[500] Microtubules have long been appreciated to emanate from the AC (Fig. 12.13C)[545] and likely direct the transport of glycoprotein containing vesicles and possibly tegumented virus particles to the AC. Although specific protein interactions that direct the tegumented particle to sites of envelopment in the AC are not well defined, tegument proteins including UL47 and pp150 have been implicated.[91,264] The interaction between the cellular protein bicaudal D1 and pp150 has been shown to be essential for efficient infectious virus production as well as trafficking of pp150 to the AC.[263] Interestingly, a small GTPase Rab6a plays a key role in vesicular trafficking in the Golgi body and also targets bicaudal D1 and pp150 to the AC, suggesting a linkage between microtubule transport of tegumented particles to the AC and AC formation.[264] Viral gpUL132 is required for reorganizing of viral and cellular proteins to form the AC and is required for efficient replication.[678]

Subsequent budding of tegumented particles into viral glycoprotein containing vacuoles presumably requires some specificity that can be inferred by interactions between the cytoplasmic tail of a viral glycoprotein(s) and tegument proteins on the maturing particle, or alternatively between tegument proteins on the particle and the membrane bound viral tegument pp28 (*UL99*) or possibly pUL71.[156,547] These mechanisms of particle envelopment are similar to those described for RNA viruses that acquire their envelope through interactions between viral glycoproteins and viral matrix proteins. Alternatively, in the case of HCMV envelopment, budding into an envelope protein–studded vacuole and assembly of an infectious virion could be entirely random and perhaps account for the large numbers of enveloped but noninfectious particles that are released from HCMV infected cells maintained in culture. Evidence consistent with such a random process of envelopment was provided by quantitative analyses of different types of virion associated vacuoles in the AC using EM.[553] Results from this study indicated that tegumented particles were enveloped in all regions of the AC and not in a specific location within the AC. Finally, it is important to note that most of the current understanding of envelopment and in particular, the morphogenesis of the AC, has been derived from studies of laboratory adapted strains of HCMV utilizing productive infections in human fibroblast cells. Studies using clinical isolates and nonfibroblast cells have demonstrated the formation of the AC and cytoplasmic envelopment of tegumented particles. However, studies to align findings from human fibroblasts with results obtained in cells such as endothelial cells are limited as illustrated by the importance of UL135 and UL136 proteins for the formation of cytoplasmic structures required for assembly in endothelial cells but not fibroblasts.[78]

Once enveloped, mechanisms leading to the release of the infectious HCMV virions from infected cells remain undefined, particularly mechanisms that could account for the cell-to-cell spread of clinical strains of HCMV. Observations from *in vitro* studies of productive infections in human fibroblasts infected with laboratory strains of HCMV suggested that extensive cell lysis could be the major source of cell-free virus. Yet even under productive infection in permissive human fibroblasts, only about 50% of total infectious virus is released into the supernatant with the remaining infectivity associated with the infected cell. Moreover, in many low-passage clinical isolates almost all infectious virus is retained intracellularly and spread within cell monolayers.[430] Relevant to any mechanism that can account for cell-to-cell virus spread are observations from studies of viral mutants with deletions in virion structural proteins that nearly eliminate the release of cell-free infectious virus, yet appear to spread equally as well as wild type virus in assays of cell-to-cell spread.[569] In contrast, deletion of essential envelope glycoproteins including gB, gO, and gM can limit both the production of infectious extracellular virions and cell-to-cell spread.[267,282,386] Utilizing high-throughput siRNA screens, two groups have identified host cell proteins that appear to interfere with release of HCMV into the supernatant of infected cells.[407,486] Although findings from at least one of these studies provided insight into possible mechanisms virus release including exocytosis, definitive evidence of this pathway is lacking.[486]

LATENCY

A unifying characteristic of herpesviruses is that they persist for the lifetime of their host by way

of a latent infection. Latency at the cellular level is the maintenance of viral genomes in a reversibly quiescent state such that the virus does not replicatein the absence of a reactivation stimulus. Within the host organism, true latency is elusive as sporadic and localized reactivation events are thought to occur frequently and subclinically in immune competent individuals. The universal risk of transplanting stem cells or an organ from a CMV-seropositive individual into a CMV-seronegative individual provides the most striking evidence of lifelong infection and the propensity for virus reactivation. Reactivation from latency in the context of immune deficiency and during pregnancy remain is central to CMV disease pathogenesis.[593] The disease implications of CMV in transplant recipients highlight the importance of understanding the mechanisms governing latency and reactivation and in designing antiviral strategies to target latent reservoirs.

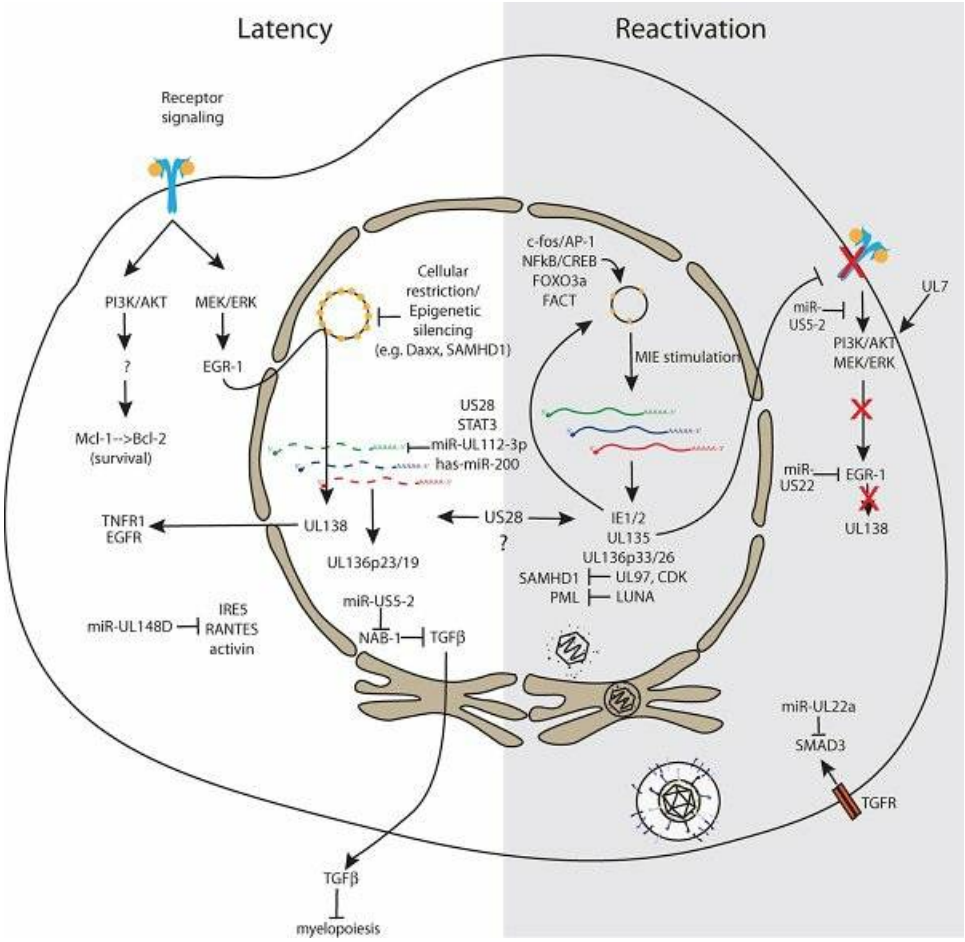

FIGURE 12.14 Latency and reactivation. During latency, viral genome is chromatinized and gene expression is restricted by host factors, including, but not limited to, PML, SAMHD1, PRC2, and FACT. Viral genes appear to be broadly expressed but at very low levels, in part due to viral and host miRNAs. miRNAs also regulate cellular responses to infection. Sustained PI3K/AKT signaling is important for cell survival and HCMV latency, as it is for all herpesviruses. MEK/ERK signaling stimulates the transcription factor, EGR-1, which drives the expression of the UL138 latency determinant. Viral proteins and miRNAs contributing to the establishment of

latency are indicated. miRNAs regulate the signaling and secretion of TGFb, which is responsible for HCMV inhibition of myelopoiesis in uninfected bystander cells. During reactivation, host signaling changes induce reexpression of viral gene expression and viral replication ensues. Viral proteins and miRNAs target host cell signaling to facilitate reactivation. UL135 and viral miRNAs attenuate PI3K/AKT and MEK/ERK signaling, while UL7 is activated later and stimulates. miR-UL22a blocks TGFb signaling in infected cells to maintain myelopoiesis. US28 has been described to play roles in both latency and reactivation, likely depending on mode of signaling and context.

The first evidence of HCMV latency came from the observation that infectious virus-free leukocytes could transmit HCMV infection. While CMV infects a diverse array of cells in the human host, the latent reservoir for HCMV is primarily considered to be hematopoietic, including CD34+ hematopoietic progenitor cells and cells of the myeloid lineage, including monocytes. The evidence for a hematopoietic reservoir consists of the detection of viral genomes in these cells in seropositive individuals in the absence of disease and the ability to stimulate reactivation from latently infected hematopoietic cells. The HCMV genome is estimated to persist episomally at a frequency of 10^{-4} to 10^{-5} with 2 to 15 genome equivalents per infected cell in myeloid progenitors.[50,576] While multiple hematopoietic cell subtypes may support latent infection, there are undoubtedly important differences that remain to be systematically understood.

Latent persistence of the virus poses a number of molecular and cellular challenges for the virus, including maintaining viral genomes through cellular division, reversibly repressing viral gene expression, and sensing host cues for reactivation. Defining natural latency beyond the identification of cell lineages that carry the HCMV genome has been challenging to understand at the molecular level in hematopoietic cells because of the heterogeneity of primary hematopoietic subpopulations cells and the scarcity of primary human progenitor cells. In an attempt to circumvent this issue, a number of cell line models have been developed that recapitulate varying degrees of the latent infection. These include acute monocytic leukemia THP-1 cells,[129,688] acute myeloblastic leukemia Kasumi 3 cells,[451] embryonal carcinoma NTera2,[208] and inducible pluripotent stem cells (iPSC)[488] and human embryonic stem cell (hESC)-derived CD34+ HPCs.[134] Cell line models offer key advantages in their homogeneity and synchronous reexpression of viral gene expression following a reactivation stimulus, and the absence of donor variability—all limitations inherent to primary cell systems. While cell line models recapitulate key aspects of CMV latency (e.g., MIEP silencing, genome maintenance), some have blocks in later steps associated with reactivation, such as amplification of the viral genome or progeny virus production. hESC-derived CD34+ HPCs offer a strong alternative to primary cells as a model that supports multi-lineage hematopoietic differentiation, HCMV-mediated myelosuppression, and recapitulate quantifiable phenotypes associated with viral genes important to latency or reactivation.[134] A key advantage is that reactivation in hESC-derived CD34+ HPCs occurs at a frequency approximately 30 times greater than that of primary cells. It is important to recognize that none of these experimental models factor contribution of the antiviral T cell immune response that dictates outcomes in immunocomppromised hosts.

Establishment and Maintenance

HCMV latency is established through a complex network of virus–host interactions that remain ill defined (Fig. 12.14). Even more ill defined are the means by which the HCMV genome and its latent state are maintained. HCMV binding to the cell surface stimulates EGFR signaling in CD14+ monocytes[98] and CD34+ progenitor cells[303] and results in downstream activation of AKT. EGFR and integrin signaling up-regulates the cytoskeletal regulators N-WASP and paxillin, which drives trafficking of the internalized virion to the nucleus and increases infected monocyte motility. These initial signaling events are also important for the establishment of latency.[303] Trafficking of the viral genome in primary monocytes is delayed relative to fibroblasts permissive for virus replication and takes a retrograde route through the trans-Golgi network and recycling endosomes that requires Src signaling.[304] Similar to monocytes, trafficking of the HCMV genome to the nucleus requires 4 to 8 hours in CD34+ cells.[303]

A prerequisite for latency is the maintenance of the viral genome, although these mechanisms have not been defined for HCMV. This is particularly important because latency is established in cells capable of division. The γ-herpesviruses EBV and KSHV encode proteins that tether the viral genome to host chromosomes. HCMV IE1-72 kDa associates with mitotic chromatin and binds histones H2A-H2B and H3-H4 and these interactions may serve to tether chromatin in the context of the latent infection,[423] although such a role has been elusive. Further, a smaller IE1 protein composed only of exon 4 is reported to interact with topoisomerase IIb for maintenance of the viral genome.[615] In the absence of a fully defined mechanism for genome maintenance, it remains possible that frequent subclinical reactivation events serve to constantly reseed the population of infected hematopoietic cells.

Critical to latency is the ability of infected hematopoietic cells to avoid programmed cell death pathways, including apoptosis. While the virus encodes a number of anti-apoptosis and anti-necroptosis factors (e.g., UL36, UL37, UL38, TRS1, and β2.7RNA, see section *Regulation of Host Cell Death*), it is not clear if these are expressed or functioning in the context of latency.[97] Infection up-regulates cellular survival signals, including ERK/MAPK[298] and Mcl-1[510] in CD34+ cells and Mcl-1[97] and Bcl-2[128] in monocytes. Mcl-1 and Bcl-2 block the formation of proapoptotic complexes, such as Bax and Bak, in mitochondrial membranes. In the case of monocytes, activated cell survival pathways dramatically extends the life span of otherwise short-lived monocytes (1 to 3 days in circulation). Mcl-1 is induced through EGFR and integrin activation during virus entry via PI3K signaling and an atypical AKT pathway.[97,121] However, Mcl-1 is down-regulated to allow basal activation of caspase-3 as a requirement for differentiation and integrin-dependent Bcl-2 increases concomitantly to continue to ensure survival. This Mcl-1-to-Bcl-2 switch is an example of the intricacy of viral manipulation of the host cell underlying HCMV persistence. Sustained PI3K/AKT signaling downstream of EGFR is important for the establishment and maintenance of HCMV latency in CD34+ HPCs, as well as that of other herpesviruses. Inhibition of the EGFR, PI3K/AKT or MEK/ERK pathways in CD34+ cells stimulate reactivation.[76,77]

In monocyte-derived dendritic cells, the signaling changes associated with reactivation are distinct. IL-6-stimulated reactivation requires MEK/ERK signaling[299,511] and the concomitant activation of src family kinase, hematopoietic cell kinase (HCK), which is up-regulated upon DC differentiation.[164] The activation of these pathways results in increased acetylation of histones and CREB binding to the MIEP.[299] Importantly, contact with infected cells stimulates uninfected

monocyte-derived DCs to secrete soluble, non-IFN factors that suppress expression of viral genes and inhibit CMV spread.[294] However, direct infection of monocyte-derived DCs and macrophages stimulates cGAS/STING-dependent type-I IFN (IFN) production,[462] and type I and type II IFNs reversibly suppress viral gene expression or reactivation in mice infected with MCMV.[143,250] Direct infection of monocytes in culture or monocytes from patient samples induces up-regulation of IFN-stimulated genes, contributing to an inflammatory response in the hematopoietic niche.[559] Together these studies suggest that the establishment and maintenance of latency are driven by both infected cell–extrinsic as well as infected cell–intrinsic factors.

Control of Gene Expression for Latency

The latent program of gene expression has been an area of intense focus and controversy. Classically, herpesvirus latency is characterized by a transcriptionally silent state where gene expression is limited to a small number of genes that play important roles in establishing or maintaining latency. However, sensitive transcriptomic evaluation reveals broader patterns of gene expression associated with latency. As has been observed for other α- and γ-herpesviruses, HCMV infection of cells destined to support a latent infection results in a low-level, but promiscuous burst of gene expression from across the HCMV genome.[109,129,533,565] While this initial burst of gene expression eventually subsides,[129] low-level, broad gene expression may persist.[109,565] Although defining the latent transcriptome is complicated by the heterogeneous nature of bulk hematopoietic cell populations, the observation of broad low level gene expression is mirrored in studies of cells from latently infected healthy carriers.[109] Further, single-cell RNA sequencing has revealed heterogeneity in patterns of expression and also support low level gene expression from across the genome.[565] Therefore, while gene expression is restricted, it is likely not entirely silenced nor limited to a small number of latency genes.

In cell types that support latency, viral gene expression is restricted by chromatinization and epigenetic regulation of the viral chromosome. Many host factors with the potential to suppress viral gene expression are components of PML or ND10 bodies, including PML, Daxx, and Sp100[539,540,676] (see sections *Pre-IE Events and Intrinsic Responses to Infection* and *Regulation of Major Immediate Early Gene Expression* for further discussion). Type 1 IFN up-regulates these host factors and reversibly blocks IE gene expression for latency in MCMV-infected endothelial cells.[143] While knockdown of Daxx increases IE gene expression in THP-1 or CD34+ cells infected with the AD169 laboratory strain,[540] it fails to rescue IE expression in cells infected with a low-passage strain[541] or in undifferentiated THP-1[648] or NTera2[221] cells. These findings indicate that the repression of gene expression for latency is multifactorial. Despite the ability of the pp71 tegument protein to stimulate viral gene expression by antagonizing Daxx, pp71 fails to traffic to the nucleus and degrade Daxx in cells that support latency,[541] although high intravirion pp71 may be able to overcome this restriction and enhance replicative fitness and impede the establishment of latency.[103]

A number of other restriction factors are emerging that contribute to the establishment of latency. SAMHD1, a host factor that depletes the pool of available dNTPs to suppress DNA polymerase processivity, has been shown to restrict MIE gene expression and replication by impeding NFκB activation in myeloid cells.[302] In primary human macrophages, HCMV counteracts this restriction by inducing SAMHD1 phosphorylation (T592) through the activation of CDKs and/or through UL97 kinase-mediated phosphorylation, in addition to transcriptional

down-regulation and increased proteasomal degradation.[82,155,302,698] This viral strategy is conserved in MCMV where the M97 kinase phosphorylates SAMHD1.[155] These findings suggest that SAMHD1 suppresses replication for latency and SAMHD1 inactivation is required for reactivation. Further, the phosphatases CDC25B and CDK1 are repressive to viral gene expression, and inhibition of CDK1 stimulates viral gene expression in the Kasumi-3 model of latency.[463] Finally, cellular miRNAs have also been shown to down-regulate *UL122* and *UL123* transcripts encoding IE2 and IE1, respectively.[216,453] The human miR-200 cluster is more highly expressed in undifferentiated hematopoietic progenitors or early myeloid lineage-committed cells than more differentiated cells and targets *UL122* transcripts encoding IE2 to reduce viral gene expression.[453]

Genome chromatinization is an important control point in regulating programs of gene expression that ultimately dictate replicative or latent states.[1,15,428,513] The histone tails to nucleosomes associating with viral genomes are regulated by posttranslational modifications, such as acetylation and methylation, which regulate chromatin structure and gene expression. Studies of chromatin changes associated with latency and reactivation have primarily focused on chromatinization and regulation of the MIEP as control of IE gene expression is critical for productive replication or the establishment of latency.[220,676] In cell line models for quiescent infection, histone deacetylase activity reduces viral gene expression, corresponding to increased association of heterochromatin protein 1 (HP1)[428] and the corepressor KAP1[504] with the MIEP to contribute silencing the viral genome. Heterochromatinization of the HCMV genome has not been defined as facultative or constitutive, which is an important determinant in HSV-1 latency. However, PRC2 increases trimethylation of histone 3 at lysine 27 (H3K27me3), a promiscuous chromatin mark indicative of facultative heterochromatin, on the HCMV genome in undifferentiated THP-1 cells,[1] which correlates with reduced viral gene expression. Despite an apparent role for PRC2 in chromatinization and repression of the viral genome for latency, PRC1 and 2 have also been shown to promote replication in fibroblasts as inhibition of the histone H3K27 methylase EZH2 component of PRC2 impairs HCMV gene expression[24,582] and promotes viral genome synthesis and replication in a catalytically independent manner.[609]

Viral Determinants Associated With Latency and Reactivation

In the past decade, viral genes and miRNAs have been identified that impact infection outcomes in hematopoietic cells. A polycistronic locus within the UL*b′* region of the viral genome that spans *UL133-UL138* encoding, UL133, UL135, UL136, and UL138 encode genes that are repressive to viral replication in contexts of latency and contribute to the establishment of latency or are required for reactivation.[165,210] These genes are largely dispensable for replication in fibroblasts, but they have been genetically defined to promote or suppress virus replication in hematopoietic cells; however, much remains to be understood about their mechanisms of action. Recombinant viruses lacking *UL138* exhibit a loss of latency and replicate in $CD34^+$ HPCs without a reactivation stimulus.[210,481,631] UL138 prevents the association of lysine-specific demethylases with the viral genome to limit IE gene expression.[348] By contrast, *UL135* is important for virus replication when *UL138* is expressed; disruption of *UL135* results in a severe defect for reactivation.[632] UL138 and UL135 functionally antagonize one another by differentially regulating the trafficking and signaling activity of EGFR.[77] Interactions between UL135 and the host adapter proteins, Abelson interacting protein 1 (Abi-1) and CIN85/CD2AP

are requisite for UL135-mediated turnover of EGFR and mutant viruses where these interactions are disrupted or that fail to regulate EGFR are defective for reactivation in $CD34^+$ HPCs.[502] Inhibition of EGFR or downstream PI3K/AKT signaling potently induces reactivation when coupled with stimuli for reactivation in CD34+ HPCs,[76,77,303] suggesting a role for sustained EGFR/PI3K/AKT signaling in maintaining HCMV latency, as has been shown for other herpesvirus family members. UL138-mediated stimulation of EGFR induces the early growth response-1 (EGR1) cellular transcription factor, which in turn binds to the viral genome to drive *UL138* gene expression.[76] EGR1 is highly expressed in hematopoietic stem cells and is important for maintenance of stemness. Disruption of EGR1 binding to the viral genome reduces *UL138* expression relative to *UL135* and increases virus replication in CD34+ HPCs.

UL138 also increases TNFR1 on the surface of infected cells,[344,421] which potentiates NFκB signaling in the context of infection[421] but does not drive apoptosis due to the function of UL36.[391] TNFα signaling is a signal for reactivation *in vitro*,[186] in mice, and in the context of transplantation,[130,169] and can stimulate reexpression of viral gene expression independently of differentiation.[186] Therefore, UL138-mediated up-regulation of TNFR1 on the surface of infected cells may provide a means by which the cell can sense cues for reactivation; however, role of UL138 modulation of TNFR1 on latency and reactivation remains to be evaluated.

In contrast to EGFR and TNFR1, UL138 decreases the cell surface levels of multidrug resistance-associated protein-1 (MRP1/ABC transporter multidrug resistance protein ABCC1).[659] In hematopoietic cells, UL138 down-regulation of MRP-1 results in increased sensitivity to killing by Vincristine, but it is not known why the virus targets MRP-1. It is not clear how UL138 differentially modulates levels of host receptors at the cell surface; however, mutation of dileucine or Golgi sorting motifs within UL138 that are important for the down-regulation of MRP1 do not impact Golgi localization or the maintenance of latency in embryonic stem cells.[200]

UL136 is expressed with later kinetics than UL135 and UL138 as maximal expression requires viral DNA synthesisor entry into late phase in the context of productive infection. *UL136* is expressed as multiple protein isoforms (p33, p26, p25, p23, and p19), differing only in their amino terminal end, that differentially suppress replication for latency or contribute to reactivation in both CD34+ HPCs *in vitro* and humanized mouse models.[93,94] The mechanism by which UL136 isoforms regulate the transition between latency and reactivation is unknown.

US28 has been reported to be important for both maintaining latency and for reactivation, making its precise role in latency controversial and possibly dependent on context (e.g., cell type and culture conditions, ligand binding). HCMV encodes four GPCR homologs (UL33, UL78, US27, and US28) where US28 is the best characterized.[190] US28 is constitutively active and promiscuously activated by host chemokines CCL2 (monocyte chemoattractant protein 1, MCP-1), CCL3 (macrophage inflammatory protein 1-alpha, MIP-1α), CCL4 (macrophage inflammatory protein 1-beta, MIP-1β), CCL5 (regulated on activation, normal T cell expressed and secreted, RANTES) and CXC3CL1 (fractalkine), inducing numerous ligand- and G protein–dependent signaling pathways. US28 induces chemotactic migration, chemokine scavenging, cellular adherence and tumor promotion through its binding to CC (e.g., CCL5/RANTES) and CX3C (e.g., CX3CL1/Fractalkine) families of chemokines.[403,646] Constitutive signaling (independent of ligand binding) drives induction of NFκB/PLCβ, NFAT, p38-MAPK, and CREB signaling. A 2.9 Å structure of US28 in complex with CX3CL1/Fractalkine shows that the

unique structure of the C-terminus may underlie its ligand-independent (constitutive) activity through the generation of inositol phosphates in productive infection.[79,92,416] US28 signaling drives MAPK, NFκB, and Wnt signaling in productive infection,[92,338,415,575] which likely contributes to pathogenesis of HCMV infection and spread in the host, despite being dispensable for virus replication in cultured fibroblasts.[450,642] US28 has also been shown to transcriptionally down-regulate IFN-responsive genes for latency.[171] US28 binding to RANTES stimulates smooth muscle cell migration, which can be blocked by binding to Fractalkine to stimulate migration of macrophages.[603,645] The complexity of US28 is further exemplified by its context-dependent signaling and differential functions are dictated by association with different G proteins.[420,645]

US28 is packaged within the virion tegument and is expressed during latency (prior to differentiation) and following reactivation in cell lines and primary cell models.[257,680] US28 modulates a number of signaling pathways, attenuating mitogen activated protein (MAP) kinase, NFκB, c-foscarnet, and activating STAT3.[321,322,704] US28-mediated induction of STAT3 in infected HPCs reprograms differentiation to generate a rare immunosuppressive monocyte subset that expresses high levels of IL-10 and inducible nitric oxide synthase (iNOS) and STAT3 activation is important to suppressing IE gene expression.[704] STAT3 is an important target of regulation for many contexts of HCMV infection.[239,388,516,575,628,677,699,704] In Kasumi-3 or CD34+ cells, recombinant viruses lacking US28 expresses higher levels of the MIE genes and produce infectious progeny, indicating that US28 suppresses viral gene expression and replication for latency.[257] A number of mechanistic studies have provided insights into how US28 may contribute to establishing latency. Ectopic expression of US28 in THP-1 cells attenuates MAP kinase and NFκB signaling for the establishment of latency in undifferentiated cells, which correlates with increased levels of *UL138* gene expression relative to IE gene expression.[322] However, in the same system, constitutive US28 signaling also activates MIE gene expression in TPA-differentiated cells. It was further shown that US28 decreases binding of c-foscarnet, a subunit of the AP-1 cellular transcription factor, to the MIEP, which correlates with reduced MIE gene expression.[321]

In contrast to these studies, US28 mutant viruses (nonsense and destabilized variants) maintained genomes but failed to reactivate in both $CD34^+$ primary cells and in a humanized mouse model of latency.[133] In these studies, nonsense mutation of *US28* results in a virus that failed to reactivate, but a mutation that blocks CC- and CX3C-chemokine binding (Y16F) results in a failure to establish latency and persistent replication in the absence of a reactivation stimulus. A mutation disrupting constitutive US28 signaling through the DRY box (R129A mutation) had no effect on latency and reactivation. US28 was further shown to stimulate hematopoietic cell differentiation, driving cells toward a CD14+ lineage. Constitutive US28 signaling activity stimulates PLCβ and PKC in THP-1 monocytes, an activity that stimulates monocyte-to-endothelial cell adhesion.[680] The interactions between US28 and other signaling complexes in the membrane, the resulting conformational changes, differential association with G proteins, and regulation by GPCRs that phosphorylate C-terminal residues in a tissue-specific manner may contribute to differences in US28 function in different contexts of infection or experimental systems. Resolving the complexity in US28 function will require the use of precise mutations and highly controlled contexts to assign specific functions to distinct ligand binding and constitutive signaling activities in regulating decisions to enter into or exit latency.

HCMV miRNAs represent a powerful mechanism to fine-tune expression of viral or cellular gene expression to regulate latency since they are nonimmunogenic (Supplementary e-Table 12.2). miRNA expression patterns have been shown to be distinct in the THP-1 monocytic cell line or CD34+ HPCs relative to that measured during productive infection in fibroblasts.[193,341,409] In CD34+ HPCs, all miRNAs are detected at 4 dpi[341] and decrease over time to 10 dpi with the exception of miR-UL22A-5p, miR-UL112-3p, and miR-UL148D.[463] miR-UL112-3p targets HCMV UL123 (IE1-72 kDa),[216,426] UL112/UL113 (viral DNA synthesis),[216] UL114 (viral DNA glycosylase),[596] UL17/18 (MHC-I homologue), and UL120/UL121 (MIE region exons)[216] to inhibit IE gene expression and DNA replication. miR-UL112-1-3p is reported to down-regulate IE gene expression during latency, although disruption of miR-UL112-1-3p alone did not result in reactivation.[342] miRUL112-1-3p works in conjunction with miR-US5-1 and the UL7 protein to control FOXO3a activity and preventing cell death in CD34+ HPCs,[232] indicating a role for this miRNA in reactivation other than regulating viral gene expression. As HSV, KSHV, and EBV also encode miRNAs that can down-regulate their own IE gene expression, this may be a common strategy evolved to fine-tune viral gene expression for the establishment of latency. In addition to these viral targets, miR-UL112-1-3p targets a number of cellular genes that may also contribute to latency, although this has yet to be demonstrated. These include immune activators (MICB, an NK cell activating receptor ligand),[594] IL-32,[255] vesicular trafficking proteins that modulate cytokine secretion (e.g., VAMP3, Rab5C, Rab11A, SNAP23),[253] and host restriction factors that suppress IE gene expression (e.g., BclAF1).[349]

miR-UL148D accumulates late during the latent infection *in vitro* and regulates cytokine secretion, targeting the RANTES proinflammatory cytokine,[306] which may serve to reduce recruitment of mononuclear cells to infected cells. Further, miR-UL148D targets the activin ACVR1B receptor, which promotes monocyte to dendritic cell differentiation. miR-UL148D also limits IL-6 secretion from infected monocytes,[341] which may dampen the inflammatory response during latency. However, disruption of miR-UL148D did not alter viral gene expression or the ability of the TB40/E strain to establish or reactivate from latency. miR-UL148D was also shown to target immediate early response gene 5 (IER5), which suppresses the CDC25B phosphatase that positively regulates CDK1.[463] In this study, miR-UL148D silencing of IER5 rescued CDC25B levels, resulting in CDK1-mediated silencing of the MIE gene expression in the Kasumi 3 cell line. It should also be noted that two groups independently characterized the phenotypes of miR-UL148D-mutant viruses with differing results in terms of the regulation of IE gene expression, possibly due to differences in the model systems (CD14+ monocytes vs. Kasumi-3 cell line) and virus strains (TB40/E vs. NR1).[341,463]

The reactivation of CMV from latency is intimately linked to hematopoietic differentiation. Differentiation of latently infected cells along the myeloid lineage or allogenic stimulation results in the reexpression of viral genes and reactivation.[508,578,579] Given the extent of chromatinization and repression of the viral genome that accompanies the establishment of latency, a primary objective in changes accompanying reactivation is to de-repress the restriction of viral gene expression imposed by host factors, such as Daxx, SAMHD1, IFN, or histone methylation. Chromatin remodeling is a critical part of reactivation associated with hematopoietic differentiation,[164,513] but not fully understood. The FACT (facilitates chromatin transcription) complex functions to reposition histones and to increase accessibility to RNA

polymerase. FACT is bound to the MIEP both prior to and following reactivation events in Kasumi 3 cells and is important for the reexpression of IE genes.[452]

The MIE locus contains a high density of binding sites for host transcription factors with roles in inflammation and differentiation (Fig. 12.7). Differentiation-associated changes in levels or binding of host transcriptional activators or repressors to the MIE region regulates MIE gene expression to maintain latency.[33,299,321,370,452] Because the MIEP is repressed during latency, it has been presumed that de-repression of the MIEP is a prerequisite to reexpression of IE genes upon reactivation. The CREB host transcription factor binds to CRE sites within the MIEP resulting in increased IE gene expression in infected monocytes.[299] CREB in cooperation with NF-κB also stimulates MIE expression in NTera2 cells stimulated to differentiate.[368,696] Recent studies demonstrate that additional MIE promoter elements within intron A of the MIE locus predominantly drive IE1-72 kDa and IE2-86 kDa accumulation in both in primary and cell line latency models in response to cues for reactivation.[129] FOXO3a, a member of the forkhead family of transcription factors, is induced upon differentiation and stimulates reexpression of IE gene expression from intronic promoters.[228] Host transcription factor binding in the MIE promoter or enhancer may influence 3D chromatin structure and the activity of other regions of the MIE locus, such as the intronic promoters, to drive MIE reexpression. The presence and differential use of multiple promoter elements for MIE expression in contexts of productive infection versus reactivation provides versatility to strongly repress MIE gene expression for latency, while preserving responsiveness to specific host cues for reactivation.

The identification of viral genes required for reactivation remains as elusive as those required for latency. While viral IE gene expression is sometimes observed in the context of latency, it is clear that IE gene expression alone is not sufficient for reactivation.[688] UL135 is required for reactivation[632] with functions in targeting EGFR for degradation and rearrangement of the host cytoskeleton for immune evasion.[76,502,588] The attenuation of signaling pathways downstream of EGFR, including PI3K/AKT and MEK/ERK, stimulates reactivation indicating the importance of host signaling to the maintenance of and reactivation from latency.[76,77,502] HCMV miRNA, miR-US5-2 targets the EGFR adapter protein, GAB-1, to attenuate EGFR signaling through the PI3K/AKT and MEK/ERK pathways.[234] Further, miR-US22-1 (or miR-US22a) down-regulates the EGF-responsive EGR1 host transcription factor and is required for reactivation.[411] Targeting of GAB1 and EGR1 by miR-US5-2 and miR-US22-1, respectively, indirectly decreases *UL138* expression and increases replication in CD34+ HPCs.[76,234] HCMV miR-UL22A is also required for reactivation and targets SMAD3 to negatively regulate myelosuppressive TGF-β signaling in infected cells.[233]

By contrast to the role of MEK/ERK signaling in latency, other studies have shown an important role for MEK/ERK signaling in reactivation to ensure cell survival. ERK up-regulates the cellular pro-survival factors, Mcl-1 and Elk-1, to counter proapoptotic pathway stimulation during reactivation.[298,510] Further, UL7 is a secreted protein and a ligand for the cellular Fms-like tyrosine kinase 3 receptor (Flt-3R).[135] UL7 is expressed and secreted following a stimulus that induces reactivation. UL7 binding to Flt-3 activates the PI3K/AKT and MAPK signaling cascades to prevent cell death in CD34+ HPCs and stimulate differentiation and reactivation in CD34+ HPCs, monocytes and humanized mice.[135,232] Contrasting but clear roles for PI3K/AKT and MAPK signaling in both latency and reactivation illustrate the complexity of latency and reactivation and may indicate roles dependent on timing and context of infection.

The LUNA latency-associated nuclear antigen is encoded antisense to *UL81-82* and is important for reactivation in monocytes.[300] LUNA possesses deSUMOylase activity and its overexpression induces desumoylation and dispersal of PML domains or ND10s.[490] The desumoylase activity of LUNA is required for reexpression of MIE genes, further suggesting that PML provides an important restriction contributing to viral latency.

HCMV and Hematopoietic Differentiation

The outcome of HCMV infection in hematopoietic cells depends on the lineage of cells infected within heterogeneous populations of HPCs.[134,209,315,369] This complicates understanding latency and reactivation in bulk, multilineage hematopoietic populations. In either primary or hESC-derived CD34+ HPCs, the most immature cells (CD34+/CD38-/CD90+ or lin-) support a persistent infection, whereas CD34+/CD38+/CD90+ or CD34+/CD38lo/CD90- cells support latency.[134,209] Other lineages that become infected presumably undergo abortive infection since they fail to reactivate or require a different stimulus for reactivation. Inhibition of signaling pathways (e.g., PI3K/AKT) can increase the frequency of infectious centers indicative of reactivation, but it not known if this represents an increased frequency of reactivation from CD34+/CD38+ subpopulations or if reactivation is induced in additional subpopulations.

While hematopoietic differentiation triggers reactivation of HCMV from latency, HCMV also has profound effects on hematopoietic differentiation and fate. HCMV has long been appreciated to be myelosuppressive in the context of hematopoietic stem cell transplantation.[375] The problem of myelosuppression is further complicated in the context of transplantation by the use of the antivirals, ganciclovir, foscarnet, and cidofovir, which have myelosuppressive affects. While the mechanisms by which HCMV inhibits hematopoietic differentiation are not fully mapped, there are both direct effects on the infected cell, as well as indirect effects on bystander cells or on the stroma supporting hematopoiesis. *In vitro*, direct infection reduces the formation of hematopoietic colonies, particularly multilineage colony formation by ≥50%.[233] The indirect effects on hematopoiesis are of central importance given that very few cells are infected in the host (an estimated 1 in 10,000 to 100,000 cells).[576]

Recent studies have defined HCMV gene products that induce or suppress myelopoiesis. miRUS5-2 blocks myelopoiesis by down-regulating the TGF-β transcriptional repressor, NGFI-A-binding protein (NAB1).[233] The resulting increase in TGF-β secretion is inhibitory to myelopoiesis of uninfected cells. Importantly, miR-UL22A down-regulates SMAD3 to block intracellular TGF-β signaling in infected CD34+ HPCs. These findings suggesting an intriguing model whereby HCMV miRNAs stimulate TGF-β secretion to block myelopoiesis of uninfected cells while maintaining proliferation and differentiation of infected cells. In contrast to miR-US5-2, the UL7 HCMV Flt-3R ligand stimulates myeloid differentiation *in vitro* and *in vivo*, increasing HCMV genome-positive CD14+ monocytes in the tissues of humanized mice.[135] Further, miR-US22-1 targeting of EGR1 is required for differentiation of infected CD34+ HPCs, in addition to reactivation.[411]

VIRUS CONTROL OF CELL BIOLOGY

HCMV is exquisite in its ability to manipulate cell biology for virus objectives, to replicate or establish or reactivate from latency. Virus-induced manipulation of signaling and stress pathways though virus entry and synthesis of viral genomes and proteins or through the action of specific viral proteins or miRNAs can have broad consequences for the outcome of infection and the infected cell. HCMV has been a fertile area of research for understanding the complexity of virus–host interactions—how the virus manipulates pathways for replication that might result in cell death or termination of infection unless further manipulated to precisely regulate the response. Due to space limitations, we provide online access to examples of host pathways manipulated by the virus to affect the outcome of infection. Most of these examples are best defined in the context of replicative infection in fibroblasts, and implications for latency, while likely important, are less clear.

Regulation of Cell Death

Cell death is an ancient host defense strategy that eliminates stressed or infected cells to limit viral spread. As cell death represents an immediate dead end for infection, all viruses have evolved mechanisms to control cell death. HCMV expresses cell death suppressor proteins and lncRNA early during infection of many cell types. A number of virus-encoded IE proteins were initially found to individually block apoptosis.[404] IE proteins play diverse roles impacting different regulated cell death pathways.[71,126,404] For in-depth discussion of HCMV proteins and lncRNAs that control cell death, please refer to supplementary online content: *Cell Biology of HCMV Infection 1: Regulation of Cell Death*

Regulation of the Infected Cell Proteome

As obligate intracellular parasites, viruses have evolved an array of mechanisms to ensure the synthesis of their own proteins and to shape the proteome of the infected cells for successful infection. Viruses are ultimately parasites of the host translation machinery as no virus encodes complete translation machinery. While many viruses all but eliminate host protein synthesis, cellular protein synthesis continues largely unabated or even increases in HCMV-infected cells.[649] HCMV impacts the global proteome by specifically recruiting or excluding mRNAs from polyribosomes. mRNAs encoding proteins involved in the DNA damage response, proliferation, ribosomal biogenesis, chromatin remodeling, organelle function, and vesicular transport are increased, whereas those involved in cellular differentiation and acquired immunity are decreased.[408]

HCMV regulates more than 10,000 host proteins and their transcripts during virus replication by a variety of mechanisms to shape the infected cell proteome.[443] Global proteome analysis has revealed that 89% of the 927 host proteins detected on the plasma membrane of fibroblasts change by at least twofold during HCMV infection[660] and 131 host proteins are targeted during HCMV infection for proteasomal or lysosomal degradation,[443] indicating a dramatic redesign of the host proteome. Only 1% to 5% of these have a corresponding change in mRNA, indicating a high level of regulation at the protein level. HCMV is understood to regulate the proteome by targeted proteasomal and lysosomal degradation and by miRNAs that target host RNAs for suppression. For more in-depth discussion, please refer to supplementary online content: *Cell Biology of HCMV Infection 2: Regulation of the infected cell proteome*.

Regulation of Host Cell Metabolism

Viruses depend on the host cell's metabolic resources for their replication, and cellular metabolic regulation has increasingly emerged as central to a wide range of cell fate outcomes, including oncogenesis, immune cell activation, proliferation, and cell death. Given the extent of HCMV's interactions with host cell biology, it is not surprising that it extensively modulates cellular metabolism. HCMV induces central carbon metabolism, including glycolysis, glutaminolysis, tricarboxylic acid cycle, fatty acid biosynthesis, and pyrimidine synthesis, all of which have been found to support productive virus replication.[530,563] While many questions remain, HCMV-mediated modulation of cellular stress, nutrient sensing, and proliferative pathways appears to be critical for instituting a metabolic state conducive to productive viral replication.[530,563] As an obligate parasite, it can be assumed that HCMV depends on the host cell for energy and biomolecular building blocks, yet it also appears that HCMV modulates metabolic activities for the production of specific virion components.[530,563] Many questions remain regarding the impact of HCMV-induced metabolic remodeling of host metabolism beyond virus maturation. For more in-depth discussion, please refer to supplementary online content: *Cell Biology of HCMV Infection 3: Regulation of host metabolism*.

PATHOGENESIS AND PATHOLOGY

HCMV infection and transmission in most people proceeds without symptoms or disease. Clinically apparent manifestations of HCMV infection are expressed almost exclusively in the context of congenital infection and in the immunocompromised host, including transplant recipients and HIV/AIDS and cancer patients undergoing immunosuppressive chemotherapy. This virus is also an occasional cause of infectious mononucleosis. Characteristics of CMV disease are discussed in section *Clinical Features*. Numerous books, reviews, and chapters have described person-to-person transmission, dissemination, and host control characteristics that place individuals at risk for HCMV disease.[63,66] From initial infection at the mucosal epithelium, HCMV infects diverse cell types and tissues, causing a systemic infection with persistent and sporadic shedding for life, as discussed in section *Latency*.

Entry and Transmission

Community acquisition of HCMV follows mucosal exposure to virus that is shed into oral and genital fluids, urine, and breast milk. Thus, repeated exposures to infectious virus in saliva or urine leads to virus transmission in adults and young children. Individuals exposed to infants shedding virus and infants exposed to HCMV through breast-feeding are high-risk settings for infection. Approximately 50% of breast-fed infants born to HCMV seropositive women will acquire the virus in the first few months of life and subsequently shed virus in saliva and urine for prolonged periods of time during infancy, exposing others. The high incidence of transmission in these settings makes these important routes of community acquired infections worldwide.[231] Rates of transmission between children less than 2 years of age are also elevated, likely the result of frequent exchange of saliva between young children.[88] In adults, sexual

transmission has been documented with virus shed into both cervical secretions and semen.[124] Mucous membrane epithelial cells are a portal of entry and produce progeny virus that spreads to microvascular endothelial and myelomonocytic leukocytes provide the means of dissemination throughout the body. In immunocompetent adults, these infected leukocytes likely seed the secretory organs such as salivary glands and kidneys and likely carry the virus to the placenta during pregnancy[476] as well as to bone marrow where this virus establishes lifelong residence.[566,576] Myeloid cell–mediated dissemination to distant tissues has been well described in MCMV models of virus dissemination.[176,177] The variety of cell types and organs that become involved depends on many poorly studied factors, including the size of the inoculum, the intensity of initial infection, innate immune clearance and, particularly, the adaptive immune response that generates antiviral antibodies and T cells.

Hospital-acquired (nosocomial) infections with HCMV can result from mucosal exposure but more often follows exposure to infected blood products or from allografts after transplantation. Transfusion of blood products from HCMV infected donors has long been known to represent a significant risk for the acquisition of HCMV and as a result, blood products from noninfected donors or that are leukocyte depleted[706] are now commonly employed for transfusion of at risk individuals such as premature infants and pediatric transplant recipients. In contrast to the success of strategies to limit HCMV infection from blood products, transmission of HCMV with any solid organ from infected donors remains a major route of HCMV infection in transplant recipients. Although HCMV is latent in myeloid progenitors, HCMV immunity is conferred along with bone marrow–derived cells in hematopoietic stem cell transplantation. The most risky setting for serious HCMV disease in HCT remains a HCMV seropositive recipient (R+) who receives a transplant from an HCMV seronegative donor (D-) because the donor cells lack immune experience with HCMV.

Intrauterine HCMV transmission from mother to the developing fetus results in cCMV infection. HCMV is transmitted *in utero* relatively frequently with congenital infection being present 0.2% to 1.0% of all live births.[297] Rates of cCMV are higher in maternal populations with increased rates of HIV infections, a finding that has been argued as evidence for the role of CD4 T cell–mediated immunity in limiting maternal to fetal HCMV transmission.[2,435] Interestingly, the increased transmission in pregnant women with poorly control HIV infection has been modeled in pregnant rhesus macaques which have been depleted of CD4+ T lymphocytes and challenged with rhesus CMV.[42] Unique to the epidemiology of cCMV infection is the observation that rates of cCMV infection are directly related to the seroprevalence of maternal population. There are examples of populations with high seroprevalence rates associated with high prevalence of cCMV in offspring.[65] Accordingly, cCMV can follow infection in both nonimmune women (primary maternal infection) as well as in women with preexisting immunity (nonprimary maternal infection).[65]

Intrauterine HCMV transmission has been proposed to follow maternal viremia that seeds the intervillous space of the placenta leading to infection of the villous, resulting in a villitis and loss of the cellular barrier that separates maternal and fetal blood. Because the human placenta is a hemochorial, only a single layer of cells, the placental syncytiotrophoblasts, separates the fetal circulation from the maternal circulation. Thus, focal loss of the barrier function provided by the syncytiotrophoblast layer is believed to lead to infection of underlying villous cytotrophoblasts and cells within the villous stroma containing fetal capillaries. Interestingly, HCMV DNA and HCMV-infected cells have been detected frequently in the decidua and from several sites in the

placentas from seropositive pregnant women who did not transmit HCMV to their fetuses.[477] Given that infection of the placenta is not sufficient for intrauterine transmission, there are likely to be host determinants of transmission to the fetal circulation. Finally, infection of the decidua has been shown to be associated with the infiltration of inflammatory cells, prompting suggestions that these cells serve as a reservoir for infection of the placenta and transmission to the fetus.[184,477,662] Once HCMV enters the fetal circulation, HCMV disseminates hematogenously within the systemic circulation of the fetus.

Although there have been many studies seeking to understand immune correlates in pregnant women that may guide strategies to prevent congenital infection[358,525] as well as to prevent or treat transplacental transmission,[444] the overarching picture remains complex. Mechanisms through which antiviral antibodies, T cells, or other immune mechanisms act at the maternal–fetal interface remain to be determined.[66,476] On one hand, HCMV is able to transmit in the face of natural levels of antiviral immunity during either reacquisition or reactivation from latency even though the frequency of transplacental transmission and congenital infection is dramatically lower than during primary maternal infection. On the other hand, there has been little progress in understanding differences in virus transmission occurring in primary or recurrent infection.

Even though antiviral immunity develops following acquisition of HCMV and systemic infection is brought under control, virus continues to be shed from secretory epithelium in body fluids for weeks, months or even years. The reasons for such prolonged shedding despite evidence of antiviral immunity has not been resolved, but immune mechanisms are certainly central given that the extended pattern of shedding in young children has been related to weaker CD4 T-cell response patterns.[218,359] During asymptomatic infection, epithelial, vascular endothelial and myelomonocytic cells that support HCMV replication are also likely targets of immune modulation by viral gene functions.

Immune Response and Immune Modulation

CMVs persist for life in the face of robust antiviral immunity that reduces risk of disease and sustains lifelong latency. Antiviral immune defenses are important from the initial encounter with this virus, acting within the infected cells (cell-autonomous response) as well as locally and systemically in the host. Host defense mechanisms are counterbalanced by virus-encoded immune modulators that mold response patterns to suit viral persistence and contribute to the status of HCMV as an opportunistic pathogen. Shortly after infection, nonspecific (innate) immune mechanisms restrict virus spread, handing off to antigen-specific (adaptive) immune mechanisms that generate lifelong immune memory. Natural killer (NK) cells, together with adaptive immunity mediated via B cells (antibody) and, in particular, T cells contribute to protection from reinfection and suppression of viral reactivation. Cytotoxic CD8+ T cells in particular, maintain control over this virus; although, host control is counterbalanced by viral functions that counteract T-cell effector mechanisms.[279,390,473] Evidence supporting this key immune control includes HCMV disease susceptibility of individuals with defects in T-cell function or undergoing T cell–suppressive immunotherapy.[275,277] Antiviral CD4+ T-cell immunity correlates with control over CMV shedding during childhood[491,629] and CD8+ T-cell transfer has long been recognized for conferring a benefit in settings of severe HCMV disease risk such as HCT.[560] HCMV infection has a unique relationship with the immune system, inducing virus-specific T-cell memory that expands over time (a pattern called memory

inflation), with decrease in CD4+ naïve T cells, and may reduce the ability to respond to other pathogens in old age.[276,630,664] HCMV infection shows a positive correlation with immune response parameters to other infectious agents and vaccines in small studies of young individuals, including identical twins,[68,69,196] although direct vaccination responses and host susceptibility to tuberculosis both show a negative correlation with HCMV infection.[58,424] Efforts to tie down health impacts of coinfection with HCMV in HIV-exposed newborns and children have suggested poorer outcomes[207] without any obvious impact on immune parameters.[577] Such correlations may reflect demographic or environmental factors unrelated to this particular virus,[87] such as comorbidities and other lifestyle issues, including the total number of lifelong infections.

Despite systemic HCMV-specific immunity, reinfection episodes[57] and infection with multiple strains of virus occurs relatively frequently.[139] Sporadic shedding may be high in children and young adults, but prevalence decreases with age.[20] Host immune control over HCMV is often incomplete[66] as observed in younger individuals as well as HIV-infected adults on antiretroviral therapy.[554] The extent to which host defenses are sidestepped by this virus may be ascribed to the arsenal of gene products elaborated during productive infection, persistence, and latency that act in a concerted fashion to mold cell-intrinsic, innate, and adaptive immune response parameters (see Supplementary e-Table 12.1). Because CMVs are species restricted and only infect their natural host, animal surrogates, primarily MCMV, RCMV, GPCMV, and RhCMV, have been studied in mice, rats, guinea pigs, and rhesus macaques, respectively. Information is imprecise owing to the fact that each of these surrogate models shows distinct genetic and environmental features, not the least of which is the high level of evolutionary divergence across the β-herpesvirus subgroup despite a common biology. Nevertheless, the study of such surrogates, particularly in mice and macaques has reinforced immune mechanisms that are most important in control of HCMV.[277,359] The unusual ability of CMV to superinfect, to maintain high frequencies of effector memory T cells and the ability of Rh CMV vectors lacking homologs of *UL128* and *UL130* to elicit unconventionally MHC-II-restricted and nonpolymorphic MHC-E-restricted CD8+ T-cell responses in lieu of conventionally MHC-I-restricted T cells has inspired the evaluation of HCMV vectors against immune evasive pathogens, such as HIV or TB.[191]

Immunity

Immunocompetent individuals generally retain an upper hand in the lifelong control over herpesviruses, including HCMV. Cellular immunity, both innate natural killer (NK) and adaptive T lymphocyte–mediated mechanisms, enable the host to maintain control, suppress replication, and sustain latency. Certain viral proteins, including m157-encoded NK cell activator in MCMV and the major viral tegument protein in RhCMV appear to promote host immune control over the virus. The importance of cellular immune surveillance to lifelong control over HCMV is revealed by the impact of this pathogen in immunocompromised host, supporting the importance of NK cells, helper T cells, and cytotoxic T cells in the control overactive viral infection. Sporadic virus replication in secretory epithelial cells and shedding in body fluids occurs independently of cellular immunity, but this immunity impacts systemic levels of virus. HCMV is rarely detected in the bloodstream in the immunocompetent host. Immunosuppressive therapies such as those used to prevent T cell–dependent allograft rejection following SOT

suppress cellular immunity and allow active systemic virus replication detected in the bloodstream that, depending on levels, promotes the progression to disease.

NK cells are the most prominent contributors to the innate antiviral immune response. As the major subset of group 1 innate lymphoid cells (ILCs), NK cells patrol systemically for abnormal cells, such as virus-infected and transformed cells. NK cells recognize reduced levels of natural MHC class I in the face of elevated levels of infection-induced stress ligands that trigger cytotoxic clearance.[455] These innate lymphocytes, first characterized during MCMV infection, mediate early control over HCMV as well as RhCMV.[37,185,472,604] Studies of the antiviral response to HCMV and MCMV suggest that clonal expansion of NK cells following their activation upon encounter with virus-infected cells leads to lifelong memory and readiness to respond to reinfection.[3,455] In mice that carry the NK-activating Ly49H receptor (an MHC I allele characteristic of C57BL/6 mice), MCMV-encoded m157 directly engages this receptor to trigger massive proliferation of NK cells that, despite contraction, remain elevated for life. Such memory NK cells respond to restimulation in a pattern reminiscent of memory T cells, giving this innate response at least some of the characteristics of adaptive immunity.[3] In humans, NK cells capable of an adaptive response are marked by expression of heterodimeric CD94/NKG2C receptor. Cells bearing this receptor increase dramatically over time in HCMV seropositive healthy donors, although the viral function responsible for triggering such behavior remains unknown. The inflammatory and regulatory cytokines that control NK cell expansion are better understood in MCMV-infected mice than in HCMV-infected humans. Overall the cytokine requirements for selection, expansion, contraction, and maintenance appear similar to T-cell expansion in response to viral antigen,[3] although this may be a consequence of MCMV m157 as a virus-specific activating ligand.[37,185] Much less is known about response and memory of NK cells that are activated independently of the m157–Ly49H axis, though m157-independent NK responses have been characterized.[197,436]

There is such an overwhelming and sustained expansion of antiviral T cells to CMVs that studies have sought to determine whether lifelong HCMV infection influences life span and other aspects of healthy aging.[217] Although a clear picture is yet to emerge, the commitment that most individuals make to control of HCMV is exceptionally robust. This may be important because individuals without adequate cellular immunity are at increased risk of disease, as occurs in seropositive recipients of allogenic HCT transplants from HCMV-naïve donors as compared to allogeneic transplants from MHC-matched HCMV immune donors.[560] In such settings, despite sustained serum antibody levels, host control is highly dependent on levels of memory T cells that are absent in HCMV naïve donors. Control over HCMV may be enhanced by direct transfer of MHC-matched CMV-specific CD8+ T-cell therapy. There are also specific settings where antiviral antibody contributes to host control over infection, through neutralization as well as other antibody-dependent mechanisms. Anti-HCMV antibody makes a contribution to host resistance, best illustrated by the long-standing observation that transferred maternal antibody prevents transfusion-acquired HCMV in low birth weight infants. In addition, an envelope gB subunit vaccine candidate reduces rates of infection in HCMV naive women, possibly through antibody-mediated mechanisms.[280] Protection conferred by other viral envelope glycoproteins such as the gH/gL pentamer has not yet been evaluated.[552,634] In line with the expectation that antibody directed against viral glycoproteins would protect, there is growing interest in the potential for intravenous gammaglobulin enrichs for HCMV-specific antibodies to provide prophylactic benefit by limiting intrauterine HCMV transmission or even therapeutic benefit by

limiting the congenital disease.[444]

MHC class I restricted cytotoxic CD8 T effector cells are the single most important host defense pathway responsible for controlling lifelong HCMV infection,[275,277,571] as first recognized in studies with MCMV.[487] Further insights have emerged from observational studies on clinically relevant HCMV reactivation in immunocompromised patients receiving immunosuppressive therapies that reduce cell-mediated immune surveillance, particularly in the context of SOT or HCT.[560] The appearance of active systemic infection in transplant recipients begins with triggering events that involve inflammatory cytokines, potentially acting to stimulate activation or differentiation of myeloid cells in which latent virus resides. These events compromise cell intrinsic host control mechanisms favoring reactivation (see section *Latency*). In the natural infection setting, major histocompatibility antigen mismatch triggers tissue rejection that is also associated with the production of inflammatory cytokines such as TNF.[534] These contributions are supported by studies in MCMV[130,259] in addition to direct evaluation of HCMV.[186] Most recently, SOT studies in MCMV-infected mice have brought to light a potential role of organ ischemia–reperfusion independently of MHC class I mismatch[700] that deserves additional investigation. Disease results when viral levels, as assessed by measuring viral DNA in whole blood or plasma, rise above a threshold that informs preemptive approaches for therapeutic intervention.[66]

Although viral infection is systemic, HCMV disease generally affects a particular tissue, particular organs, such as lungs, gastrointestinal tract or liver, or specific sites such as the retinal neuroepithelium or vascular endothelium. The pattern of disease suggests that immune/inflammatory signals act in concert with viral replication levels despite the immunocompromised state of the individual.[66] Analogous events likely occur in other settings where HCMV reactivation contributes to disease, such as during pregnancy in seropositive women, where reactivation and amplification precede transplacental transmission to the fetus. The cellular arm of the immune response is responsible for protection in transplant settings based on three considerations: (a) when cellular immunity is compromised, virus reactivation risk increases and classic opportunistic disease consequences follow, (b) therapies that disrupt cellular immunity, particular CD8-dependent cytotoxic T effector cells, pose the greatest threat, and (c) adoptive T-cell therapy prevents disease. Virus-specific antibody is likely to contribute to protection from exogenous infection and transplacental transmission but appears to be less critical overall for control of HCMV. Importantly, these host defense mechanisms operate despite the arsenal of immune modulators encoded by this virus.

Immune Modulation

HCMV commits the majority of its genome coding capacity to altering host defense against infection (Supplementary e-Tables 12.1 and 12.2). All classes of viral gene products expressed during productive replication (IE, E, and L) as well as latency-associated proteins and noncoding RNAs make major contributions to modulation of the host response to infection. Notably, viral genes committed to immune modulation are themselves typically dispensable for replication within cultured fibroblasts. These are sometimes lost spontaneously from laboratory strains over the course of passage in cell culture. Modulatory activity has typically been revealed experimentally by expressing an isolated viral gene product and characterized as sufficient to suppress some specific immune pathway. The necessity for particular virus-encoded modulators

to have an impact on a particular pathway can only be established using infected cells, typically comparing mutant viruses to a parental strain. Human host specificity limits full evaluation of individual HCMV-encoded modulatory gene products, driving interest in use of surrogate animal betaherpesvirus models. There are three major categories of modulatory functions: (a) gene products acting within the infected cell (intrinsic or autonomous) to restrict infection, including those that impact gene regulation, pathogen sensing, cellular metabolism, cell cycle, and cell death pathways; (b) gene products acting within the host organism in concert with innate immune mechanisms, including those that affect inflammatory cytokine and NK cell responses; and, (c) gene products acting within the host organism at the adaptive immune level, modulating either elicitation or execution of antigen-specific T- and B-lymphocyte responses. Many viral functions target immune effector mechanisms that are dependent on lymphocytes. In addition to modulatory functions that evade host clearance mechanisms, virus-encoded proteins and RNAs also exploit host response pathways. The arsenal of virus-encoded modulators ensures the success of viral infection, supporting systemic dissemination, sporadic shedding, and persistence. As with other herpesviruses, major viral regulatory and replication functions often carry secondary roles in modulating the host cell response.[4] These functions make a substantial commitment to suppressing pathogen sensing, IRF3 and NF-κB activation, type I IFN induction, and the antiviral consequences of IFN-dependent host defense pathways as well as INF-independent host-encoded restriction factors,[28,45,153,211] as overviewed in earlier sections.

Each HCMV-encoded immune modulator targets one or more steps in a host defense pathway, most often dampening the impact of the pathway. Despite elaboration of many such modulators, the host defense mechanisms against which they are deployed have proved important in the control of infection. Thus, HCMV commits substantial coding potential towards functions that modulate innate NK- and adaptive T-cell immune mechanisms that are also recognized to control infection. CMVs that infect different, even closely related animal species typically encode modulatory functions that target different points in otherwise conserved host defense pathways. Remarkably, each species of CMV appears to have coevolved within the mammalian species with which it is associated today. CMVs do not appear to jump from species to species. This species-specific evolution produced different solutions to the general problem of how to evade a common set of host immune effector mechanisms.

Although many host pathways have been shown to be suppressed by HCMV gene products, this virus also enhances specific immune pathways, including the production of certain cytokines and chemokines that recruit and activate immune cells as well as deployment of virus-encoded chemokine receptors to modulate myeloid cell behavior. These functions exploit cytokine-dependent signaling to benefit the virus.[28,76,212,279,345,422,472,473] On balance, there are more virus-encoded inhibitors than there are functions that exploit immune stimulation. Stimulated pathways are nevertheless likely to provide the signature features of HCMV infection, persistence, and disease. Virus-encoded functions that either modulate or mimic cytokine and chemokine pathways serve important roles in infection, orchestrating immune cell development, homeostasis, and trafficking in the interests of the virus. Important examples of exploitation include HCMV-encoded *UL138* enhancement of TNFR1[344,421] and EGFR,[77] conferring increased sensitivity to cytokine (TNF) and growth factor (EGF) stimulation, viral US28-encoded chemokine receptor acting constitutively as well as following stimulation by host CC and CX3C chemokines, and viral *UL146*-encoded vCXCL1 recruitment of leukocytes bearing hCXCR1 and hCXCR2. These positive-acting modulators potentially shape the antiviral immune

response as much as those that suppress immune pathways. Furthermore, UL138 and US28 have an impact on latency, but it is important to recognize that these potent positive-acting immune modulators are expressed at all times of infection.

Modulation of Cell Autonomous Response to Infection

CMVs encode many gene products that alter the cell-intrinsic response of infected cells and production of cytokines, particularly type I IFN.[28,153,212,345] HCMV counteracts host cell sensing and restriction metered out via cGAS-STING, IFI16, ZBP1, ND10-Sp100-hDaxx complex, SPOC1 and GAL-9, and MxB together with the effectors controlled by pathogen sensors and the IFN response.[153] Impacts on epigenetic regulation via LUNA, IE72, and pp71/UL35 affects replication, latency, and reactivation. NF-κB, IRF3, and IFN are all targeted by viral proteins as well as by lncRNA1.2.[340] Other IE proteins assure that viral and cellular transcriptional regulators remain balanced as described in section *Pre-IE Events and Intrinsic Responses to Infection* and ensure survival of the infected cells by inhibiting cell death. *UL36*-encoded vICA and UL37x1-encoded viral mitochondrial inhibitor of apoptosis (vMIA) are cell death suppressors whose mechanisms are well understood and whose functions are evolutionarily conserved in MCMV and HCMV.[71] In addition, studies of MCMV M45-encoded viral inhibitor of RIP activation (vIRA) brought the unique host defense value of necroptosis to light. Cell death suppressor vMIA has a direct impact on the timing and death pathways elaborated during infection of cultured cells, and the function of vICA provides broad protection from the death consequences of TNF signaling[391] as described in *Cell Biology of HCMV Infection 1: Regulation of Cell Death*.

Modulation of the Innate Immune Response to Infection

HCMV modulates cytokine signaling and encodes cytokine, chemokines, and chemokine receptors. The *UL22A* gene product is a secreted CC chemokine sponge, suggesting that attraction of certain leukocytes to sites of infection is discouraged. US28 responds to some of the same CC chemokines targeted by UL22A but in addition is a receptor for CX3CR1/fractalkine, a chemokine system that supports leukocyte patrolling the bloodstream. The balance of constitutive US28 activity and chemokine-induced activation has many effected on infected cells and viral dissemination (see section *Latency*). Virus-encoded UL146 is a potent CXCL8/IL-8–like chemokine (vCXCL1) that recruits cells expressing CXCR1 or CXCR2, including granulocytes (neutrophils) and monocytes.[274] The recruitment of these populations alters the inflammatory environment and likely facilitates viral dissemination.[241]

NK cells eliminate virus-infected cells, produce antiviral cytokines, and recruit and activate T cells. They are crucial for control over herpesviruses based on the susceptibility of individuals with NK-cell primary immunodeficiencies.[153] HCMV encodes a remarkably expansive set of gene products aimed at disarming the innate NK-cell response.[153,472] In humans, where the NKG2C receptor–positive NK cells become a long-lived memory population[3,153,185] the initial expansion appears to be mediated by a long-recognized UL40 leader peptide presented in HLA-E, a ligand for the activating CD94/NKG2C receptor[230] that may influence CD8+ T cells as well.[286] HCMV manipulates the availability of ligands for the NKG2D receptor, all stress-induced ligands rarely displayed on healthy cells that, when present, trigger NK-mediated destruction. These MHC class I–like family proteins (MICA, MICB and ULBP1 to ULBP6)

contain alpha domains but do not bind β2-microglobulin-like conventional MHC class I and are targeted for degradation by viral modulators. MICA is targeted by UL142, UL148A, US9, US18, and US20, possibly because there are many allelic variants of this stress signal. MICB is targeted by noncoding RNA miR-UL112 as well as UL16, a promiscuous modulator that also targets ULBP1, ULBP2, and ULBP6. UL142 targets ULBP3 and US18 and US20 target B7-H6, a ligand for NKp30, in addition to MICA. Other adhesion molecules that are ligands for NK CD226/DNAM-1 are targeted by UL141, which also inhibits TRAIL-dependent NK activity, and US2, most well known as an MHC class I inhibitor. Finally, MHC class I–like UL18 on the infected cell surface engages NK inhibitory receptor LIR1/ILT2. Other adhesion proteins on infected cells are impacted by UL148. This multitude of functions supports viral evasion of NK cell killing although they do not prevent control via this host defense pathway.

Modulation of Adaptive Immune Response to Infection

Natural HCMV infection is highly immunogenic, resulting in broad humoral antibody as well as cellular T-lymphocyte responses that persist for life and maintain control over the virus. Nevertheless, HCMV encodes a wide range of functions that disarm both the elicitation and the execution of the adaptive immune response. Classical DCs carry out antigen presentation. Both Langerhans cells and myeloid DCs are susceptible to HCMV infection and are likely to be impacted by viral modulation of MHC class I antigen presentation, particularly by US2, US11, and major viral tegument proteins pp65 and pp71. The elaboration of cmvIL-10 results in the activation of DC-SIGN, potentially increasing susceptibility to infection, altering the behavior of lymphocytes, and inhibiting DC functions to aid viral escape from the full brunt of adaptive immunity.

T-cell immune surveillance provides crucial control preventing amplification of virus throughout life. Some of the first HCMV-encoded immunomodulatory functions discovered downmodulate the ability of T cells to recognize HCMV-infected cells.[473] Thus, classical and nonclassical MHC class I antigen presentation is targeted by US2, US3, US6, and US11, as well as US8 and US10. UL144 triggers coinhibitory receptors on infected cells, and UL11 drives cellular IL-10 production to dovetail with viral *UL111A*-encoded cmvIL-10,[29] altogether impeding T-cell activation and effector function to the benefit of the viral persistence.[489] Importantly, cmvIL-10 is detected in the bloodstream of healthy HCMV-seropositive individuals consistent with experimental studies showing its impact on the host immune environment.[689] The ability of viral IL-10 to tag-team with host regulatory cytokines is shared with RhCMV.[168] Although each of these modulatory functions is sufficient to have an impact, it is important to note that host antiviral CD8+ T cells remain essential in lifelong immune control over systemic levels of HCMV, although specific modulation of CD4+ T cells potentially relates to patterns of viral shedding. Deletion mutant unable to reactivate from latent infection retain the ability to induce effector memory T-cell responses, providing a potential live attenuated HCMV vaccine or vector.[90] The qualities of the human immune response directed against HCMV represent the consequences of an ancient evolutionary relationship between a multitude of viral modulators and mechanisms of host defense.

EPIDEMIOLOGY

Prevalence and Epidemiology in Populations

HCMV is ubiquitous in all populations in the world with rates of infection as determined by serological evidence of infection (seroprevalence) ranging from 45% to 100% worldwide.[87] There are nearly universal rates of infection in South America, Africa, and Asia, and lower seroprevalence is reported in the United States and in some countries in northern Europe. In populations with high rates of HCMV seroprevalence, HCMV is acquired early in childhood such that by late adolescence, most individuals are infected. In the United States and in some countries in northern Europe, HCMV seroprevalence has been shown to vary between different racial and ethnic groups and is dependent on socioeconomic status resulting in the epidemiology of HCMV in some urban populations in the United States and Europe being more similar to populations in South America and Asia.[173,189,351] Sources of virus that are associated with increased rates of virus acquisition in community settings include breast-feeding, exposure to young children, crowded living conditions, group child care, and poverty.[231,261,589,701] HCMV is considered a sexually transmitted infection (STI); thus the seroprevalence in sexually active populations is increased and risk factors for acquisition of other STIs are also linked to HCMV infection.[590]

As with other human pathogens, the average age of initial acquisition depends on frequency of contacts as well as hygiene. Although breast-feeding in areas of high seroprevalence contributes substantially to early acquisition, most transmission in the world occurs early in life in direct correlation with crowding and contact frequency, features that were first established by observing transmission patterns in day care centers.[63]

Reacquisition of HCMV throughout life apparently occurs frequently in certain populations[36] despite the apparent benefit of adaptive antiviral immunity, with the consequence of that lifelong mixed infection appears more prevalent in some populations. The ability of HCMV to overcome levels of natural antiviral immunity remains a recognized concern for vaccine development. Women, as well as men, under the age of 50 who carry HCMV from childhood represent a reservoir where sporadic reactivation and shedding in urine (as well as saliva, vaginal secretions, seminal fluid, and breast milk) contribute to spread. The U.S. population sheds virus in urine between 3% and 10% of the time, decreasing with age.[20]

Genetic Diversity

Studies utilizing next generation sequencing NGS have described considerable genetic sequence diversity in virus populations even within a single individual and have provided evidence that HCMV infection is usually associated with transmission of a population of viruses with diverse genotypes.[139,465,485,521] Although there is debate about the extent of genetic diversity in viral populations from different patient populations, there is agreement that population of viruses can replace existing populations of viruses in patients who are reinfected (superinfected) by an exogenous source of virus.[139,485] The source of the genetic diversity of HCMV likely involves recombination events between viruses with different viral genotypes.[139] In addition, genetic diversity is believed to follow selection of viral mutants secondary to exposure to different pressures during virus replication such as host antiviral immune responses, antiviral therapies, or the presence of genetic bottlenecks secondary to restricted replication in different host compartments following virus dissemination.[485] Lastly, it has been argued that the generation of

genetic diversity by recombination between different viral genotypes is a relatively slow process that can explain HCMV evolution but is inconsistent with divergence of viral populations within a single individual over a short period of time.[607] Thus, the increased genetic diversity that has been observed in some individuals is believed to reflect the acquisition of new populations of viruses and potentially, the *de novo* expansion of genetic variants.

Mechanisms that contribute to the observed genetic diversity in HCMV isolates have considerable relevance to the natural history of perinatal HCMV infections. Maternal nonprimary HCMV infections during pregnancy account for most cases of congenital HCMV infection, yet the source of these infections remains poorly defined in most maternal populations.[434,651] Two mechanisms have been suggested: (a) reactivation of virus during pregnancy in a previously infected women and spread to the developing fetus, and (b) exogenous infection with a new and genetically diverse populations of HCMV.[64] Even though virus reactivation leading to a recurrent infection represents a decades-old paradigm, evidence supporting this mechanism cannot be considered definitive because of limitations in methodologies used to establish this paradigm in these early studies. Exogenous reinfection of previously infected women as a mechanism for nonprimary maternal infection is supported by several findings including (a) early studies that demonstrated sequential infection by new viral genotypes in normal infants and children in group care settings, (b) epidemiological associations between nonprimary infections and known exposures risks for virus acquisition, (c) sequential recovery of genetically divergent viruses from women attending an STI clinic, and (d) evidence of serological conversion to a new "serotype" of HCMV in women undergoing nonprimary infection during pregnancy with subsequent transmission their fetus.[36,52,531,687] Although ongoing studies will more definitively address the importance of genetic diversity of HCMV in maternal nonprimary infections, defining the source of HCMV infection in previously infected women is of considerable importance to current strategies to induce protective immunity through vaccination of women of childbearing age.

CLINICAL FEATURES

Immunocompetent Host

Community acquisition of HCMV is sometimes associated with mild influenza-like symptoms or infectious mononucleosis, but disease is typically self-limiting. Although HCMV infections are common in all age groups, clinically apparent infection is infrequent in every age group. Early studies described an infectious mononucleosis syndrome similar to that described in EBV infection and estimated that HCMV could account for 20% of cases of heterophile negative infectious mononucleosis. Although clinical and laboratory findings in cases of HCMV mononucleosis are nonspecific, individuals with HCMV mononucleosis and those with asymptomatic infection can shed infectious virus in the saliva, urine, and genital secretions for prolonged periods of time. In young children and in particular, infants infected in the postnatal period, high levels of virus shedding can persist for months and, in some cases, years after infection and thus, likely represent a major source of community exposure to HCMV.[86]

Perinatal Infections

Perinatal HCMV infections include infants infected *in utero* (congenital infection, cCMV), during birth, and following exposure to virus containing breast milk. Of these, cCMV infections are the most important. cCMV infection is the most frequent viral infection acquired *in utero* with a prevalence of 2 to 10 per 1,000 live births. More than one million new congenital infections are predicted to occur each year worldwide with 20% of these babies showing damage either present at birth or developing over the first few years of life. About 30% of women undergoing a primary HCMV infection during pregnancy transmit virus to their offspring with virus transmission to the fetus being highest in the late 2nd and 3rd trimester, but reported in all trimesters of pregnancy.[172,297] Intrauterine transmission in the late 1st trimester and early 2nd trimester is associated with a greater likelihood of clinical abnormalities at birth (symptomatic infection), central nervous system (CNS) damage, and long-term neurodevelopmental abnormalities.[172,178] Transmission rates following nonprimary maternal infections remain undefined, and definitive data demonstrating that maternal immunity prior to pregnancy can limit intrauterine transmission are limited.[65] Notably, the incidence of symptomatic infection and neurodevelopmental sequelae in infants infected *in utero* following a nonprimary maternal infection is strikingly similar to that in infants infected *in utero* after primary maternal infection.[62,614,627] Lastly, the incidence of hearing loss, the most frequent long-term sequelae in infants with cCMV infection, appears similar in infected infants regardless if born to women with primary or nonprimary infections during pregnancy.[532,686] Thus, the role of preexisting maternal adaptive immunity in the natural history of cCMV infection, in modifying both intrauterine transmission and the consequences of intrauterine infection, remains incompletely defined and impacts strategies to limit disease by prophylactic vaccines.

Overall, about 90% of infants with cCMV have asymptomatic infections with 10% having clinical findings associated with intrauterine infection. Clinical and laboratory findings in infants with symptomatic infections are described in Table 12.1. Nearly 50% of infants with symptomatic infection will have long-term neurodevelopmental sequelae while about 10% to 15% of infants with asymptomatic infection will have long-term neurodevelopmental abnormalities. Long-term sequelae of cCMV are limited almost exclusively to the CNS and can include severe neurodevelopmental findings in infants with microcephaly and structural brain damage, findings present in about 35% of infants with symptomatic infection and overall, less than 5% of all infants with cCMV infections.[162] More frequently, infants with symptomatic infection exhibit delayed neurodevelopment, hearing loss, disorders in balance, and, rarely, visual disturbances. Sequelae in infants with asymptomatic infections are most often limited to hearing loss and balance disturbances. While viral burden appears to be related to the severity of cCMV infection,[51] recent results from animal models of CNS disease in infants with cCMV suggest that the pathogenesis of the CNS infection in infants with cCMV cannot be attributed solely to virus replication and that other mechanisms of disease including virus-induced neuroinflammation could contribute to CNS damage.[558] Lastly, infants with cCMV, regardless whether with symptomatic or asymptomatic infections, shed large amounts of virus, sometimes on the order of 10^6 genomes/mL of urine or saliva for years and thus serve as a reservoir for spread of HCMV to other infants and adult caretakers.[86]

HCMV infection acquired during birth or early in the perinatal period rarely result in clinical symptoms and long-term sequelae in term infants. In contrast, premature infants infected in the

postnatal period can develop severe infections with multiorgan disease. More recently, the importance of HCMV infection in premature infants exposed to HCMV containing breast milk from seropositive women has been well documented as a cause of clinically significant infections, including hepatitis, pneumonitis, and sepsis-like syndromes; however, quantifying the importance of HCMV infection to long-term neurodevelopmental outcomes in these infants has been confounded by the impact of prematurity on neurodevelopment.

Opportunistic Infections in Immunocompromised Hosts

Serious HCMV disease generally follows when virus levels rise above a threshold, such as in immunocompromised people with genetic or acquired immunodeficiency or when subjected to immunosuppressive therapy, after transplantation or during cancer chemotherapy.[66,217] HCMV pathogenesis in the immunocompromised first came to attention in solid organ transplant recipients[663] but rose to prominence with the AIDS epidemic.[245]

HIV/AIDS

Prior to remarkable success achieved by antiretroviral therapies (ART) for HIV/AIDS, HCMV was one of the most common opportunistic infection in patients with HIV/AIDS. Not only was HCMV a major cause of end organ disease, but HCMV DNAemia was strongly associated with more rapid progression to AIDS defining illnesses and mortality in individuals with HIV.[584] Common clinical manifestations of end-organ disease associated with HCMV infections included esophagitis, colitis, hepatitis, and, unique to HIV-infected hosts, retinitis. Although HCMV retinitis has been rarely reported even in the most immunocompromised transplant recipients, prior to the availability of ART HCMV retinitis was commonly diagnosed in patients with AIDS.[608] Currently, HCMV end-organ disease is relatively infrequent and is observed only in untreated HIV/AIDS patients or those with poorly controlled HIV infection.

Solid Organ Transplantation

Herpesvirus infections in allograft recipients are frequent in the posttransplant period secondary to transplant protocols and immunosuppressive agents that limit both adaptive and innate responses. Infections with HCMV are perhaps the most common and occur in a significant number of SOT recipients, depending on specific risk factors. Although a risk stratification based on the HCMV immune status of the SOT recipient was established decades ago, it remains relevant for all but the most immunosuppressed SOT recipients. The highest risk category is an allograft from a seropositive donor transplanted into a seronegative recipient (D+/R−), whereas the lowest risk is an allograft from a seronegative donor transplanted in a seronegative recipient (D−/R−). The transplantation of an allograft from a seropositive (or seronegative) donor into a seropositive recipient (D+/R+ or D−/R+) represents an intermediate risk. In addition to these risk stratifications, the selection of T lymphocyte–depleting agents used to prevent early graft rejection are also major determinants of the risk for HCMV infections. The use of a polyvalent rabbit antithymocyte globulin (ATG) may result in a higher risk of severe infection than treatment with monoclonal antibodies against CD25 or CD52.[244,624,667] These and other data argue strongly for the critical role HCMV-specific T-cell immunity plays in the control of HCMV in SOT recipients, a finding that was first described in the 1980s and that now has been

translated into quantitative assays of HCMV-specific T-cell reactivity to refine estimates of the risk for HCMV infection and disease in SOT recipients.[331]

The clinical spectrum of HCMV infection in the early posttransplant period of SOT recipients ranges from a collection of clinical findings and symptoms described as the CMV syndrome to organ- and life-threatening end organ disease. The CMV syndrome is perhaps the most common presentation of HCMV infection in SOT recipients and includes fever, fatigue, low white blood counts, reactive lymphocytes, elevated hepatic transaminases, and HCMV DNAemia.[374] Other manifestations of HCMV infection in the early posttransplant period are described in Table 12.2. In contrast to a direct role for HCMV in end organ disease in the early posttransplant period that is likely related to virus replication, the contribution of HCMV to chronic rejection and graft loss in the late posttransplant period is well appreciated but poorly defined mechanistically. HCMV infection has been associated with loss of cardiac allografts secondary to graft rejection and the development of characteristic histopathological findings associated with narrowing of the lumen of coronary arteries of the allograft termed cardiac allograft vasculopathy (CAV).[152,283] Although mechanisms leading to CAV remain undefined, the combination of ongoing allograft rejection and HCMV replication appears to hasten the loss of the allograft.[278] Similarly, HCMV has been linked to chronic rejection and loss of renal allografts with characteristic histopathological findings of tubulointerstitial nephritis and tubular atrophy.[166,461,580] Animal models of both CAV and chronic renal allograft rejection have provided evidence consistent with the contribution of HCMV to chronic allograft rejection, including a direct role for HCMV infection of relevant cell types in the allograft.[266,601,602]

Hematopoietic Cell Transplantation

HCMV infection or reactivation in HCT recipients has been associated with decreased survival, including decreased survival unrelated to relapse of the underlying malignancy.[215,617] HCMV infection can be demonstrated in about 50% of HCT recipients and depends on several risk factors for HCMV acquisition and/or reactivation. A significant risk for HCMV in HCT is previous HCMV infection in the recipient such that the highest risk category is donor seronegative and recipient seropositive (D−/R+) while the combination of donor seropositive and recipient seronegative (D+/R−) represents an intermediate risk category. This risk stratification is in contrast to donor/risk stratification in SOT presumably because the risk for HCMV transmission from a seropositive donor is dependent on the number of nucleated cells in the graft and the efficiency of transmission relative to that of an infected allograft in SOT is reduced.[464,478] Other risk factors for HCMV infection that have been identified are related to the level of suppression of adaptive immune responses and include specific T lymphocyte–depleting strategies, MHC (HLA) mismatches between donor and recipient, umbilical cord stem cell transplantation into seropositive recipients, and graft versus host disease requiring steroid therapy.[394,573] The clinical findings in HCT transplant recipients with HCMV infection range from virus shedding to life-threatening end organ disease, such as HCMV pneumonia (Table 12.2). In these severely immunocompromised populations, differentiating patients with asymptomatic virus shedding from those who will progress to end-organ disease and thus benefit from aggressive interventions with antiviral agents remains a significant challenge. Lastly, an issue that continues to complicate HCT in a small but significant number of recipients is the development of late-onset HCMV disease after discontinuation of antiviral prophylaxis.[27,48]

Clinically, late-onset disease can have mortality rates as high as 50%.[174] Analogous to the role of adaptive immune response in the control of HCMV in the early transplant period, individuals with late-onset disease appear to have persistent deficits in HCMV-specific T-lymphocyte responses.[48,141,182]

TABLE 12.2 Clinical manifestations of HCMV infections in solid organ transplant recipients

Clinical Findings	Laboratory Findings
CMV syndrome • Fever • Fatigue • Nonspecific clinical findings	• Decreased white blood cells • Decreased platelets • Reactive lymphocytes • Elevation of hepatic transaminases • HCMV DNAemia
End organ disease • Gastrointestinal disease, including esophagitis, colitis, and hepatitis • Pulmonary disease with increasing oxygen requirements • Central nervous system findings consistent with encephalitis	• HCMV DNAemia • Elevation of hepatic transaminases • Biopsy evidence of HCMV infection • Abnormal lung imaging findings • HCMV positive bronchoalveolar lavage fluid • CSF pleocytosis • Abnormal CNS imaging findings
Allograft dysfunction	• Declining graft function • Evidence of graft rejection

Associations With Other Diseases Including Chronic Disease

HCMV infections have been associated with a spectrum of human diseases for which specific etiologies remain undefined. In some cases, HCMV has been proposed to exacerbate the underlying mechanism of disease such as the proposed role of HCMV in vasculature disease including coronary artery disease through its contribution to both local and systemic inflammation.[138,528] HCMV has also been associated with human cancers, including glioblastoma.[119,343] Studies from a number of laboratories have consistently demonstrated the presence of HCMV-encoded proteins or viral nucleic acids in tissues from human glioblastoma and animal models have provided evidence for a contribution of HCMV to malignant phenotype of these tumors, yet a mechanistic role for HCMV in this human cancer remains to be defined.[167] Diseases commonly associated with lifelong HCMV infection include other cancers, inflammatory syndromes, chronic periodontal disease, neurodegenerative diseases, and immune deterioration as individuals age.[281]

In contrast to these associations, HCMV infections have been more convincingly argued to contribute to the immune dysfunction observed in older individuals.[446] The immune dysfunction associated with HCMV has been attributed to the large proportion of the adaptive immune response directed against this persistent virus.[312] Studies have demonstrated that in normal individuals persistently infected with HCMV, up to 15% of circulating T lymphocytes will have reactivity specifically for HCMV.[610] The commitment of significant proportion of the normal T-cell repertoire to HCMV is thought to contribute to immune dysfunction described in older individuals, although recent studies have argued against restriction of the T-cell repertoire by HCMV infection or loss of function of T cells as explanations for the immune dysfunction in the elderly.[363] HCMV infections have also been proposed to increase the severity of the clinical course of patients with bacterial sepsis through mechanisms that do not appear directly related to

virus replication.[360,392] Lastly, HCMV infection as defined by the presence of HCMV DNAemia or HCMV in biopsy specimens has been considered to be a cofactor in the exacerbations of inflammatory bowel disease (IBD), particularly ulcerative colitis.[120,157,347] The role of HCMV in exacerbations of intestinal inflammation in patients with IBD remains to be defined, but recent studies have suggested that HCMV infection could induce a proinflammatory phenotype in lamina propria macrophages.[154] In summary, these examples of interactions between HCMV and the adaptive and innate immune systems argue that persistence of this virus and its capacity to induce a variety of proinflammatory responses that could, in turn, negatively impact human health, at least in later years. Curiously, the overall elevation of immune markers in matched HCMV-seropositive and -naive twins together with a direct correlation of long-term HCMV infection with better vaccine responses in young adults has suggested this infection comes with benefits to the host.[68]

DIAGNOSIS

Characteristic cytomegalic cells are present in the epithelium lining the secretory ducts of the salivary glands, kidney, lactating breast, vaginal tract, seminal vesicles, and placenta of both immunocompromised adults or congenitally infected newborns and asymptomatic immunocompetent individuals, consistent with ubiquitous patterns of persistent shedding and transmission across the general population[20] as well as across the placenta.[63,66] Within the host HCMV remains cell associated such that common patterns of shedding in saliva and urine originates from infected epithelial cells in secretory organs. In other secretions such as semen and breast milk, both cell-free and cell-associated viruses have been observed. Whether present in healthy or diseased tissues, or in cultured cells, HCMV cytopathology coincides with late-phase productive infection (Fig. 12.13) in which enlarged cells take on a kidney-shaped nucleus distorted by a distinct cytoplasmic inclusion formed by the viral assembly compartment (Fig. 12.12).

Viral nucleic acid amplification technologies (NAATs) and viral antigen detection represent contemporary approaches for the laboratory diagnosis of HCMV infections. Virus-specific serology, including IgM testing and IgG avidity assays, remains an important tool for detection of both recent and previous HCMV infection (Table 12.3). The detection of HCMV DNA by quantitative PCR is the most frequently employed approach for the diagnosis of HCMV infection, and serial measurements of viral DNA has largely replaced other assays for virological monitoring patients at risk for invasive HCMV infection. Harmonization of the results from NAAT assays reported from laboratories in different centers has been attempted because center-specific methodologies have often confounded the interpretation of viral loads that have been reported in clinical studies.[192,240,505] In contrast to the experience in monitoring of transplant patients, successful application of qPCR assays to large-scale screening of newborn infants for HCMV shedding was accomplished in a multi-institutional study (CHIMES) using a saliva-based qPCR assay.[53] Detection of HCMV nucleic acids in tissues from biopsy by *in situ* DNA hybridization represents a sensitive approach to identify invasive HCMV infections by providing definitive evidence of HCMV in tissues from infected individuals. Viral antigen detection by immunohistochemistry remains a standard approach to complement routine histopathology of

tissue specimens from patients suspected of having invasive HCMV disease and often provides evidence of HCMV infection with a greater sensitivity than that achieved with routine histologic stains.

TABLE 12.3 Diagnostic approaches for detection of HCMV infection

Assay	Application	Characteristics
Traditional assays		
Virus Isolation	Recovery infectious virus from clinical specimens	Dependent on quality of clinical material; prolonged culture periods; low sensitivity
Histopathology	Identification of HCMV infected with typical inclusions (owl-eyes)	Routine tissue processing; low sensitivity
Contemporary assays		
Nucleic acid amplification (NAT)	Quantitation of HCMV DNA in variety of specimens	Rapid, sensitive, and quantitative; can be used to define viral genotypes
DNA *in-situ* hybridization	Semiquantitative, sensitive detection of HCMV DNA in tissue	Technically challenging; long turnaround times
Viral antigen detection (Immunohistochemistry)	Sensitive detection of HCMV in tissue, blood cells, and infected cells in tissue culture	Rapid; technically straightforward; semiquantitative
HCMV-specific IgM serology	Identification of recent infections	Limited by variability in duration of response and low titers of IgM antibodies
HCMV-specific IgG serology	Detection of past infection with HCMV; seroprevalence studies; risk stratification for allograft recipients	Rapid; technically straightforward; quantitative
HCMV-specific IgG avidity	Useful to estimate duration of HCMV infection when only IgG serological reactivity present	Interpretation limited to high and low values of avidity; not of value in allograft recipients

The demonstration of HCMV-specific antibody reactivity has been long recognized as a reliable approach for the detection of HCMV infection and remains a standard laboratory approach for identification of infected individuals, for seroprevalence studies, and in stratifying risk for HCMV infection in allograft donors and recipients. Although the detection of HCMV-specific anti-IgM antibodies in immunocompetent individual has been used to estimate recent infection with HCMV, results from this assay can be confounded by the persistence of anti-HCMV IgM antibodies for months following primary infection in some individuals and limited sensitivity secondary to low titers of HCMV-specific anti-IgM antibodies. Modification of standard assays for anti-HCMV IgG antibodies by the inclusion of chaotropes such as urea to disrupt IgG antibody binding to HCMV antigens have been used to classify anti-HCMV IgG binding antibody responses into high and low avidity as an estimate of the duration of the IgG responses following primary HCMV infection. This assay has been used to identify pregnant women undergoing primary infection with only IgG anti-HCMV reactivity and without evidence of IgG seroconversion during pregnancy. The IgG avidity assay as well as most standard serological assays have limited use in monitoring transplant populations in the posttransplant period because of the confounder of immunosuppressive therapies.

PREVENTION AND CONTROL

Treatment/Antivirals and Antiviral Resistance

Antiviral agents have been used to control HCMV infections in allograft recipients, individuals with HIV/AIDS, and, more recently, infants with cCMV infections. With the advent of ART, the

number of HIV/AIDS patients with invasive HCMV infections has fallen significantly, and currently, HCMV infections in allograft recipients represent the most frequent indication for HCMV antiviral therapy. Approaches for antiviral treatment of HCMV infections in transplant recipients include (a) prophylaxis in which antiviral drugs are given immediately after transplantation and continued for the period of most significant immunosuppression and (b) preemptive therapy in which transplant recipients are monitored intensively during the posttransplant period and treatment initiated when quantitative assays indicate increasing virus replication. It should be noted that current antiviral therapies have provided clear clinical benefit but overall, there remains an unmet for more effective antiviral agents and treatment strategies. The superiority of one strategy for improving outcomes of allograft recipients remains to be determined. Lastly, treatment of infants with cCMV infections with antiviral agents has been reported to improve short-term outcomes in infants with symptomatic infections.[311]

Currently approved antiviral agents for the treatment of HCMV infection include four agents that target viral genome replication either by inhibition of the activity of the UL54 DNA polymerase or by preventing viral DNA packaging through inhibition of the virus-encoded terminase complex (UL51:UL56:UL89). The agents include ganciclovir (and its oral formulation valganciclovir), cidofovir, foscarnet, and the terminase inhibitor, letermovir. Other agents include an antisense phosphorothioate oligonucleotide, fomivirsen, that has specific indications for local therapy of HCMV retinitis. There are a number of newer agents that have been tested in clinical trials, but with the exception of the UL97 inhibitor, maribavir (Maribavir), interest in further development of these agents is limited. Ganciclovir remains the widely used agent, and treatment with this drug has been shown to provide clinical benefit in immunocompromised patients and infants with cCMV infections.[311,318] Ganciclovir is an analog of deoxyguanosine and is a nonobligate DNA chain terminator that must be phosphorylated by UL97 and cellular kinases to a triphosphate metabolite to inhibit the viral DNA polymerase. Once fully active, the drug inhibits DNA chain elongation.[106] Because of the dependence on phosphorylation by UL97, resistance to ganciclovir can develop following mutations in UL97, the UL54 viral DNA polymerase, or both with mutations leading to resistance under clinical settings more commonly mapping to UL97.[113,382] Resistance to ganciclovir develops at different rates depending on the clinical setting and duration of therapy with ganciclovir such that resistance can develop in up to 10% in high-risk SOT recipients.[113]

A recently approved antiviral agent, letermovir, has been shown to be of considerable value in HCMV prophylaxis in HCT recipients secondary to both its antiviral activity and, importantly, a lack of myelosuppression that is associated with ganciclovir therapy. Letermovir is a small molecule inhibitor that specifically inhibits the packaging of HCMV DNA but not rodent CMVs or other herpesviruses.[396] Letermovir inhibits the activity of the terminase complex and resistance to the drug has been mapped to UL56, UL89, and more recently, UL51.[114,205] Letermovir is currently licensed for HCMV prophylaxis in HCT recipients, and clinical studies are currently under way in the SOT. Two less commonly used agents, cidofovir and foscarnet, both target viral DNA replication. Cidofovir is an analog of deoxycytidine monophosphate and has activity against a broad spectrum of DNA viruses. Activity of cidofovir requires only host cell kinases for conversion to a deoxycytidine triphosphate analog that is incorporated into viral DNA and inhibits viral DNA elongation secondary to chain termination. Cidofovir resistance mutations in HCMV map to UL54 and can map to the same region of the enzyme that confers resistance to ganciclovir, thus conferring cross resistance.[382] Although a potent and effective

antiviral agent, it also has significant toxicity including irreversible renal toxicity that often precludes its use in some patients. Foscarnet is a broad spectrum inhibitor of viral DNA polymerases that acts as a noncompetitive inhibitor of polymerase activity that interferes with incorporation of nucleoside triphosphates into viral DNA.[137] Resistance maps to UL54, and although infrequent, cross-resistance between ganciclovir and cidofovir and foscarnet has been reported.[382] As in the case of cidofovir, foscarnet can have dose-limiting toxicity and is utilized primarily to treat HCMV infections associated with the development of ganciclovir resistance.

A number of newer agents in varying stages of testing and/or development, of which two have been tested in human transplant populations. Brincidofovir (CMX001), a derivative of cidofovir with improved bioavailability has demonstrated potent activity in preclinical animal models of HCMV infections.[254] Although early clinical trials were encouraging, a Phase III trial in HCT failed to reach the primary endpoint of the trial.[401] Maribavir was shown to be a specific inhibitor of the kinase activity of UL97.[46] Because UL97 has pleiotropic effects in the infected cell, maribavir has been shown to inhibit phosphorylation of viral targets of UL97 including UL44, UL83, UL27, and its own autophosphorylation.[44,292,493] In addition, phosphorylation of a number of cellular targets by UL97 kinase activity are also inhibited by maribavir including Rb, RNA pol II, eF1, and components of the nuclear lamina.[32,258,295,414] There remains continued interest in this agent for treatment of HCMV infections in transplant population even though in Phase III study in HCT recipients, treatment with maribavir failed to meet the primary endpoint of the trial.[402] More recently, maribavir was shown to have efficacy similar to that of valganciclovir in the clearance of HCMV viremia when used in a preemptive treatment protocol but adverse effects were more frequent in the maribavir-treated patients.[389] Resistance to maribavir maps to UL97 and interestingly to UL27 secondary to the role of UL97 in the inhibition of the activity of UL27 on Tip60, a host acetyltransferase that induces expression of the host cell cyclin-dependent kinase inhibitor P21.[44] Of note, a mutant virus containing a deletion of UL27 exhibits a less than one-log decrease in virus production, suggesting that this mechanism of resistance could be of uncertain clinical importance *in vivo.*[496]

Vaccines to Prevent or Modify Infection

The decreased risk of invasive HCMV infection in seropositive as compared to seronegative SOT recipients (D+/R+ vs. D+/R−) and an extensive literature suggesting that HCMV seroimmunity can limit transmission and severity of fetal infection in pregnant women have resulted in considerable effort directed towards the development of prophylactic HCMV vaccines. Notably, the Institute of Medicine has identified the development of a HCMV vaccine as a high priority. Vaccine trials in seronegative SOT recipients using an attenuated replication-competent HCMV (Towne strain) suggested that protection from symptoms consistent with what is now termed the CMV syndrome could be achieved with this vaccine and that vaccine recipients could be protected from low titers of HCMV in challenge studies.[484] Subsequent studies have provided conflicting data on the protection induced by this vaccine, including clinical trials in seronegative women of childbearing age.[8] This vaccine has not been licensed for use in any human population.

Interest in subunit vaccines increased following the identification of antigenic virion proteins and targets of functional antiviral antibodies, primarily virus neutralizing antibodies. An adjuvanted recombinant glycoprotein B vaccine has been tested in women of childbearing age

and in SOT recipients.[219,471] Although not controlled for the effect of the adjuvant, the results from the trial in women of childbearing age suggested a modest efficacy in prevention of virus infection.[471] A subsequent trial with the same gB vaccine in adolescent women failed to demonstrate a difference in HCMV infection between vaccine recipients and placebo recipients.[40] Although discordant, these studies raised that possibility that immunity induced by this recombinant gB vaccine could provide some degree of protection. Similarly, immunization of SOT recipients with this vaccine demonstrated some benefit as reflected by a decrease in the duration of antiviral treatment and longer intervals without detectable DNAemia in vaccinated SOT recipients.[219] The correlates of protective immunological responses induced by this vaccine in both SOT recipients and women of childbearing age have been difficult to deconvolute because the vaccine induced both HCMV-specific T-lymphocyte reactivity and a broad spectrum of antiviral antibody activities. Attempts to identify specific antiviral antibody responses that correlated with outcomes in vaccine recipients have provided inconclusive and discrepant results.[35,437] The development of prophylactic HCMV vaccines remains a high priority with several candidate vaccines progressing through early clinical trials in humans including an adjuvanted replication defective HCMV, a mRNA-based candidate vaccine, a replication competent attenuated virus consisting of a chimeric genomes derived from multiple virus isolates, and a vectored peptide-based vaccine.[6,7,284,334]

The enthusiasm for vaccine development to limit HCMV disease in transplant recipient and intrauterine HCMV transmission and fetal damage in pregnant women has been tempered by the recognition of potential hurdles including the lack of an understanding of qualitative and quantitative correlates of protective immune responses in transplant recipients and in pregnant women. As an example, deficits in HCMV-specific T-lymphocyte immunity in the posttransplant period appear to be the best predictor for the development of invasive HCMV infections with a less convincing role for antiviral antibodies. Yet this interpretation of existing data must be tempered by the results from studies in animal models of HCMV infections in the posttransplant period that have repeatedly demonstrated a protective role for antiviral antibodies.[323,400] In addition, early trials with intravenous immunoglobulins in SOT recipients indicated that antibody preparations could modify HCMV infections in these patients. Finally, the design of clinical trials to define HCMV vaccine efficacy in limiting the impact of HCMV infection in graft loss during the late posttransplant period will represent a significant challenge.

In addition to hurdles for vaccine development that are shared with transplant recipients, several unanswered questions continue to surround the potential efficacy of HCMV vaccines to modify the natural history of cCMV infections, including identification of the end point such vaccines, that is, prevention of maternal infection, prevention of fetal infection, and/or prevention of sequelae associated with fetal infection. A second conundrum relevant to HCMV vaccine development is the large number of infants with cCMV born to women with preexisting HCMV immunity derived from natural infections. In some populations, over 90% of infected infants are born to women with immunity prior to conception and antiviral antibody responses are similar between women who transmitted virus *in utero* and those who did not.[433,634] Furthermore, because in most populations 3 to 4 times as many infants with cCMV are born to women with preexisting HCMV immunity as compared to women with primary infections during pregnancy, clinical trials of HCMV vaccines must also define the impact of such vaccines in women with preexisting HCMV immunity.[433,651]

Biologics

Biologics, such as intravenous immune globulins (IVIG), have been used as prophylactic and therapeutic agents for control of HCMV infections and for the prophylaxis of SOT recipients. However, with the exception of their continued use in heart–lung allograft transplantation, the routine use of these products diminished rapidly with the introduction of effective antiviral agents. Although studies also suggested that HCMV IVIG products could also provide some benefit in HCT recipients, careful analysis of the results from these trials suggested that the benefit was secondary to immunomodulatory effects and not an antiviral activity.[9,131,674] Finally, there has been considerable interest in the use of human anti-HCMV monoclonal antibodies as prophylaxis for HCMV infections in SOT. Specific monoclonal antibodies have been selected primarily based on their functional capacity in *in vitro* neutralization assays. Recent clinical trials using a cocktail of anti-gH and antipentamer (gH/gL UL128-131) monoclonal antibodies have provided evidence that such preparations could modify HCMV infections in high-risk SOT.[269]

The success of HCMV IVIG preparations in prophylaxis in SOT prompted interest in the potential use of these biologics to modify HCMV infections in pregnant women and in infants infected *in utero*. Results from a controversial study suggested that treatment of pregnant women with primary HCMV infection could dramatically reduce transmission as well as the severity of infection in infants infected *in utero*.[445] This study was uncontrolled and contaminated by selection bias and thus, was not viewed as definitive. Subsequently, a controlled trial using the same IVIG preparation failed to demonstrate any benefit of IVIG in the prevention of intrauterine transmission.[524] Most recently, an expansive clinical trial sponsored by the NIH in the United States to determine the impact of IVIG on intrauterine HCMV transmission in women with primary HCMV infections in pregnancy was discontinued secondary to lack of statistically differences between outcomes in the treatment and control groups. In contrast to results from these large clinical studies, a smaller study carried out in Germany using more frequent infusions of IVIG provided some evidence of protection from intrauterine transmission by HIG.[288] Thus, the potential value of antibodies present in IVIG in prevention of intrauterine transmission and modification of fetal infection in HCMV infected pregnant women remains to be defined.

PERSPECTIVES

HCMV is one of the most complex viruses infecting humans. HCMV infection and its inevitable persistence in the host has been fine-tuned over millions of years of coevolution. The study of HCMV has revealed tremendous depth in our understanding of the biology of virus infection and replication. In addition, the complexity of interactions with the host cell and its biology makes HCMV a master teacher of cell biology, providing a remarkable path towards discerning pivotal control points for cellular pathways and responses to infection. The advent and application of advanced genetic, molecular, and global omics approaches to HCMV infection has permitted unprecedented advancement in understanding the intricate biology of CMV infection. However, much work remains to achieve successful control of HCMV disease and congenital infection. The large HCMV genome has yet to be fully annotated, yet it is clear that it has greater potential for protein coding capacity than we currently understand. Many viral genes have yet to have

functions fully ascribed. Further, functions of the lncRNAs and miRNAs encoded by HCMV are just beginning to emerge. While much is understood about the biology of infection in fibroblasts, the important differences in the biology of infection in other cell types that undoubtedly contribute to persistence and pathogenesis in the host is far from complete. HCMV offers a powerful model to understand the coup d'etat resulting in persistence of the virus at the level of latency in infected cells. It is important to continue to understand the unique immune response to HCMV infection and to define how this immune response impacts persistence and the host. Understanding virus–host interactions important to viral persistence, viral immunology, and multipathogen infection is an important future goal, as is defining the costs or benefits of CMV persistence. CMV is currently investigated as a cofactor or driver in the development of pathologies associated with aging and cancer. Long-term, low-level virus shedding and the corresponding inflammatory response, in addition to CMV-induced alterations to metabolic, signaling, and stress pathways may contribute to chronic pathologies that are not currently attributed to CMV infection.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of their colleagues in helpful discussions and art for the chapter. FG, WB, and EM are supported by grants from the NIH. We apologize to those investigators whose contributions could not be included due to space constraints. This chapter focuses largely on work since the year 2000, and previous editions should be consulted for earlier work.

CHAPTER 12

Cytomegalovirus

CELL BIOLOGY OF HCMV INFECTION 1: REGULATION OF CELL DEATH

Mitochondria-associated Bcl2 family members play pro- and antiapoptotic roles in the intrinsic apoptosis pathway, a pathway important in development as well as host defense that leads to the release of cytochrome *c* with subsequent activation of caspase-3 or caspase-7 to execute cells. Beta2.7 RNA (lncRNA2.7) binds to mitochondrial complex I to prevent stress-induced death, influence ATP synthesis, and sustain metabolism, although viruses that do not express beta2.7 RNA fail to show any dramatic phenotypic features when evaluated.

While the beta2.7 lncRNA is only found in HCMV, there are two evolutionarily conserved IE cell death suppressors, HCMV UL37x1-encoded viral mitochondria-localized inhibitor of apoptosis (vMIA) targeting intrinsic apoptosis, and UL36-encoded viral inhibitor of caspase-8 activation (vICA) targeting extrinsic apoptosis. These proteins are expressed by both rodent and primate CMVs. The first, vMIA, is composed of an alpha-helical Bcl2 homology-like domain and a mitochondrial targeting domain that act in concert to prevent proapoptotic Bcl-2 family member, Bax, and, in some settings, Bak from assembling at the outer mitochondrial membrane where lysis and fission are outcomes.[7,10,11] Importantly, vMIA blocks Bax-dependent cytochrome *c* release from mitochondria and therefore reduces antiviral responses mediated through cell stress, cell cycle alteration, and metabolic changes. During infection, the interaction with Bax also blocks another, caspase-independent mitochondrial pathway. This HCMV-induced cell death pathway, mediated by mitochondrial HtrA2 serine protease, naturally terminates infection in fibroblasts,[10] so vMIA-deficient mutant-infected cells exhibit premature death that cuts short productive replication and reduces overall virus production.

The second cell death suppressor that is crucial to the biology of CMVs is UL36-encoded vICA, the single most highly conserved modulatory function encoded by betaherpesviruses. In HCMV and MCMV, vICA acts directly to prevent the autocleavage activation of caspase-8 during infection. Thus, vICA is a potent suppressor of extrinsic apoptosis triggered by TNF family death receptors. Using vICA-deficient mutants, this cell death suppressor was initially believed to function independently of TNF signaling as a macrophage-specific modulator of cell death induced by the stress of infection[2,10]; however, recent studies on MCMV[9] have revealed an important but underappreciated role for TNFR1 signal transduction in infected myeloid as well as nonmyeloid host cells. It is worth noting that vICA-deficient virus-infected cells do not exhibit Bid-mediated amplification of extrinsic apoptosis because vMIA prevents amplification through interactions with Bax. In MCMV-infected cells and mice, the elaboration of vICA contributes to resisting T cell–mediated cytolysis[1] as well as sensitizing infected cells to an alternate form of regulated cell death mediated by the protein kinase RIPK3, called necroptosis.[3]

MCMV encodes a RIP homotypic interaction motif (RHIM)-based cell death suppressor, the viral inhibitor of RIP activation (vIRA) that blocks the recruitment of RIPK3 by the pathogen sensor ZBP1,[16] which surprisingly has been found to be triggered by Z-RNA in infected cells.[8,14] This pathway is preserved in HSV[6] but not in HCMV, a virus that blocks necroptosis at a step following RIPK3-mediated phosphorylation of MLKL[12] where vICA may degrade or otherwise sequester this necroptosis executioner[5] in addition to blocking caspase 8 activation.

Other viral proteins have also been implicated in controlling cell death, although their mechanism of action is less well defined. UL38 encodes a protein that counteracts ER stress by impacting the tuberous sclerosis complex, preventing USP24-dependent lysosomal stress, and increasing metabolism,[13,15] at least when evaluated in a vICA-deficient virus background (AD169). US21, IE72, and IE86 appear to reduce stress-associated death, again in a vICA-deficient viral background. Current understanding suggests that the cluster of genes (*UL36*, *UL37x1*, and *UL38*) act somehow synergistically.[4] Finally, evidence has accumulated that HCMV also harnesses the host cell death suppression machinery in settings where viral IE expression is suppressed, particularly monocytes where infection has the potential to drive cellular differentiation pathways.[2] The overall impact of cell death suppression is to sustain the viability of host cells, whether the outcome is productive replication, persistence, or latency.

CELL BIOLOGY OF HCMV INFECTION 2: REGULATION OF THE INFECTED CELL PROTEOME

The following section discuss the regulation of the infected cell proteome during HCMV infection through the manipulation of protein synthesis, protein turnover or inhibition mediated by miRNAs targeting host transcripts.As obligate intracellular parasites, viruses have evolved an array of mechanisms to ensure the synthesis of their own proteins and to shape the proteome of the infected cells for successful infection. Viruses are ultimately parasites of the host translation machinery as no virus encodes complete translation machinery. While many viruses all but eliminate host protein synthesis, cellular protein synthesis continues largely unabated in HCMV-infected cells (751). HCMV impacts the global proteome by specifically recruiting or excluding mRNAs from polyribosomes. mRNAs encoding proteins involved in the DNA damage response, proliferation, ribosomal biogenesis, chromatin remodeling, organelle function, and vesicular transport are increased, whereas those involved in cellular differentiation and acquired immunity are decreased (470).

HCMV regulates more than 10,000 host proteins and their transcripts during virus replication by a variety of mechanisms to shape the infected cell proteome (514). Global proteome analysis has revealed that 89% of the 927 host proteins detected on the plasma membrane of fibroblasts change by at least twofold during HCMV infection (761) and 131 host proteins are targeted during HCMV infection for proteasomal or lysosomal degradation (514), indicating a dramatic redesign of the host proteome. Only 1% to 5% of these have a corresponding change in mRNA, indicating a high level of regulation at the protein level. HCMV is understood to regulate the proteome by targeted proteasomal and lysosomal degradation and by miRNAs that target host RNAs for suppression. For more in-depth discussion, please refer to the sections below.

Protein Synthesis

HCMV infection regulates the eukaryotic initiation factor 4F (eIF4F) eukaryotic translation initiation complex for its replication by increasing activation or abundance of its core components.[26,39,40] HCMV increases the overall abundance of eIF4F components, eIF4E, eIF4G, and poly A binding protein (PABP), while decreasing the abundance of the translational repressor, eIF-4E binding protein 1 (4E-BP1). HCMV-mediated up-regulation of PABP increases the assembly of eIF4F to initiate translation and is important for viral protein synthesis and replication.[26,40] HCMV ensures eIF4E activity by stimulating the eIF4E kinase mnk through both ERK and p38 MAPK signaling[40] and by maintaining mechanistic (previously, mammalian) target of rapamycin (mTOR)-mediated inactivation of 4E-BP1 to induce the release eIF4E, in addition to its role in activating ribosomal p70 S6 kinase (HCMV regulation of mTOR also discussed in *Regulation of Host Metabolism*).[21], [22], [23,29] Both mnk and mTOR kinases are required for HCMV replication.[23,29,40] mTOR is relocalized to a juxtanuclear region in the cells where it is maintained in an active form even in the context of stresses (e.g., amino acid starvation) that would typically down-regulate mTOR activity.[5] Both the maintenance of mTOR

activity and the induction of PABP require the UL38 protein.[26,28] UL38 activates mTOR by antagonizing the tuberous sclerosis complex 2 (TSC2) protein,[28] in addition to additional mechanisms that have yet to be defined.[1] Much remains to be understood about the role of mTOR and mTOR-independent (insensitive to mTOR inhibition) pathways in regulating protein synthesis and other aspects of stress and metabolism in HCMV infection.

The HCMV-induced up-regulation of ribosomal biogenesis results in increased levels of steady-state ribosomes,[27,39] but this increase in ribosomes does not promote viral protein translation and virus replication. Paradoxically, limiting ribosomal biogenesis during HCMV infection enhanced translation of viral proteins and viral replication.[2] The antiviral effect of increased ribosomal biogenesis is linked to heightened production of IFN-β and interferon-stimulated genes (ISGs) in response to double-stranded DNA, which are reduced when ribosome biogenesis is limited. These findings suggest a link between the regulation of ribosomal biogenesis, DNA sensing, and the interferon response. Moreover, the up-regulation of translation factors may not uniformly favor sustained protein translation for virus replication. While the UL38 protein-induced accumulation of PABP favors viral protein translation and replication, it results in a corresponding increase in the PABP inhibitor Paip2 and its E3 ligase, EDD1.[26] Paip2 limits virus replication in the absence of PABP, indicating an innate restriction conferred by Paip2 that HCMV overcomes by up-regulating PABP. Further, HCMV-induced accumulation of eIF6 is also inhibitory to virus replication,[27] suggesting that the up-regulation of some host translation factors may function to assuage replication, prolong infection, or reduce infection-related cytotoxicity. These results collectively indicate the complexity of cellular processes regulated through what would be characterized as protein translational control.

Protein Turnover

Primary protein targets for degradation include immune ligand proteins and restriction factors. US2 protein alone targets 10 cell-surface proteins for degradation. While immune receptors and ligands, such as major histocompatibility complex I (MHC-I) and NK-activating ligand CD112, are targeted by US2 protein for degradation via the sterol-regulated TRC-8 ubiquitin ligase,[15] CD112 down-regulation requires cooperation between US2 and UL141 proteins. US12 family members (comprising US12-21) function together to down-regulate numerous plasma membrane proteins that function as natural killer (NK) cell activating ligands, T-cell costimulatory proteins, cell adhesion proteins, and cytokine or cytokine receptors.[11] As discussed in the main chapter, several host restriction factors comprising PML bodies, including MORC3, Daxx, and Sp100, are targeted for SUMOylation and proteosomal degradation.[16,17,19,31,36,37]

Studies screening HCMV–host protein interactions in fibroblasts identified 69 HCMV proteins interacting with one or more E3 ubiquitin ligases, indicating a strategy to broadly shape the host proteome.[32] UL145 recruits Cullin 4/DDB1 ligase complex to direct the proteosomal degradation of RING helicase-like transcription factor (HTLF).[31] HTLF binds nascent single-stranded DNA and ubiquitinates the proliferating cell nuclear antigen DNA processivity factor (PCNA) at stalled replication forks to enhance error-free DNA damage tolerance and impedes immediate-early gene expression. UL21a protein induces the proteosomal degradation of subunits of the anaphase-promoting complex.[10] In addition to E3 ligases, a number of other host factors are targeted for proteosomal or lysosomal degradation. For example, BclAF1 is a nuclear restriction factor that is targeted for degradation by pp71 and UL35 proteins from the virion

tegument upon entry, and then later in infection by the HCMV miR-UL112-3p (also referred to as miR-UL112-1).[25] SPOC1, while initially induced by IE1-72kDa, is degraded late in infection in a GSK-3β-dependent manner.[35] UL135 induces the turnover of endocytosed the receptor tyrosine kinase EGFR[4] through its association with Cbl-E3 ligase adapter proteins in infection[34] and overexpression of *UL135* protein induces degradation of Rho-associated coiled-coil kinase 1 (ROCK1, regulator of the actomyosin cytoskeleton) by mechanisms not yet known.[39] Both EGFR/PI3K[4] signaling and ROCK1[9] contribute to cell survival, motility, and proliferation but inhibit virus replication following entry.

Inhibition

Viral miRNAs serve to fine-tune the host and viral proteome. Over 250 viral miRNAs have been identified, and the vast majority are encoded by members of the herpesvirus family. 20 Many HCMV miRNAs are regulated through time postinfection or in a cell type–dependent manner.[18,38] The majority of miRNAs target 3′ UTRs to suppress translation or stimulate mRNA decay. Like all miRNAs, HCMV miRNAs are short approximately 22 nucleotide non-coding RNAs that are generated from single-stranded, hairpin-forming RNA precursors that are sequentially cleaved by Drosha and Dicer. miRNAs are incorporated into the RNA induced silencing complex (RISC) complex and target the RISC complex to mRNAs with partial complementary to degrade or inhibit their translation. Viral miRNAs have the potential to target both viral and cellular transcripts. HCMV genome encodes 24 miRNAs from 13 pre-miRNAs from across the genome See Supplementary Table 12.2.[8,12,33,38] Viral targets of HCMV miRNAs include the MIE IE-72kDa and other exons (UL120-121), genes involved in DNA synthesis (*UL112-113*), vesicular trafficking and evasion of NK cell activation (*UL17-18*).[7]

miRNA-medidated Silencing

Other HCMV miRNAs have been shown to target cellular transcripts encoding proteins involved in cell cycle progression, proliferation, differentiation, apoptosis, immune detection, signaling, and trafficking.[7,41] RISC complex immunoprecipitation identified over 20 cellular targets for miR-US25-1, including 5 cell cycle-related targets; cyclin E2 controls progression into S Phase and has been validated, while CD147, BRCC3, EID1, and MAPRE2 await validation.[13] This data exemplifies that exceptional complexity that viral miRNAs add to understanding virus host regulation.

miR-UL112-3p targets the 3′UTR of the Toll-like receptor TLR2, which recognizes bacterial and viral ligands, including gB and gH,[3,6] to attenuate NFκB signaling and to reduce proinflammatory cytokine signaling.[24] Proinflammatory signaling is further dampened by miR-UL112-3p- and miR-US5-1-mediated reduction in IKKα and IKKβ levels to prevent degradation of IκBα and limit proinflammatory cytokine production in fibroblasts, endothelial cells and THP-1 cells.[14] Further, miR-UL112-3p targets the NK cell activating receptor of MHCI-related chain B (MICB) to limit NK cell toxicity.[30] From these examples, HCMV miRNAs play clear and important roles in modulating cellular responses and processes important to infection. These findings suggest intriguing roles for HCMV miRNAs in regulating latency and reactivation, which are further discussed in section *Latency*.

CELL BIOLOGY OF HCMV INFECTION 3: REGULATION OF HOST METABOLISM

Global transcriptomic[11,20] and lipidomic/proteomic[32,33,38,41,45] analyses have revealed extensive stimulation of lipid metabolism and energy pathways to facilitate HCMV replication. HCMV infection increases glucose uptake and pool size to support an increase in the metabolic flux of glucose-consuming pathways.[25,28,32,33,37,43,47] Glucose metabolism is critical for both viral genome synthesis and virus progeny production.[7,27,28] Glycolysis is increased, and glucose-derived citrate leaves the mitochondria and is converted to OAA and acetyl-CoA in the cytoplasm to support fatty acid synthesis to produce membranes needed for progeny virion production.[32,33,39] The expression and activity of acetyl-CoA carboxylase (ACC1), the rate limiting fatty acid biosynthetic enzyme, and fatty acid biosynthesis are induced by HCMV infection.[33,39,48] This diversion of glucose carbon from the TCA cycle in infection requires the virus to stimulate the uptake of exogenous glutamine and the expression or activity of enzymes for the conversion of glutamine to α-ketoglutarate to feed the TCA cycle downstream of citrate.[7] HCMV induces c-myc early in infection,[16] which is known to drive glutaminolysis in tumor cells. HCMV specifically supports the synthesis of very long chain fatty acids (VLCFA, C20-C34 long tails) by stimulating fatty acid elongase 7 (ELVOL7) to extend the carbon length of fatty acids prior to being incorporated into lipids.[21,34] HCMV infection also induces the activity of lipogenic transcription factors such as SREBP1.[34,39,48] UL37x1 induces ELOVL7 and the ER stress kinase, PERK, and is required for HCMV-induced synthesis of VLCFA.[45] PERK activity also contributes to induction of SREBP1.[49] As discussed above mTOR is also important for fatty

acid synthesis and elongation.[34] HCMV is also known to induce cholesterol and low-density lipoprotein receptor 1 (LRP1) that regulates lipid and cholesterol metabolism.[1,15] Lipids and fatty acids are the constituents of membranes and are also important signaling molecules. Virion envelopes are enriched in saturated VLCFAs, and these are important for infectivity,[21] and it is not yet clear if HCMV modulation of fatty acid synthesis serves roles in infection other than synthesis of the viral envelope. Much remains to be understood about the mechanisms by which HCMV induces and manipulates pathways for glucose and glutamine uptake, glycolysis and glutaminolysis, and fatty acid synthesis and the importance of these pathways to virus infection beyond virion production.

AMP-activated protein kinase (AMPK) is a cellular kinase that senses energy and genotoxic stress. AMPK is activated by the reduced production or increased consumption of ATP (sensed by changes in the AMP:ATP ratio) and induces catabolic pathways (e.g., increased import of glucose) to generate ATP while simultaneously inhibiting the rate-limiting steps of pathways that consume energy for fatty acids (e.g., acetyl coA carboxylase 1, ACC1) and cholesterol (e.g., 3-hydroxy-3-methylgluaryl 1 [HMG] co-reductase) synthesis and translation (e.g., mTORC1). HCMV induces glycolysis, exchanging expression of the GLUT1 transporter for the higher capacity GLUT4 transporter,[27,47] through the stimulation of AMPK (phosphorylation of Thr372 by Ca2+-calmodulin-dependent kinase kinase, CaMKK), and this is required for virus production.[27,28,41] This induction of GLUT4 appears to require IE1-72 KDa and early gene expression.[47] AMPK activation negatively regulates ACC1 and HMGCoR for fatty acid and cholesterol synthesis required for HCMV replication. How the virus activates AMPK while protecting fatty acid and cholesterol synthesis is not fully understood,[33,39] but nuances in the expression of specific AMPK regulatory subunits to drive metabolic activation and virus replication could be involved.[13]

Amino acids are the basic building blocks for protein synthesis and also provide cellular energy through the TCA cycle. HCMV infection induces glutamine uptake and breakdown and is important for HCMV replication.[7,27,33,37] Glutamine deprivation inhibits HCMV replication, which can be rescued by supplementing catabolic products of glutamine breakdown,[7] suggesting that glutamine catabolism maintains the TCA cycle to support the energy demands of the infected cells. The consumption and secretion of other amino acids is also modified by infection,[37] but the significance of this to infection is not fully understood. Induction of amino acid consumption could serve to fuel the increased demands for protein synthesis in infection or could provide metabolic intermediates to generate energy or support lipid synthesis and regulatory networks, such mTOR.

The mTOR complex 1 (mTORC1/Raptor) and complex 2 (mTORC2/Rictor) are kinases important for coordinating cell growth, proliferation, protein synthesis, and metabolism by balancing anabolic and catabolic processes in response to stress and other environmental cues. HCMV induces mTORC1 and mTORC2[9,23,24] and blocks the inhibitory effect of AMPK activation on mTORC1 function.[22] Infection induces a dynein-dependent localization of mTOR to the juxtanuclear viral assembly compartment and is maintained in an activated form even in the presence of stresses that typically inactivate it,[8,10,22,23] as are other kinases such as EGFR.[6] Inhibition of mTORC1 with chemical inhibitors or mTORC1 depletion by shRNA impairs virus replication.[9,23,24,31] mTORC1 functions as nutrient/energy/redox sensor to regulate protein synthesis, glycolysis, lipogenesis, and autophagy. mTORC1 positively regulates translation and

lipogenesis by phosphorylating and inactivating 4E-BP1 repressor of eIF-4E and the lipin-1 repressor of SREBP-mediated transcriptional activation of lipogenic genes, respectively. mTOR also positively regulates translation by the phosphorylation and activation of p70 S6 kinase 1 for ribosome biosynthesis. mTORC1 is primarily activated through PI3K/AKT signaling and is negatively regulated by nutrient deprivation and other stresses. HCMV maintains mTORC1 activity in the presence of amino acid deprivation or oxidative stress and despite increased AMPK activity and decreased AKT activity, in part, by inactivation of the tuberous sclerosis complex TSC,[10,22,30,42] and in part by dynein-mediated perinuclear localization of mTOR where it is activated by positioning with its lysosomal activator Rheb-GTP.[8,10] TSC is activated by AMPK and is a negative regulator of the Rheb-GTPase for the activation of mTOR. mTOR may also be activated by phosphatidic acid species that are elevated by CMV infection,[26] linking the regulation of mTOR to lipogenesis.

The UL38 protein antagonizes the tuberous sclerosis complex 1 and 2 (TSC1/2) to induce mTOR kinase activation and subsequent phosphorylation and inactivation of the translational suppressor 4E-binding protein 1 (4E-BP1), which inhibits bound eIF4E.[30] However, UL38 protein also induces mTORC1 independent of TSC2 by mechanisms that are not yet defined.[2] In addition to maintaining mTOR activity, UL38 interaction with TSC2 may also alter its interaction with the Cip/Kip family member, p27, to induce infected cells to exit quiescence and enter G1 phase of the cell cycle. UL38 protein-mediated inactivation of 4EBP also up-regulates poly A binding protein (PABP) concentration to regulate eIF4F assembly for translation, and this is important for viral late protein accumulation and viral replication.[29] The UL38 protein prevents ER stress to inhibit cell death.[35,40] UL38 protein up-regulates phosphorylation of PKR-like kinase (PERK), the alpha subunit of eukaryotic initiation factor 2 alpha (eIF-2α), and ATF4, protecting infected cells from persistent JNK activation and ER stress-induced cell death.[46] Blocking ER stress-related cell death requires 239 amino acids at the amino terminus of the UL38 protein, whereas full activation of mTORC1 requires carboxyl terminal residues of UL38,[35] demonstrating the multifunctional nature of UL38. The modulation of mTORC1 has important implications not only for protein synthesis but also for cell cycle progression, DNA damage, and autophagy. Most recently, UL38 has been shown to induce TSC2-dependent, mTOR-independent glycolysis and the catabolism of specific amino acids,[37] strongly suggesting other roles for TSC2 in the context of infection other than inhibiting mTOR.

Metabolic stress and the demand for protein synthesis in HCMV infection induce the unfolded protein response (UPR).[18] ER-resident transmembrane proteins regulate the UPR. These include inositol-requiring enzyme 1 (IRE1), protein kinase R (PKR)-like ER kinase (PERK), and activating transcription factor 6 (ATF6). Under ER stress, the immunoglobulin heavy chain binding protein (BiP) chaperone releases IRE1, PERK, and ATF6, resulting in the homodimerization and activation of IRE1 and PERK and the cleavage and activation of ATF6. BiP is increased during HCMV infection, with roles in viral assembly compartment formation, protein folding, and the potential to dampen the UPR,[3, 4, 5] although this is countered by HCMV modulation of PERK, IRE-1, and ATF6.[18]

HCMV also induces pyrimidine nucleotide biosynthesis, and this induction is important for replication HCMV infection.[12,44] Pyrimidine nucleotides are important precursors of RNA and DNA, but also produce UDP-sugars to support glycosylation and glycogen synthesis. Inhibition of UDP-GLcNAc transferases or the CAD rate-limiting enzyme of pyrimidine biosynthesis

hinders glycosylation of viral proteins and production of infectious progeny.[12,36]

In its quest for energy, HCMV infection also induces mitochondrial DNA accumulation and mitochondrial transcription and translation early in infection, inducing the synthesis of respiratory chain components and the expression of oxidative phosphorylation genes.[14,17,19] Viral replication is negatively impacted by the knockdown of the mitochondrial-encoded respiratory chain component mitochondrial RNA methyltransferase 3.[19] These changes may drive the production of ATP and NADH to support the energy demands of infection.[7,32] As most studies that form our understanding of metabolism in HCMV infection have been performed in fibroblasts, major questions remain in how HCMV-mediated metabolic modulation impacts infection in diverse clinically important cell types and how host metabolism is manipulated in latent states of infection.

SUPPLEMENTAL TABLE 12.1 Annotated human cytomegalovirus genes and gene products[a]

HCMV[a,c]	HHV-6/HHV-7[b]	Properties/Expression/Gene Family[d]	Gene Function/Comments/(Gene Product Name)[e]
RL1		RL1 family, LL	
lncRNA2.7		Most abundant noncoding RNA, E	Binds mitochondrial complex I, enhancing metabolism and suppressing cell death; possible role in latency[132,224,283,288,349,371,382,515] (β2.7, RNA2.7)
RL5A		RL11 family; membrane-like gp, LL	
RL6		RL11 family, membrane-like gp, LL	
lncRNA1.2		Abundant noncoding RNA, E	Suppression of TPRG1L-regulated, NF-kB-dependent cytokine production[142,233] (β1.2, RNA1.2)
RL8A		LL	Multiply spliced[142]
RL9A		LL	[142]
RL10		Envelope gp, LL	[424,425]
RL11		RL11 family; envelope gp, LL	IgG Fc-binding protein (vFcR); modulates antibody activity[22,53,94,249,307,430] (gp34)
RL12		RL11 family; membrane gp, LL	IgG Fc-binding protein (vFcR); modulates antibody activity[95] (gp95)
RL13*		RL11 family; envelope gp, LL	IgG Fc-binding protein (vFcR)[95]; NUDT14-binding protein[475]; restricts replication and is lost in cell culture[304,432]; retained and promotes cell-to-cell spread in the presence of antibody[326] (gpRL13)
UL1		Virion envelope gp, RL11 family, TL	Tropism determinant[410]
UL2		Membrane gp, LL	
UL3			Alters nuclear PML and Cajal bodies[386]
UL4		RL11 family; envelope gp, E	Translational stalling mechanism, at uORF2[23,63,64] (gp48)
UL5		RL11 family; envelope gp, E	Binds IQGAP1 in assembly compartment[14] (gpUL5)
UL6		RL11 family; membrane gp, LL	[401]
UL7		RL11 family; shed membrane gp, LL	CD229/SLAM family homolog; inhibits inflammatory cytokine production[121]; activates FLT3R increasing myeloid cell differentiation[100]; promotes angiogenesis[270] (gpUL7)
UL8		RL11 family; membrane gp, LL	Inhibits inflammatory cytokine production; UL7-common exon[336] (gpUL8)
UL9*		RL11 family; membrane gp, LL	Impairs replication in fibroblasts[117]
UL10*		RL11 family; shed membrane gp, LL	Impairs replication and cytokine production in fibroblasts[117]; inhibits T-cell activation[53] (gpUL10)
UL11		RL11 family; membrane gp, LL	Membrane associated[264]; activates CD45 to inhibit immune cell function,[139,140] regulates T_H lymphocytes, and induces IL-10[520] (gpUL11)
UL13*		Secreted protein, IE	[477]
UL14		UL14 family; membrane gp, E	
UL15A		Membrane-like protein, E	
UL16*		Membrane gp, E	Sequesters NKG2D ligands MICB, ULBP1, ULBP2, and ULBP6 to impede NK-cell killing[97,109,225,300,333,462,493] (gpUL16)
UL17		LL	
UL18		MHC homolog, LL	LILRB1 (LIR-1, ILT2, CD85j) ligand[76,96,491,502]; impedes NK- and T-cell activation[242,390,502,503] dependent on pUL40[109,333,360] (pUL18)
UL19		LL	
UL20		Putative T-cell receptor γ chain homolog, E	Rapidly degraded in lysosomes[142]

HCMV[a,c]	HHV-6/HHV-7[b]	Properties/Expression/Gene Family[d]	Gene Function/Comments/(Gene Product Name)[e]
UL21A* (UL20A)		E	Inhibits cyclin A to prevent mitotic catastrophe[60,118,482]; inactivates anaphase promoting complex[91,125] (pUL21A)
UL22A (UL21.5)		Virion-associated, secreted gp, LL	RANTES binding protein; CC chemokine decoy[471,478]
UL23*	U2	US22 family; tegument, LL	Impedes Nmi recruitment of STAT1 to reduce the IFNγ response[126] (pUL23)
UL24	U3	US24 family; tegument, LL	Binds UL46 and UL85 capsid proteins[454] (pUL24)
UL25		UL25 family; tegument, LL	Prevents degradation of UL26[579] (pUL25)
UL26		US22 family; tegument, LL	Confers resistance to interferon; inhibits NF-κB activation by blocking phosphorylation of IκB kinase; regulated by ISG15ylation[148,204,280] (pUL26)
UL27	U4	Maribavir resistance, E	Inhibits histone acetyltransferase KAT5/Tip60, driving CDK inhibitor p21/Cip1 cell cycle arrest; collaborates with UL97 kinase[36,87,88,154,207,374,375] (pUL27)
UL29-UL28	U7x2/U5 U7x1/U7 U8	US22 family; tegument, E	Stimulates IE gene expression via the NuRD complex[450]; inhibit p53 responsive gene expression[389]; nucleolar localized[386]
UL30	U9	UL30 family, LL	Disrupts nuclear PML and Cajal bodies[386] (pUL30)
UL30A		UL30 family, LL	ACG initiation codon[107,436]
UL31	U10	DURP family, LL	Associates with pUL76; inhibits cGAS sensing[172]; nucleolar impact[386,484] (pUL31)
UL32	U11	Tegument, LL	Nucleocapsid-proximal stabilization protein (NSP); stabilization of maturing capsids[23,446] likely by direct capsid interaction[29,253,504,505]; regulated by ROCK[120] (pp150, ppUL32)
UL33x1 UL33x2	U12x1 U12x2	GPCR family, envelope, LL	Constitutive signaling[67]; heterodimerize with and inhibit pUS28, CCR5, and CXCR4[134,443,458] (pUL33)
UL34	U13	LL	AAACACCGTA/T-specific DNA-binding protein; repression of US3 and US9 transcription[35,232,255,365]; binds oriLyt and enhances viral DNA synthesis[419] (pUL34)
UL35	U14	UL25 family; tegument pp, LL	Binds to ppUL82; disrupts PML, reduces IFN response through TBK1[123,386]; DNA damage response modifier via DCAF[385]; binds to SNX5 to block retrograde transport[277] (pUL35)
UL36x1 UL36x2	U17x1 U17x2	US22 family; tegument pp, IE	Blocks extrinsic apoptosis[79,90,273,285,287,418]; influences T-cell cytolysis[78]; sequesters MLKL[121] (vICA, inhibitor of caspase-8-induced apoptosis, pUL36)
UL37x1		Localizes to ER and mitochondria, IE	Binds and sequesters Bax and Bak, drives mitochondrial fission; potent suppressor of Bax-dependent intrinsic cell death, apoptosis, autophagy, and HtrA2 serine protease–dependent death, associated with MAVs ab block peroxisomal signaling with direct and indirect impact on cellular metabolism and release of Ca^{2+} [19,34,82,146,193,271,284,286,318,408,499,510]; resistance to T-cell cytolysis[361]; (vMIA, mitochondria-localized inhibitor of apoptosis, pUL37x1)
UL37x1-x3	U18	Membrane gp, IE	Gene regulation; includes UL37x1 at amino terminal[448] (gpUL37)
UL38	U19	Tegument, E	Blocks ER stress via tuberous sclerosis complex[363,450]; prevents USP24-dependent lysosomal stress and cell death[442]; increases metabolic activation[381] (pUL38)
UL40		Membrane gp, E	Leader peptide binds HLA-E to impede NK-cell killing; up-regulates UL18[360]; differential expansion of NKG2C+ NK cells[109,156,333]; target of HLA-E-restricted T-cell responses[189] (gpUL40)

HCMV[a,c]	HHV-6/HHV-7[b]	Properties/Expression/Gene Family[d]	Gene Function/Comments/(Gene Product Name)[e]
UL41A (UL41.5)		Envelope, LL	
UL42		Membrane protein	Sequesters Nedd4 family E3 ligase Itch[213]; cGAS antagonist[136] (pUL42)
UL43	U25	US22 family; tegument, LL	[2]
UL44	U27	(core) DNA synthesis, E and TL	Complex with pUL54; DNA polymerase processivity subunit[11,16,17,81,122,208,258,329,414,417,509]; suppressor of IRF3 and NF-κB[136] (PPS, pp50, ppUL44)
UL45	U28	(core) Tegument pp, E	Binds to pUL48 and suppresses RIPK1-dependent NF-κB activation[228,305]; (enzymatically inactive large subunit of ribonucleotide reductase homolog or ppUL45)
UL46	U29	(core) Capsid, LL	Forms capsid triplex with pUL85; binds pUL32[80,253,457,504] (TRI1, capsid triplex component 1, pUL46)
UL47	U30	(core) Tegument pp, LL	Supports intracellular capsid transport and final tegumentation[66,105,202] (pUL47, LTPbp, LTP-binding protein)
UL48	U31	(core) Tegument pp, LL	Complexes with pUL77 and pUL93 linking capsid triplexes and terminase; stabilizing capsid during assembly/uncoating as a deneddlyase/deubiquitinase)[196,202,228,247,476] (pUL48, LTP, largest tegument protein)
UL48A (UL48.5)	U32	(core) Capsid, LL	Forms the tips of hexons on capsids[45,104,229,504] (SCP, smallest capsid protein, pUL48A)
UL49	U33	(betagamma), Membrane protein, E	Alternatively spliced[501,516]
UL50	U34	(core) Nuclear egress, membrane protein, LL	Complex with pUL53 at inner nuclear membrane; mediates capsid egress to cytoplasm.[62,236,241,292,301,387,396,397,406,470] Also, suppressor of UPR[431] and UBE1L-dependent ISGylation[237] (NEC1, nuclear egress complex membrane anchoring component 1, pUL50)
UL51	U35	(core) DNA encapsidation, LL	Terminase complex with pUL56 and pUL89; DNA cleavage/ packaging into capsids[44,144,247,310,311] (pUL51)
UL52	U36	(core) LL	Supports terminase during DNA packaging, required for concatemer cleavage[10,46,144] (pUL52)
UL53	U37	(core) Nuclear egress. Tegument pp, LL	Complex with pUL50 at inner nuclear lamina[62,241,291,292,301,352,387,396,397,406,470] (NEC2, nuclear egress complex component 2, pUL53)
UL54	U38	(core) DNA synthesis, E	Complex with pUL44; DNA polymerase catalytic subunit; target of ganciclovir and foscarnet antivirals[16,81,122,257,329,507,509] (POL, pUL54)
UL55	U39	(core) Envelope gp, LL	Binds heparan sulfate and mediates fusion for entry into cells; forms homomultimers; antibody target[58,74,93,177,185,272,378,407,412,465] (gB, gpUL55)
UL56	U40	(core) DNA encapsidation, LL	Terminase complex with pUL51 and pUL89; DNA packaging motif and nuclease activity for DNA cleavage and packaging into capsids[248,310] binds to *pac1* motif[42,147,247,452] (pUL56)
UL57	U41	(core) DNA synthesis, E	Single-stranded DNA-binding protein[13,329] (SSB, pUL57)
oriLyt	oriLyt	Initiation site for DNA synthesis on viral genome	DNA synthesis origin for productive infection; position conserved across herpesviruses[12,13,191,279,329]
vRNA-1 vRNA-2		oriLyt-associated RNA, E	Virion RNA[13,357]
lncRNA4.9		Abundant noncoding RNA, E	Potential source of vRNA-1 and vRNA-2 associated with oriLyt; initiation of DNA synthesis[448]

HCMV[a,c]	HHV-6/HHV-7[b]	Properties/Expression/Gene Family[d]	Gene Function/Comments/(Gene Product Name)[e]
UL69	U42	(core) tegument pp, E	Nucleocytoplasmic shuttling, enhancing nuclear export, and translation of unspliced mRNA[15,103,218,453]; E3 SUMO ligase[108]; cell cycle block; binds SPT6; adopts a dimer of dimers conformation[460] (pUL69)
UL70	U43	(core) DNA synthesis, E	Complexes with pUL102 and pUL105, binds snapin; DNA helicase–primase subunit; primase homology[13,329,409] (HP2, pUL70)
UL71	U44	(core) tegument pp, E	Secondary envelopment; forms oligomers[113,289,368,392,494]
UL72	U45	(core) DURP family; tegument pp, E	Deoxyuridine triphosphatase homolog (enzymatically inactive)[65] (DURP, pUL72)
UL73	U46	(core) envelope gp, LL	Complex with gM to support envelopment; high sequence variability[219,266,341,342] (gN, gpUL73)
UL74	U47	envelope gp, TL	Complexes with gH/gL and enhances entry and interaction with PDGFRa[93,186,190,272,384,464,498,512] (gO, gpUL74)
UL74A (UL73.5)	UL47A	Putative envelope gp	Multiple spliced[142,391]
UL75	U48	(core) envelope gp, TL	Complex with gL; gH/gL, alone, in association with gO or with UL128-UL131A mediates entry recognizing cellular receptors[92,93,165,190,272,466,497,498] (gH, gpUL75)
UL76	U49	(core) Virion-associated, TL	Interacts with pUL31[484]; nucleolar protein[286] that induces DNA damage[98] and aggresome formation[250,513]; translational impact on UL77[178] (pUL76)
UL77	U50	(core) DNA encapsidation, LL	Complex with pUL48 and pUL93 (links capsid triplexes and terminase; stabilizes capsid during assembly/uncoating)[43,111,202,211,247] (pUL77)
UL78	U51	GPCR family; envelope gp, E	Heterodimerize with and inhibit pUS28[458] and CCR5[443] while supporting viral spread[463] (pUL78)
UL79	U52	(betagamma), LL	Complex with pUL87, pUL91, pUL92, and pUL95; elongation factor in L gene transcription[75,179,327,337,338] (pUL79)
UL80	U53	(core), LL	Maturational protease (N terminus) and capsid assembly (scaffold) protein (C terminus)[129,448,506] (PR-AP precursor, pUL80)
UL80.5 (UL80a)	U53.5	(core), LL	Capsid assembly (scaffold) protein[128,448,506] (AP precursor, pUL80.5)
UL81-UL82ast		Nuclear protein	Latency-associated protein disrupts nuclear PML bodies as a deSUMOylase[30,195,351,370] (LUNA)
UL82	U54	DURP family; tegument pp, LL	Virion transactivator; disrupts nuclear PML bodies via degradation of Daxx and Rb[176,315]; inhibits STING[137,192,319] (pp71, ppUL82, upper matrix protein)
UL83		DURP family; tegument pp, LL	Scaffold for optimal tegumentation[379]; suppresses interferon response by inhibiting cGAS, AIM2, IFI16, NF-κB, IRF3[1,18,37–39,52,101,170,231,245,276] (pp65, ppUL83, lower matrix protein)
UL84	U55	DURP family; DNA synthesis, E	Strain-dependent initiator of DNA synthesis; interaction with IE2; binds IE2, UL112-113, pUL34, and ppUL44[141,191,329,419,427,429] (pUL84)
UL85	U56	(core) capsid, LL	Forms capsid triplex with pUL46[80,253,457,504] (TRI2, capsid triplex component 2, pUL85, minor capsid protein)
UL86	U57	(core) capsid, LL	Composes hexons and pentons of capsid[80,253,457,504] (MCP, major capsid protein, pUL86)
UL87	U58	(betagamma), LL	Complex with pUL79, pUL91, pUL92 and pUL95; putative TATA-binding protein for L gene transcription[75,179,243,327,337] (pUL87)
UL88	U59	(betagamma) tegument	Putative cytoplasmic egress; pUL48 interaction[202] (pUL88)

HCMV[a,c]	HHV-6/HHV-7[b]	Properties/Expression/Gene Family[d]	Gene Function/Comments/(Gene Product Name)[e]
UL89x1 UL89x2	U66x1 U66x2	(core) DNA encapsidation, LL	Terminase complex with pUL56 and pUL77 (ATPase subunit) DNA cleavage/packaging[144,247,306,370,451,480] (Wang, 2019, p. 9163)(pUL89)
UL90			
UL91	U62	(betagamma), LL	Complex with pUL79, pUL87, pUL92, and pUL95; L gene transcription[75,323,327] (pUL91)
UL92	U63	(betagamma), LL	Complex with pUL79, pUL87, pUL91, and pUL95; L gene transcription[75,324,327] (pUL92)
UL93	U64	(core) DNA encapsidation, LL	Complex with pUL48 and pUL77 (links capsid triplexes and terminase; stabilizes capsid during assembly/egress)[43,111,112,144,247] (pUL93)
UL94	U65	(core) tegument pp, TL	Secondary envelopment in association with ppUL99[354,380,448]; antagonizes cGAS recruitment of STING[522] (pUL94)
UL95	U67	(betagamma), LL	Complex with pUL79, pUL87, pUL91, and pUL92; L gene transcription[75,179,327,337] (pUL95)
UL96	U68	Tegument, LL	Stabilization of maturing capsids[447]; independently of pUL32[50] (pUL96)
UL97	U69	(core) Viral serine–threonine protein kinase; tegument pp, LL	Protein kinase mimic of cdc2/CDK1; phosphorylates viral and cellular proteins and antiviral drug ganciclovir; target of maribavir; regulates SAMHD1[27,59,86,89,174,180,181,197,221,244,251,321,353,354,356,399,423,434,435,440,441,492,493] (VPK, viral protein kinase, ppUL97)
UL98	U70	(core), LL	5′ → 3′ deoxyribonuclease producing 5′ monophosphate nucleosides[226] (NUC or pUL98)
UL99	U71	(core) myristylated tegument pp, TL	Secondary or final envelopment in the cytoplasm; trafficking and multimerization[110,196,210,290,388,402–405,415,416,448] (pp28, ppUL99)
UL100	U72	(core) 8TM virion envelope gp, TL	Complex with gN; role in envelopment or release[222,223,303,326,448] (gM, gpUL100)
UL102	U74	(core) DNA synthesis, E	Complexes with pUL70 and pUL105, DNA helicase–primase[13,329] (HP3, pUL102)
UL103	U75	(core) tegument, LL	Virion and dense body egress protein; enhances virion release from cells[4,105] (VEP, pUL103)
UL104	U76	(core) DNA encapsidation, LL	Capsid portal protein for DNA encapsidation; interacts with terminase[114,144] (PORT, portal protein, pUL104)
UL105	U77	(core) DNA synthesis, E	Complexes with pUL70 and pUL102, DNA helicase–primase; helicase homology[13,264,329] (HP1, pUL105)
lncRNA5.0	lncRNA3	Least abundant noncoding RNA, IE	Stable nonpolyadenylated intron[142,171,227]
UL111A		LL	Viral IL-10 (cmvIL-10) and latency-associated (LAcmvIL-10)[24–26,166,183,184,214,256,267,420]; regulate CD4T cell response[84,276,350] (vIL-10)
UL112-UL113	U79	DNA synthesis accessory, E	Multiple spliced; transcriptional activation and DNA synthesis via isoforms p43 and p84 recruitment of ppUL44[7,201,203,332,398] (p34, p43, p50, and p84 isoforms)
UL114	U81	(core) DNA synthesis accessory, E	Complex with pUL44 and pUL54; Excision of uracil from DNA and control of DNA synthesis[99,355,358,366,367,437] (UNG, uracil-DNA glycosylase)
UL115	U82	(core) envelope gp, TL	Complex with gH; gH/gL associates with either gO or UL128-UL131A for receptor binding and entry[47,92,190,272,466,498] (gL or pUL115)
UL116		Envelope gp, LL	Putative novel gH complex independent of gL[61]

HCMV[a,e]	HHV-6/HHV-7[b]	Properties/Expression/Gene Family[d]	Gene Function/Comments/(Gene Product Name)[e]
UL117	U84	LL	Enhances viral DNA synthesis; impairs cell DNA synthesis[362] (pUL117)
UL118-UL119	U85[f]	IgG Fc-binding envelope gp, LL	IgG Fc-binding protein (vFcR) related to OX-2[22,94,308,328,430] (gp68)
UL120		UL120 family; membrane-like gp, LL	
UL121		UL120 family; membrane gp, LL	
UL122	U86	Alternatively spliced exon 5; shared amino terminus IE1 (p86, IE; p60, LL; p40, TL)	Principle transactivator of viral gene expression; sequence-specific DNA-binding repressor with cell cycle impact; role during initiation of DNA synthesis[7,8,28,54,69,83,115,133,149,152,153,157,158,161,162,169,199,203,206,243,252,263,268,269,298,302,312,334,343–345,369,376,422,427,428,469,485,486,488,500,514] (IE2-86 kDa, IE2-p86, IE86 as well as late carboxyl-coterminal p60 and p40 isoforms)
UL123	U90[f]	Alternatively spliced exon 4; shared amino terminus with IE2	Major IE protein; enhances IE2 transactivation of transcription; binds HDACs; counteracts the IFN response[3,5,6,21,68,124,143,149,173,175,198,200,206,212,215,231,274,281,282,297,312,322,334,372,373,393–395,411,449,479,490,495,508,517] (IE1-72 kDa, IE1-p72, IE72 as well as additional carboxyl-coterminal isoforms)
UL124	U91[f]	Membrane gp, LL	Multiply spliced
UL126		Nuclear protein	Counteracts 2′,5′ oligoadenylate synthetase; possible role in latency and reactivation[209,230,445,467] (pORF94)
UL128		Envelope gp, LL	Component of pentameric gH/gL/pUL128/pUL130/pUL131A complex; enhances monocyte, endothelial, and epithelial cell tropism[93,272,377,383,438,472] (gpUL128)
UL130		Envelope gp, LL	Component of pentameric gH/gL/pUL128/pUL130/ pUL131A complex; enhances endothelial and epithelial cell tropism[93,272,377,383,472]; interacts with snapin[474] (gpUL130)
UL131A		Envelope gp, LL	Component of pentameric gH/gL/pUL128/pUL130/ pUL131A complex; enhances endothelial and epithelial cell tropism[93,272,377,383,472] (gpUL131A)
UL132		Envelope gp, LL	Enhances endocytosis and assembly of virions[220,426,495] (gpUL132)
UL148		Membrane gp, LL	Reorganizes the ER; retains CD58 and enhances unfolded protein/ integrated stress responses via IRE1 and PERK[313,314,413,473,511] (gpUL148)
UL147A		Membrane-like gp, TL	
UL147		UL146 CXC family; chemokine-like, TL	Chemokine-like[335] (vCXCL2, pUL147)
UL146		UL146 CXC family, TL	Potent hCXCR1/hCXCR2-specific chemokine; highest sequence variability[160,168,265,335] (vCXCL1, pUL146)
UL145		RL1 family, E	Recruits cullin4 E3 ligase to degrade HLTF and STAT2, impeding antiviral responses and enhancing IE gene expression[235,316] (pUL145)
UL144		Membrane gp, LL	HVEM mimic; inhibits NF-κB activation; triggers coinhibitory BTLA to inhibit T-cell activation; high sequence variability[40,346,348] (gpUL144)
UL142		MHC family; membrane gp, TL	Sequesters NKG2D ligands MICA and ULBP3 to impede NK-cell killing[20,31,73,109,333] (gpUL142)
UL141		UL14 family; membrane gp, LL	Sequesters TRAIL-R and restrains DNAM-1 ligands CD155 and, with US2, CD112to impede NK-cell killing[167,309,333,359,421,495]; interacts with CELF5 to impact viral DNA synthesis[521] (gpUL141)

HCMV[a,c]	HHV-6/HHV-7[b]	Properties/Expression/Gene Family[d]	Gene Function/Comments/(Gene Product Name)[e]
UL140		Membrane protein, LL	
UL139		Membrane gp, LL	
UL138		Golgi localized membrane protein, E	Enhances TNFR1 and EGFR levels and activity; impairs replication in CD34+ cells; degrades ABCC1/MRP1[55,56,234,239,240,296,299,339,681] (pUL138)
UL136		Golgi localized membrane protein, E	Binds to ATP1B1; cell tropism determinant in endothelial cells; *in vitro* and *in vivo* possible role in latency and reactivation[57,71,72,102,246,296] (p19, p23, p25, p26, p33 isoforms)
UL135		Actin cytoskeleton, Golgi localized Membrane protein, E	Binds to ABI1 and ABI2, drives CPE and restricts immune recognition through remodeling actin[333,433]; Binds ABI1 and CIN85 to traffic EGFR for degradation[56,57,296,364] (pUL135)
UL133		Membrane protein, E	[296,461]
UL148A		Membrane protein	Degrades NKG2D ligand MICA to impede NK-cell killing[196,333] (pUL148A)
UL148B		Membrane-like protein	
UL148C		Membrane-like protein	
UL148D		Membrane protein, E	
UL150		Secreted protein, LL	Multiply spliced[142]
UL150A			Multiply spliced[142]
IRS1		US22 family; tegument, IE	Binds dsRNA and PKR (blocks PKR pathway)[49,275,518] (pIRS1)
US1		US1 family, TL	
US2		US2 family; membrane gp, E	Dislocates from ER and degrades MHC-I, MHC-II, and other cellular proteins via TRC8[32,135,145,167,260,267,317,325,456,489] (gpUS2)
US3		US2 family; membrane gp, IE	Inhibits maturation and transport of peptide complexes with MHC-I and MHC-II[32,187,188,238,295,317] (gpUS3)
US6		US6 family; membrane gp, E	Inhibits TAP-mediated ER peptide transport[9,32,116,155,159,163,317] (gpUS6)
US7		US6 family; membrane gp, LL	Antagonizes TLR signaling via Derlin-1 and Sec61[330, p. 9965]
US8		US6 family; membrane gp, E	Binds MHC-I; antagonizes TLR signaling[317,330] (gpUL8)
US9		US6 family; membrane gp, E	ER/mitochondria-localized; sequesters NKG2D ligand MICA to impede NK-cell killing[333,400]; blocks nuclear localization of IRF3[85] (gpUS9)
US10		US6 family; membrane gp, E	Degrades HLA-G[331] (gpUS10)
US11		US6 family; membrane gp, E	Dislocates and degrades MHC-I from ER[32,260,267,317,325] (gpUS11)
US12		US12 family; 7TM-like, E	Sequesters NKG2D ligand ULBP2 to impede NK-cell killing[130,333] (pUS12)
US13		US12 family; 7TM-like, E	Sequesters NKG2D ligand MICB to impede NK-cell killing[130,333] (pUS13)
US14		US12 family; 7TM-like, E	Sequesters PTPRM[130] (pUS14)
US15		US12 family; 7TM-like, LL	Sequesters IL6ST[130] (pUS15)
US16*		US12 family; 7TM-like, E	Enhances replication in endothelial and epithelial cells[51] via increased gH/gL pentamer levels[261] (pUS16)
US17		US12 family; 7TM-like, E	Activates host cell signaling[151] (pUS17)
cORF29		E	Interacts with pUL50[294] (Nuclear rim–associated cytomegaloviral protein, RASCAL)
US18		US12 family; 7TM-like, E	Degrades NKG2D ligand MICA and NKp30 ligand B7-H6 to impede NK-cell killing[77,109,129,130,333] (pUS18)

HCMV[a,c]	HHV-6/HHV-7[b]	Properties/Expression/Gene Family[d]	Gene Function/Comments/(Gene Product Name)[e]
US19*		US12 family; 7TM-like, E	Enhances replication in HMVECs[117] (pUS19)
US20		US12 family; 7TM-like, E	Promiscuous degradation of NKG2D ligand MICA and NKp30 ligand B7-H6 to impede NK-cell killing[77,109,129,130,333]; Enhances replication in endothelial cells[70] (pUS20)
US21		US12 family; 7TM-like, TL	Viroporin modulates intracellular Ca^{++} and cell death[262] (pUS21)
US22	DR1x1 DR1x2	US22 family; tegument, E	(pUS22)
US23		US22 family; tegument, E	(pUS23)
US24		US24 family; tegument, E	Enhances early infection[127] (pUS24)
US26	DR6x1 DR6x2	US22 family; tegument, E	Enhances release[259] (pUS26)
US27		GPCR family; 7TM envelope gp, LL	Enhances release[320]; forms complex with CXCR4 and IL-10R[41,459] (pUS27)
US28		GPCR family; 7TM envelope gp, LL	Constitutive and CC/CX3C chemokine-activated signaling and cell migration[257,293,380,439]; possible role in latency and reactivation[119,216] (pUS28)
US29		Membrane-like gp, LL	Enhances replication in RPE cells[117]
US30*		Membrane-like gp, LL	
US31		US1 family	Interacts with and drives NF-κB activation[150] (pUS31)
US32		US1 family, LL	Localization to and alteration of PML[286] (pUS32)
US33A		DE	[142,436]
US34		Putative secreted protein, DE	
US34A		Putative membrane protein, DE	
TRS1		US22 family; tegument, IE	Binds dsRNA and PKR (blocks PKR activity)[49,275,467,468] (pTRS1)

[a]Coordinated with HCMV genome map (Fig. 12.3).

[b]Commonly annotated protein-coding and long noncoding RNA genes of HCMV, together with selected genes conserved in roseoloviruses, HHV-6A, HHV-6B, and HHV-7. Disruption of genes within the HCMV genome have yielded enhanced replication depending on cell type (*) or one of three phenotypes on fibroblasts: failure to replicate (bold black[†]), reduced replication (bold gray[¥]) or no change in replication (normal type). Genes in normal type are often referred to as dispensable for replication.

[c]Betaherpesvirus-common genes are in shaded fields and include herpesvirus-common (core) as well as genes conserved between betaherpesviruses and gammaherpesviruses (betagamma).

[d]Gene family and expression class based on accumulation of gene products (IE, immediate early or α; DE, delayed early or β; LL, leaky late or γ1; TL, true late or γ2). Protein characteristics indicated as glycoprotein (gp) or phosphoprotein (pp).

[e]Functional information is based on information from studies on HCMV, together with insights from related CMVs and, for core genes, other herpesviruses. Relevant publications focused on gene function are cited.

[f]Positional homolog lacking substantial sequence similarity.

SUPPLEMENTARY TABLE 12.2 Summary Information on HCMV miRNAs

miRNA[a,b]	Sequence[c]	Abundance[d]	Function/Comments[e]
miR-UL22A-1-5p	TAACTAGCCTTCCCGTGAGA	0.041	Down-regulates SMAD3 to block TGFβ signaling and is required for genome maintenance and latency[9]
miR-UL22A-1-3p	TCACCAGAATGCTAGTTTGTAG	0.094	Down-regulates SMAD3 to block TGFβ signaling and is required for genome maintenance and latency[9]
miR-UL36-1-5p	TCGTTGAAGACACCTGGAAAGA	0.284	Down-regulates adenine nucleotide translocator3 (ANT3)[6] Down-regulates UL138 to promote viral DNA synthesis[13]
miR-UL36-1-3p	TTTCCAGGTGTTTTCAACGTG	0.004	
miR-UL70-1-5p	TGCGTCTCGGCCTCGTCCAGA	ND	Detected in cells infected with HCMV AD169[3] and clinical isolates AF2380 U8795,[31] but not Towne[29]
miR-UL112-1-5p	CCTCCGGATCACATGGTTACTCA	<0.001	
miR-UL112-1-3p	AAGTGACGGTGAGATCCAGGCT	0.012	Down-regulates pUL123 (IE1),[4,23] pUL112/113,[4] pUL120/121,[4] pUL114,[31] MHC I-related chain B (MICB),[30] BclAF1,[20] and interferon regulatory factor 1 (IRF-1)[21]; elevated expression in plasma of hypertensive patients versus normals ($p < 0.0001$)[21]; down-regulates ATG5 to inhibit autophagy[16]; down-regulates TLR2 to limit TLR2-IRAK1and NFκB signaling[18]; in conjunction with miR-US5-1, down-regulates IKKα and IKKβ to inhibit proinflammatory NFκB signaling[10]; synergizes with miR-US5-1 and miR-US5-2-3p to down-regulate components of the endocytic recycling compartment including VAMP3, RAB5C, RAB11A, and SNAP23,[12] coregulates FOXO3a to protect against cell death in CD34+ HPCs with miR-US5-1 and UL7 protein[8]
miR-UL148D-1	TCGTCCTCCCCTTCTTCACCGT	0.001	Accumulates during latency; down-regulates immediate early response gene 5 (IER5) to rescue CDC25B, resulting in increased CDK1 and decreased viral IE gene expression for the establishment of latency[24]; down-regulates ACVR1B to inhibit IL-6 secretion response to activin[19]; down-regulates RANTES/CCL5[17]
miR-US4-1-5p	TGGACGTGCAGGGGGATGTCTG	0.002	Down-regulates aminopeptidase ERAP1 to inhibit CD8+ T-cell responses[15]; high serum levels correlate with positivity to IFN treatment responsiveness[25]
miR-US4-1-3p	TGACAGCCCGCTACACCTCTCT	<0.001	
miR-US5-1	TGACAAGCCTGACGAGAGCGT	0.001	Synergizes with miR-US5-2-3p to down-regulate pUS7[32]; in conjunction with miR-UL112-1, down-regulates IKKα and IKKβ to inhibit proinflammatory NFκB signaling[10]; down-regulates DNA synthesis inhibitor Geminin[14]; synergizes with miR-UL112-3p and miR-US5-2-3p to down-regulate components of the endocytic recycling compartment including VAMP3, RAB5C, RAB11A, and SNAP23[12]; coregulates FOXO3a to protect against cell death in CD34+ HPCs with miR-UL112-1-39 and UL7 protein[8]
miR-US5-2-5p	CTTTCGCCACACCTATCCTGAAA	0.001	
miR-US5-2-3p	TATGATAGGTGTGACGATGTCT	0.382	Synergizes with miR-US5-1 to down-regulate pUS7[32]; down-regulates the NAB1 TGFβ transcriptional repressor and contributes to HCMV myelosuppression[9]; synergizes with miR-US5-1 and miR-UL112-3p to down-regulate components of the endocytic recycling compartment including CDC42[12]; down-regulates GAB-1 attenuating EGFR and diminishing UL138 expression[11]
miR-US22-1-5p	TGTTTCAGCGTGTGTCCGCGGG	0.007	Down-regulates early growth responsive factor-1 (EGR-1), resulting in reduced CD34+ cell proliferation and differentiation; required for reactivation[22]; down-regulates ATG5 to inhibit autophagy[16]
miR-US22-1-3p	TCGCCGGCCGCGCTGTAACCAGG	0.001	

miRNA[a,b]	Sequence[c]	Abundance[d]	Function/Comments[e]
miR-US25-1-5p	AACCGCTCAGTGGCTCGGACC	0.063	Down-regulates cyclin E2 and other cell cycle genes by targeting 5′UTRs[5]; down-regulates viral DNA replication but not specific to HCMV[31]; down-regulates ATP6V0C involved in the acidification of endosomal compartments[26]
miR-US25-1-3p	GTCCGAACGCTAGGTCGGTTCT	<0.001	
miR-US25-2-5p	AGCGGTCTGTTCAGGTGGATGA	0.028	Down-regulates IE1 and pp65 and viral DNA synthesis but not specific to HCMV[31]
miR-US25-2-3p	ATCCACTTGGAGAGCTCCCGCGG	0.037	Down-regulates eIF4A1 with a resulting defect in viral gene expression[28]
miR-US29-5p	TGGATGTGCTCGGACCGTGACG		Down-regulates ATG5, IFNAR2[16]; same sequence as miR-US33as-1
miR-US33-1-5p	GATTGTGCCCGGACCGTGGGCG	0.015	Down-regulates syntaxin 3 with a resulting block to viral DNA synthesis and replication[7]
miR-US33-1-3p	TCACGGTCCGAGCACATCCAA	0.001	
miR-US33as-1-5p	TGGATGTGCTCGGACCGTGACG	0.022	
miR-US33as-1-3p	CCCACGGTCCGGGCACAATCA	0.002	

[a]miRNAs were identified by a combination of small RNA cloning and sequencing,[2,27] comparison of HCMV and chimpanzee genomes,[3] and deep sequencing of small RNAs[29] from infected fibroblasts. miR-UL23-5p, miR-UL23-3p, and miR-US24[2] were renamed miR-UL22A-5p, miR-UL22A-3p, and miR-US25-1, respectively.[1]

[b]miRNAs are named for the viral ORF with which they overlap; or, if they reside between ORFs, they are named for the nearest upstream annotated ORF encoded on the same strand of the viral genome. ORF designations are followed by a number to distinguish multiple miRNAs in the same ORF location, and the two arms processed from a common pri-miR hairpin are distinguished by 5p versus 3p.

[c]Most abundant form in fibroblasts at 72 hpi with the HCMV Towne strain.[29]

[d]Relative abundance at 72 hpi is based on a calculation from deep sequencing results reported in Ref.[29], i.e., the number of sequence reads for each miRNA divided by the combined sequence reads for all miRNAs (except miR-UL70-1-5p, which was not detected, ND, in this analysis).

[e]Target identification/validation methods required for citation: luciferase reporter assay or ectopic expression; protein assay in infected cells; virus mutated for miRNA; virus mutated for target site; immunoprecipitation.

INTRODUCTION AND HISTORY

Varicella–zoster virus (VZV) belongs to the alphaherpesvirus subfamily of the *Herpesviridae*. Primary VZV infection usually occurs in childhood and causes varicella (chickenpox), characterized by a pruritic vesicular rash. VZV tropism for T lymphocytes allows viral dissemination from mucosal sites of inoculation to skin (Fig. 13.1). VZV then becomes latent in ganglionic neurons and may reactivate to cause zoster (shingles), characterized by pain and a dermatomal rash due to anterograde axonal transport of the virus. VZV persists in the human population by transmission to susceptible individuals from contacts with either varicella or zoster.

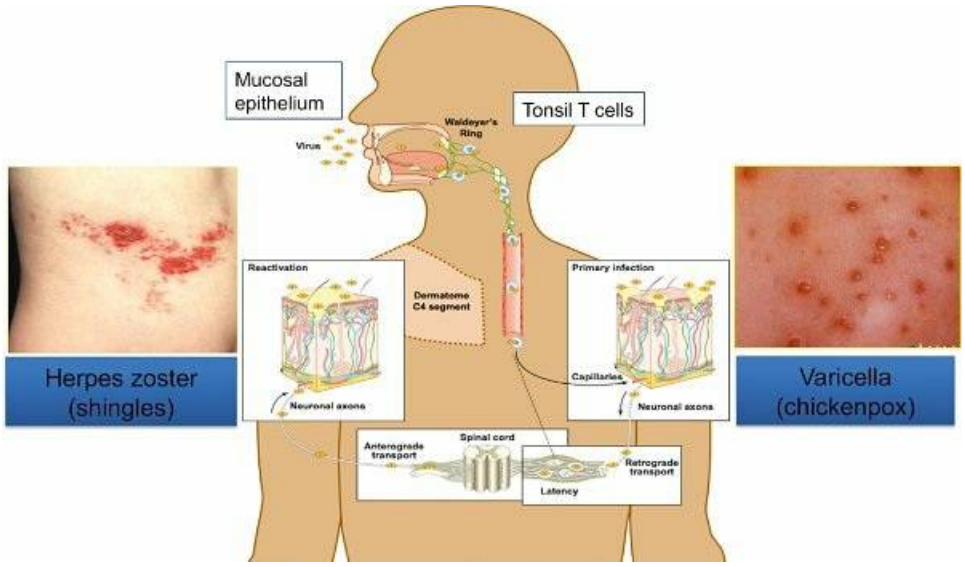

FIGURE 13.1 Model of the pathogenesis of varicella–zoster virus (VZV) infection. Primary VZV infection is acquired by inoculation of mucosal epithelial cells of the upper respiratory tract. Replication at the site of entry allows VZV transfer into tonsils and other local lymphoid tissues, where T cells become infected. Infection of dendritic cells in the mucosal epithelium may support virus transfer to regional lymph nodes. VZV-infected T cells transport the virus to skin sites of replication via a cell-associated viremia. After a 10- to 21-day interval, skin infection produces the vesicular rash associated with varicella (chickenpox). In the course of primary infection, VZ virions gain access to the sensory nerve cell body by retrograde axonal transport or via T-cell viremia to establish latent infection within neurons of the sensory ganglia. Episodes of reactivation, during which VZV gains access to skin via anterograde axonal transport, can cause symptoms of zoster (shingles).

Milestones in understanding VZV include the distinction between varicella and smallpox by Herberden (1768), the association of ganglion inflammation with the dermatomal distribution of the zoster rash by Von Barensprung (1863) and Head and Campbell (1900),[158] and confirmation of a proposed common infectious etiology for varicella and zoster (1892)[37] by the observation of varicella in children inoculated with zoster lesion fluid.[393] The suggestion by Garland[119] and Hope-Simpson[166] that zoster resulted from reactivation was documented by Weller et al. who showed that inoculation of varicella and zoster lesion fluid produced identical virions and cytopathic effects in cultured cells.[461,462] VZV latency in neurons was proved by Gilden et al. using VZV DNA probes[129] and Hyman et al. with VZV RNA.[171] Straus et al. compared restriction endonuclease patterns of VZV DNA from episodes of varicella and zoster in an immunocompromised patient to show that reactivation was caused by the original infecting virus.[402] Breuer et al. documented VZV reinfection using genotyping of viruses from two episodes of zoster in an immunocompetent person.[42]

VZV was the first herpesvirus genome to be fully sequenced, done by Davison and Scott,[90] and genome sequencing has since revealed several geographically distributed clades.[41,181,307,376] The construction of recombinant viruses with targeted mutations using cosmids or bacterial

artificial chromosomes (BAC) has established the functions of many VZV genes and promoter elements *in vitro*[30,261,413,496] and for VZV pathogenesis *in vivo* by Arvin et al. using human tissue xenografts in a severe combined immunodeficiency (SCID) mouse model.[281,282,486,488,489] Major clinical advances were achieved with the development of effective antiviral drugs,[24,102,465] the live attenuated Oka vaccine derived from a clinical isolate by Takahashi (1974),[323,408] and the recombinant glycoprotein E vaccine.[87,235] VZV remains the only vaccine-preventable human herpesvirus infection.

CLASSIFICATION

The genus *Varicellovirus* of the alphaherpesvirus subfamily includes VZV, simian varicella virus (SVV) (cercopithecrine herpesvirus 9), pseudorabies virus (PRV) (suid herpesvirus 1), and equine herpesvirus 1 (equid herpesvirus 1). VZV is most closely related to SVV.[140] These viruses infect the skin, mucous membranes, and visceral and nervous system tissues and share a genomic arrangement encoding many orthologous genes. Of the three human alphaherpesviruses, VZV is a highly human-restricted pathogen, whereas the other human alphaherpesviruses, herpes simplex viruses HSV-1 and HSV-2 can infect many species.

VIRION STRUCTURE

Morphology

The four major components of VZV particles are the core, nucleocapsid, tegument, and envelope (Fig. 13.2). One copy of the linear, double-stranded (ds) DNA VZV genome is presumed to be incorporated into each virion forming the core. Particles imaged by electron microscopy (EM) have a loose fibrillar cage of strands surrounding a dense cylindrical core of DNA fibers.

Varicella-zoster virus infections: biology, natural history, treatment, and prevention. *Ann Intern Med* 1988;108(2):221–237. Courtesy of Dr. William Ruyechan.)

Like other herpesviruses, the VZV nucleocapsid consists of 162 capsomere proteins with a 5:3:2 axial symmetry, in which pentameric proteins form the vertices of an 80 to 120 nm icosahedron, while hexameric elements constitute its facets. VZV nucleocapsids recovered from cell culture often lack genomes, consistent with the low infectivity of VZV particles produced *in vitro*. The VZV gene products that constitute the nucleocapsid have not all been verified but are expected to include the products of VZV open reading frames (ORFs) *20*, *21*, *23*, *33*, *40*, and *41*, by analogy with their herpesvirus orthologs.

The VZV tegument includes three immediate early (IE) proteins encoded by *ORFs 4*, *62*, and *63*.[213,216] In addition, the *ORF9* to *ORF12* gene cluster, conserved in alphaherpesviruses, encodes three tegument proteins, ORF9 to ORF11, and the putative tegument protein, ORF12.[61,248] The viral kinases, encoded by *ORF47* and *ORF66*, are also tegument proteins. ORFs 22, 38, 53, 57, and 64/69 are putative tegument proteins.[496] Nucleocapsids and associated tegument proteins are enveloped within patches of host cellular membranes that display virally encoded glycoproteins. Since particles can capture membranous elements of the endoplasmic reticulum (ER), cytoplasmic vesicles, and the cell surface, the VZV envelope does not appear to have a single source. The mature VZV particle, consisting of the nucleocapsid, tegument, and lipid membrane envelope, is pleomorphic to spherical and 180 to 200 nm in diameter.

Physical and Chemical Properties

The lipid envelope renders VZV susceptible to loss of infectivity by organic solvents, detergents, or proteases; heating to 60°C; prolonged storage at temperatures of −70°C or above; extremes of pH; or ultrasonic disruption. In cesium chloride gradients, enveloped VZV particles band at a buoyant density of 1.274 g/cm^3, while VZV DNA exhibits a buoyant density in cesium chloride of 1.705 g/cm^3.

GENOMIC STRUCTURE AND ORGANIZATION

The VZV dsDNA genome is approximately 125,000 bp,[90] consists of a unique long region (UL) of about 105,000 bp flanked by inverted repeat regions, the terminal repeat long (TRL) and internal repeat long (IRL) sequences (88.5 bp), and a unique short region (US) (5,232 bp) flanked by the terminal repeat short (TRS) and inverted repeat short (IRS) (7,319.5 bp) (Fig. 13.3). Overall, 46% of VZV bases are G + C, whereas the G + C content of its repeat elements is approximately 60% to 68%.[401] Unlike SVV and other varicelloviruses, VZV lacks a terminal region with flanking inverted repeats at the left end of the genome.[140]

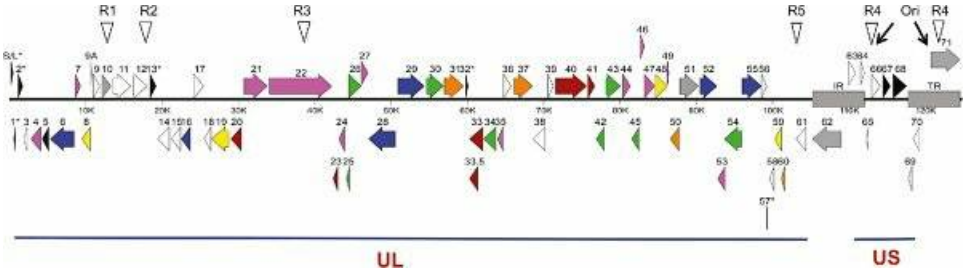

FIGURE 13.3 Organization of the varicella–zoster virus (VZV) genome and known or predicted open reading frames encoding viral proteins. The VZV genome has unique long (UL) and unique short (US) regions flanked by internal repeat (IR) and terminal repeat (TR) regions. VZV has 40 core genes that are conserved among α-, β-, and γ-herpesviruses; these gene products participate in DNA replication (*blue*), DNA cleavage and packaging (*green*), nucleic acid metabolism (*yellow*), and capsid protein assembly (*red*); or envelope glycoproteins (*orange*); or have other functions (*pink*). The genes that are not conserved among the other herpesviruses may be nonessential for VZV replication in cultured cells (*white*) or may be essential (*gray*), three of which are envelope glycoproteins (*black*). Six VZV genes have no HSV-1 ortholog (*). *Open arrows* and *black arrows* indicate repeats (R1–R5) and the origins of DNA replication (ori$_s$), respectively. When the genome is circularized, ORF S/L (ORF 0) begins at the right end and extends across the terminal repeat into the UL region at the left end.

VZ virions usually contain the viral genome as a linear molecule; a circular, supercoiled

conformation is rarely detected.[219] The genome has two predominant isoforms,[105] with 50% having the US and 95% having the UL region directed in a single orientation.[89,219] An unpaired cytosine at its left end and a guanine at the right end allow the genome to form a circular molecule[89]; the termini are covalently joined in latency.[69] ORFS/L (or ORF 0), located at the end of the UL, encodes a protein essential for replication[194,197,495] and the sequence at the 5′ terminus of ORFS/L is required for DNA cleavage.[194] This UL sequence is not duplicated at the opposite end of the UL, which may explain the single orientation of UL in 95% of VZV genomes.

The VZV genome encodes at least 71 ORFs, 3 of which are present in two copies in the IRS and TRS regions, 63 are in the UL, 4 are in the US and the ORF-S/L gene (Fig. 13.3; Table 13.1). Mutagenesis studies indicate that about 44 ORFs are required for replication *in vitro*, with some variations depending on conditions. Twelve of twenty-six dispensable genes are in the *ORFS/L* to *ORF15* region.[66,496] Gene duplications are highly preserved since removal of one copy of the gene pairs *ORF62/71*, *ORF63/70*, or *ORF64/69* is corrected after a few replication cycles.[316,387] Many VZV ORFs are arranged in unidirectional groups of up to four genes with a single putative polyadenylation signal at the 3′ end of the group. Eleven VZV ORFs have overlapping coding sequences. *ORFs 42* and *45* are thought to be spliced segments of the same gene.[90] *ORFS/L* is spliced in the 3′ noncoding region[197] in VZV strains including parent Oka but not vaccine Oka.[226] Small noncoding RNAs, including potential micro-RNAs, have also been identified in VZV-infected cells, which may contribute to the regulation of VZV gene expression and viral replication.[268]

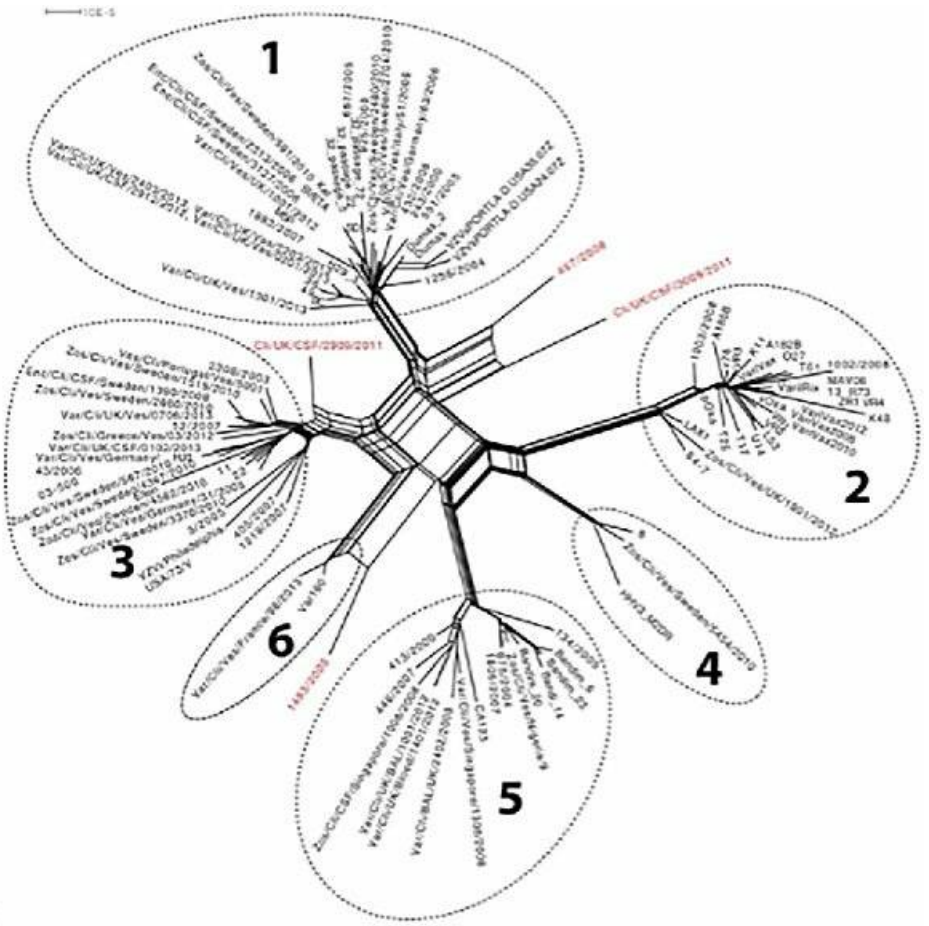
NL: normal as compared to wild-type VZV.

[a]Defined by mutagenesis of the VZV genome (pOka or vaccine Oka) using cosmids or BACs to delete, insert stop codon or introduce targeted changes in the coding sequence.



[b]Indicates differences among published observations about whether the gene is essential or dispensable, including variations in mutations tested and/or experimental conditions used to assess growth requirement.

[c]Indicates predicted function based on conserved sequence.Abbreviations: TGN-trans Golgi Network; IDE-insulin degrading enzyme

The VZV genome has five small regions of unknown function, R1 through R5, which vary in length and contain different numbers of identically oriented short tandemly repeating elements,[90,180,400] which are relatively few compared to PRV and HSV-1.[407] R1, located within *ORF11*, consists of four separate 15- or 18-bp repeats. R2, located within *ORF14*, which encodes glycoprotein C (gC), consists of 42-bp repeats in multiples that differ among VZV isolates. The largest, R3 (1,000 bp), is in *ORF22*.[90] R4 has multiple 27-bp elements located in both IRS and TRS regions between *ORF62* and *ORF63* (and *ORF70* and *ORF71*). R5 is A-T instead of G-C rich and consists of 88-bp and 24-bp repeats located between *ORF60* and *ORF61*. The Dumas strain of VZV has only one copy of the R5 repeat.

The VZV genome exhibits limited geographic diversity.[41,181,307,376] The classification of geographically distinct VZV isolates into seven phylogenetic clades using single nucleotide polymorphisms (SNP) has been modified based on whole VZV genome sequences, which has

identified six clades (1 to 6) and three provisional clades (VII-IX) (Fig. 13.4).[181,307] Their predominant distributions are Europe, clades 1 and 3 with some clade 6; Japan and East Asia, clade 2 with some clade 4; and Africa, clade 5.[337] Clades 1 and 2 are the most divergent but are still 99.83% identical. Comparison of the sequence of the Oka vaccine virus (clade 2) with that of the parent Oka virus revealed 63 sites that differ[81]; however, the analysis was limited because the Oka vaccine stock is a mixture of genomes reflecting its derivation by tissue culture passage. Deep sequencing demonstrates at least 224 SNP differences between vaccine and the parent Oka virus[95] and also that despite the presence of multiple genome populations, the genetic composition of these vaccines remains stable. VZV has been calculated to undergo about 20 replicative cycles in the human host before latency is established, suggesting limited opportunity for the accumulation of genetic mutations. Whole genome sequencing has also revealed that circulating VZV strains exhibit markers of homologous recombination, including both intraclade and interclade events,[307] which is evidence of both reinfection of an individual host and simultaneous replication of different VZV strains within a single host cell.

FIGURE 13.4 Phylogenetic network based on complete genomes of VZV strains and VZV single nucleotide polymorphisms SNP-based genotyping. **A:** Full VZV genomes recovered from 115 zoster cases cluster in clades *1* to *5* and a novel sixth clade; four outliers are classified as putative interclade recombinants or novel clades (in *red*). Clades *1*, *3*, and *5* include isolates of European origin; clade *2* has Asian isolates, including the parent Oka virus used to derive VZV vaccines; and clade *4* has isolates from tropical Africa. (From Norberg P, Depledge DP, Kundu S, et al. Recombination of globally circulating varicella zoster virus. *J Virol* 2015;89(14):7133–7146. Copyright © 2015 American Society for Microbiology. Reproduced with permission from American Society for Microbiology.) **B:**

Genotyping of 89 full VZV genomes identified single nucleotide SNP at positions based on the reference strain Dumas (Clade 1, GenBank accession #NC 001348). (Republished with permission of Microbiology Society Jensen NJ, Rivailler P, Tseng HF, et al. Revisiting the genotyping scheme for varicella-zoster viruses based on whole-genome comparisons. *J Gen Virol* 2017;98(6):1434–1438.)

Comparison of the VZV genome with those of the seven other human herpesviruses indicates that VZV shares at least 40 conserved genes, all of which are among the 62 genes located in the UL region. These conserved genes encode an IE protein (*ORF4*); the DNA polymerase; helicase–primase complex proteins; other viral enzymes; the ORF47 kinase and structural proteins, including the major nucleocapsid and related proteins for assembly; and the glycoproteins gB, gH, gL, gM, and gN.

The predicted amino acid sequences of many VZV and HSV-1 gene products have similarities (Table 13.1). Of the 62 genes in the VZV UL region, 56 have HSV orthologs, as do all 4 of the genes encoded in the VZV US region. Nevertheless, while functions may be conserved even with limited sequence similarities,[116] they must be confirmed experimentally, as illustrated by differences in the roles of VZV ORF61 and HSV-1–infected cell protein (ICP) 0,[443] and of ORF10 and HSV-1 VP16 (UL48).[62] Each of the six VZV ORFs (*ORFs 1*, *2*, *13*, *32*, *57*, and *S/L*) that lack HSV-1 orthologs is dispensable for VZV replication in cell culture.[78,80,86,197,227,349,370] *ORFs 1*, *32*, and *57* have orthologs in SVV and the equine herpesviruses.[140] *ORF13* has no related gene in the other alphaherpesviruses but has an ortholog in human herpesvirus 8, a gammaherpesvirus. The VZV genome can be engineered to express genes from other viruses.

STAGES OF REPLICATION

Overall Pattern of Replication

VZV is presumed to attach to cells by fusion of the viral envelope with the cytoplasmic membrane followed by endocytosis (Fig. 13.5). On entry, VZV tegument proteins encoded by *ORFs 4*, *10*, and *62*[213,216] are likely transported with the nucleocapsid to the nucleus to initiate transcription. ORF61 is expressed along with IE62 shortly after virus entry[351] but is not a tegument protein. IE63 and the viral kinases ORF 47 and 66 are also likely to be important early in infection. Replication compartments containing IE62, the single-stranded DNA (ssDNA)-binding protein, ORF29, and nascent VZV DNA are formed within 4 hours after infection[351] (Fig. 13.5). Thereafter, proteins encoded by late mRNAs enter the nucleus for assembly into nascent capsids and VZV DNA is encapsidated by mechanisms that are not well defined[426]; ORF25 protein interacts with several encapsidation proteins.[427] The life cycle from entry to formation of mature enveloped VZ virions is completed in about 9 hours *in vitro.* By 12 hours, enveloped viruses are abundant in the cytoplasm and extracellularly along plasma membranes where they are presumed to bind surface receptors, fuse with membranes of adjacent cells, and begin synthesis of progeny virions. While syncytia formation is a hallmark of VZV infection,

cell–cell fusion is not required to initiate the infectious process; however, the uninfected cell must be in close proximity to an infected cell, suggesting that virions attached to cell surfaces are transferred into neighboring cells.[351]

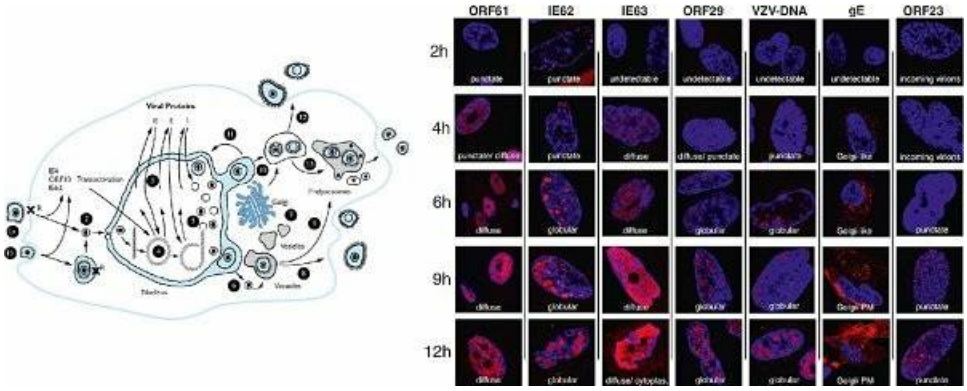

FIGURE 13.5 Replication of varicella–zoster virus (VZV). **Left panel:** The schema shown accommodates observations from multiple sources and relies on analogies drawn from studies of herpes simplex virus (HSV) replication. VZV may enter cells by attaching to cell surface glycosaminoglycans followed by binding to receptor(s) (*R*) on the plasma membrane (*1a*), or by endocytosis followed by interaction with a receptor(s) in the endosome (*1b*). The nucleocapsids penetrate the cell (*2*) and enter the nucleus where, with the aid of regulatory tegument proteins encoded by IE4, ORF10, and IE62, a cascade of viral immediate-early (*IE*), early (*E*), and late (*L*) transcripts and proteins is synthesized (*3*). Viral DNA replication follows a rolling-circle model (*4*). Nucleocapsids are assembled and package newly synthesized DNA (*5*). Nucleocapsids appear to be transiently enveloped as they bud through the inner nuclear lamellae *(6)*. These nucleocapsids lose their envelopes upon fusion with the rough endoplasmic reticulum, resulting in the release of naked nucleocapsids into the cytoplasm (*7*). Virion glycoproteins are synthesized in the rough endoplasmic reticulum, mature in the Golgi apparatus, and line the inner surfaces of cytoplasmic vesicles. Viral tegument proteins are synthesized by free ribosomes and line the outer surfaces of the cytoplasmic vesicles. Nascent particles are drawn into these vesicles, where intact, enveloped virions coalesce (*8*). (From Gershon AA, Sherman DL, Zhu Z, et al. Intracellular transport of newly synthesized varicella-zoster virus: final envelopment in the trans-Golgi network. *J Virol* 1994;68:6372–6390.) These vacuoles may fuse with the cell membrane to release infectious progeny *(9)*, although some fuse with prelysosomes in which the particle is partially degraded before release. Alternatively, nucleocapsids may retain their envelopes as they egress the nucleus. (*10*) Their envelopes are glycosylated by fusion with Golgi-derived vesicles. Late in infection, some particles may reenter the nucleus (*11*), although most are transported to the cell surface for release (*12*) or to prelysosomes (*13*). **Right panel:** The spatiotemporal pattern of expression of selected varicella–zoster virus (VZV) immediate-early, early, and late proteins and viral genomic DNA. Cells were fixed and imaged at 0 (not shown), 2, 4, 6, 9, and 12 hours after inoculation of unlabeled human fibroblasts with input cells labeled with green CellTracker. Cells were then stained with specific antibodies for VZV proteins ORF61, IE62, IE63, ORF29, gE, and ORF23 (*from left to*

right) followed by Texas red–conjugated secondary antibodies to detect proteins (*red*). VZV DNA was detected by *in situ* hybridization (*red*). Cell nuclei were counterstained with Hoechst 22358. Ten fields of 30 to 50 output cells were scanned to determine the representative staining patterns in newly infected cells at each time point. Single representative cells or nuclei are shown. PM, plasma membrane; cytoplas, cytoplasm. (Reprinted from Reichelt M, Brady J, Arvin AM. The replication cycle of varicella-zoster virus: analysis of the kinetics of viral protein expression, genome synthesis, and virion assembly at the single-cell level. *J Virol* 2009;83(8):3904–3918.)

The basic events in VZV replication have been defined in cell culture using intact virus and VZV recombinants with targeted mutations in viral genes and promoter regions to map protein and promoter functions (Table 13.1).[30,206,208] However, many important characteristics of the regulation of gene expression and the essential or important functions of viral gene products during the viral life cycle are not identifiable *in vitro* but are evident when human tissue explants or differentiated human cells are infected *in vitro* or in their tissue microenvironments in human xenografts in the SCID mouse model *in vivo* (Table 13.1).

Attachment, Entry, and Uncoating

The initial attachment of alphaherpesvirus particles to the cell surface appears to entail nonspecific electrostatic interactions between viral envelope glycoproteins and cell surface glycosaminoglycans such as heparan sulfate. Whereas HSV gD and its orthologs in other alphaherpesviruses bind to cell surface receptor molecules known as herpesvirus entry mediators, VZV lacks a gD ortholog and may not use any of these receptors. The αV integrin subunit contributes to VZV-mediated fusion and infection,[477] and the cation-independent mannose-6-phosphate receptor may facilitate VZV entry by interacting with viral glycoproteins that contain phosphorylated N-linked complex oligosaccharides.[67,498]

After attachment, the herpesvirus glycoproteins gB, gH, and gL are required for fusion of the viral envelope with the cell membrane. In VZV, these glycoproteins also form the core fusion complex required for cell–cell fusion. High-resolution structures of VZV gB and gH show similarities and differences from their orthologs in other herpesviruses[315,472] (Fig. 13.6). VZV gB residues in the primary loop are essential for VZV replication[312] and gB domain IV is important for triggering fusion.[315] VZV gH appears to facilitate fusion of the VZV envelope with the cell membrane since antibodies to gH block VZV entry in cultured cells; however, anti-gH antibody is also internalized by infected cells,[429] inhibiting syncytia formation and virion egress. The gH C terminus has a loop structure essential for gB/gH/gL-mediated fusion.[428] The extreme N terminus of VZV gH is important for replication *in vitro* and in skin and may bind the αV subunit since this region of gH in other herpesviruses interacts with αβ integrins.[428,477] Interactions of gB with the myelin-associated glycoprotein (MAG) contribute to cell–cell fusion mediated by gB and gH/gL in neural cells.[404] VZV gE is an abundant glycoprotein that forms heterodimers with gI and binds to insulin-degrading enzyme (IDE) in VZV-infected cells.[5,244,245] Inhibition of IDE reduces VZV infectivity, while IDE expression enhances infection of nonhuman cell lines, suggesting a contribution to entry.[54] However, since gE mutants with disrupted IDE binding can infect cells in culture and are not impaired in their ability to enter T

cells *in vitro* or *in vivo*, gE does not appear to be a primary entry mediator.[29]

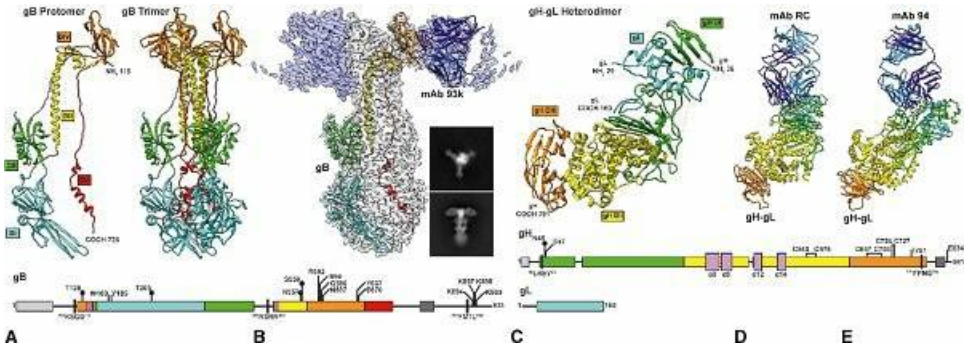

FIGURE 13.6 VZV gB and gH–gL structures and disruption of VZV gB/gH–gL fusion function by human neutralizing antibodies and site-directed mutagenesis. A and B: X-ray crystallography structure of the VZV gB trimer (A; 2.4Å) and a cryo-EM structure (B; 2.8Å) of native VZV gB (*gray*) in complex with Fab fragments from human neutralizing mAb 93k. A single gB protomer along with the VH and VL chains of mAb 93k are represented as ribbons. The two inset panels show examples of 2D class averages used to generate the cryo-EM structure of the gB-93k complex. **C–E:** X-ray crystallography structures of the VZV gH–gL heterodimer (**C**; 3.2 Å) and gH–gL in complex with Fab fragments from human neutralizing mAbs RC (**D**; 3.1Å) and 94 (**E**; 3.6Å). The gH–gL heterodimer and either mAb RC or mAb 94 are represented as ribbons. Each domain of the VZV gB, gH–gL, and the mAb structures are colored accordingly: gB structures DI (*cyan*), DII (*green*), DIII (*yellow*), DIV (*orange*), DV (*red*), linker regions (*hot pink*); gH–gL structures DI (*green*), DII (*yellow*), DIII (*orange*), and gL (*cyan*); mAb VH (*blue*) and VL (*light blue*) chains. Sites of mutagenesis that effect gB/gH–gL fusion function are mapped on the linear diagrams below the structures. All domains are colored as for the X-ray crystallography structures in **(A)** and **(C)**. Other features include the signal sequence (*light gray box*), the transmembrane domain (*dark gray box*), and sites of mutagenesis. Mutations that affect fusion function are either shown above (single) or below (motifs) the diagrams. Glycosylation sites are indicated by *black bars* with *black circles*. For gH, the disrupted α-helices (8, 9, 12, and 14) that abolished fusion are depicted as *plum-colored boxes*. The disulfide bonds in gH that were mutated are shown with connecting *lines*. (**A, B** adapted from Oliver SL, Xing Y, Chen DH, et al. A glycoprotein B-neutralizing antibody structure at 2.8 Å uncovers a critical domain for herpesvirus fusion initiation. *Nat Commun* 2020;11(1):4141. https://creativecommons.org/licenses/by/4.0/. **C, D, and E** based on Xing Y, Oliver SL, Nguyen T, et al. A site of varicella-zoster virus vulnerability identified by structural studies of neutralizing antibodies bound to the glycoprotein complex gHgL. *Proc Natl Acad Sci U S A* 2015;112:6056–6061.)

Once virus entry has occurred, herpesvirus nucleocapsids are transported to the nuclear membrane and the viral genome is delivered into the nucleus. Neither the role of specific viral proteins and cellular cytoskeletal elements in facilitating the movement of VZ virions to the

nucleus nor the composition of the virion reaching the nuclear membrane has been determined, although dynamic changes in the cytoskeleton appear upon infection.[314]

Transcription and Translation

The transcription and translation of VZV genes in infected cells depends on viral transactivating proteins that act in conjunction with host cell RNA polymerase II and the cellular transcription and translation machinery (Fig. 13.5). VZV proteins with transactivating capacity are encoded by *ORFs 4, 10, 61, 62*, and *63*; IE62 is the predominant viral transcription factor. Infection in the presence of cycloheximide followed by actinomycin-D indicates that VZV *ORF4*,[91] as well as *ORF62* and *ORF63*, encodes IE proteins. Although each of the HSV-1 orthologs of *ORF 4, 62*, and *63* contains an upstream TAATGARAT sequence element, only the VZV *ORF62* promoter region has TAATGARAT-like promoter elements.[220] The transcriptional cascade of VZV gene expression has remained undefined because synchronous infection cannot be established due to low titers of cell-free VZV recoverable from cultured cells. However, the kinetics of expression of six representative VZV proteins, ORF61, IE62, IE63, ORF29 (ssDNA-binding protein), ORF23 (small capsid protein), and gE was established using markers differentiating inoculum from newly infected cells[351] (Fig. 13.5). IE62 and ORF61 are synthesized first (within 1 hour); IE63 is expressed at 4 hours. The localization of IE62 to small nuclear puncta is a marker of the earliest stage of replication.

Transcriptional arrays from VZV-infected melanoma cells showed highest expression of *ORFs 9, 48, 49, 57, 58*, and *64*.[198] VZV transcription mapping revealed 78 abundant transcripts of 6.8 kb or smaller, many of which were located in regions corresponding to ORFs predicted by Davison and Scott.[90] Long-read sequencing reveals that lytic infection is associated with novel mRNAs, suggesting that VZV encodes viral proteins not yet identified, together with start- and end-site isoforms and splicing for many viral transcripts, and noncoding RNAs of undefined function.[338]

As is observed in other herpesviruses, multiple colinear and coterminal transcripts can encode a single VZV protein. VZV uses TATA elements and polyadenylation signals whose sequences may differ from consensus sequences.[90,246,330] VZV, like HSV-1, contains GU-rich sequences GTCTGTGT and TGGTGGTA downstream of polyadenylation sites that may be important for termination of transcription.[246] *ORF14* (gC)[246] and *ORF61*[76,446] appear to be expressed from unspliced transcripts, in contrast to their HSV-1 orthologs. VZV strain differences may also affect the level of transcription of a given gene. For example, VZV strain Scott expresses about 20 times more gC mRNA than does VZV strain Oka.[246] Another feature of VZV transcription is the regulation of VZV polymerase (ORF28) and the major DNA-binding protein (ORF29) by a single bidirectional promoter with shared promoter elements. Both this *ORF28–29* bidirectional promoter[270,348,360] and the *ORF4* promoter are activated by the interaction of IE62 with the transcription factor upstream stimulatory factor (USF). A binding site for the nuclear regulatory protein Sp1 modulates the activity of both of these promoters, whereas one TATA box controls expression from the *ORF28* promoter and two other TATA elements regulate expression from the *ORF29* promoter.[478] Transcription of *ORFs 62* and *63* is also mediated from a bidirectional promoter.[190]

VZV Proteins That Regulate Viral Gene Transcription

Five VZV proteins, encoded by *ORFs 4, 10, 61, 62,* and *63*, can regulate viral gene expression. Most promoters of VZV genes also have binding motifs for cellular transcription factors, such as Sp1, USF, and activating transcription factor (ATF), that contribute to viral gene expression. These cellular transactivators can be critical for VZV replication *in vitro* and in human skin and T-cell xenografts *in vivo*.[360] ORF61 and IE62 also have important functions in counteracting intrinsic antiviral cellular responses (see **VZV Effects on Host Cell Functions**).

IE62

ORF62 (at least one copy) is essential for VZV replication.[369] This gene encodes IE62, a 1310-amino acid protein that is the most potent and promiscuous viral transactivating factor.[216] IE62 has an acidic transcriptional activation domain (TAD) and a DNA-binding domain.[417] IE62 binds directly to the cellular transcription factors Sp1 and USF and to the cellular TATA-binding protein and general transcription factor (TFIIB).[360] The serine-rich tract of IE62 interacts with the nuclear ribosomal protein EAP and is important for *ORF61* transcription.[212] IE62 binding to the viral proteins IE4 and IE63 modulates its transactivating functions. IE62 has a nuclear localization signal (NLS)[27] and is localized primarily in the nuclei of infected cells (Fig. 13.5). IE62 is phosphorylated and requires the kinase activity of ORF47 protein for cytoplasmic versus nuclear localization.[32,302] Coexpression of the ORF66 kinase with IE62 results in cytoplasmic accumulation of IE62[215] (although not in T cells),[375] and ORF66 is required for IE62 incorporation into virions in cultured cells. Mutations of the IE62 NLS and the S686A/S722A phosphorylation sites in recombinant viruses are not lethal but delay VZV growth.[206]

A single amino acid change in the DNA-binding domain of IE62 results in loss of its transactivating function[478] and is lethal for VZV replication, as is disrupting the IE62 dimerization domain.[206] IE62 is the ortholog of HSV-1 ICP4 and can complement ICP4 mutants. However, the DNA-binding domain of IE62 is less sequence specific and, unlike ICP4, does not induce DNA binding on binding its own promoter.[417] The TAD at the IE62 amino terminus is not conserved in HSV-1 ICP4 or HSV-1 viral protein (VP)16.[72] This IE62 TAD interacts with the mammalian Mediator complex involved in RNA polymerase II–mediated transcription,[479] an interaction that appears to be required for IE62 TAD–mediated activation, specifically through the MED25 subunit (e-Fig. 13.1).

IE62 transactivates expression of putative IE (*ORF4, ORF61*), early, and late gene promoters in transient expression assays[172,333] and activates its own promoter in a lymphocyte-derived cell line but not in simian cells.[100,332] The differential activation of promoters by IE62 reflects its capacity to interact with cellular transcription factors and depends on the sequence of the TATA motif in the targeted promoter.[330]

Recruitment of IE62 is enhanced by the presence of an Sp1 site within the gI promoter.[329] Interaction with Sp1 and other Sp family members is an important aspect of IE62 activation and can also reduce effects of IE62 on a promoter-specific basis, as shown for the *ORF28/29* promoter; Sp proteins may have differential effects on the same promoter, illustrated by reduced IE62-mediated activation of gI by Sp2.[207] Several other Sp1 sites within VZV promoters have been validated as important for IE62-mediated activation, including gE[30] and ORF61.[446]

Bioinformatics analysis of the VZV genome has identified Sp1 sites within almost all predicted promoter elements.[360] The YY1 cellular transcription factor also facilitates IE62 function, shown by impaired transactivation when YY1 binding sites in the promoters of ORF10, ORF28/29, and gI are mutated.[209]

The mechanism of activation of the *ORF62* promoter is important because of the central role of IE62 in VZV gene transcription. The upstream region of *ORF62* contains three TAATGARAT-like elements that contribute to the ability of VZV ORF10 protein to transactivate expression of IE62. The *ORF62* promoter also contains cAMP-responsive and GA-rich elements that are important for its transactivation. The ORF10 protein forms a complex with two of the TAATGARAT-like elements in the *ORF62* promoter that lack an overlapping octamer-binding motif, but not with the TAATGARAT-like element that possesses an octamer motif. Two cellular proteins, Oct1 and host cell factor (HCF), form a complex with ORF10 and at least one of the TAATGARAT-like elements on the *ORF62* promoter. HCF-1 is critical for activation of immediate–early gene expression by ORF10.[301] The Oct2 cellular protein binds to the TAATGARAT-like elements on the *ORF62* promoter and inhibits ORF10-mediated transactivation. However, ORF10 is dispensable for VZV replication *in vitro* and *in vivo*. Thus, self-regulation of the *ORF62* promoter by IE62 that enters the cell with the infecting virion may be the mechanism that initiates expression of additional IE62 and other IE regulatory proteins.[360,464] The NF-Y CCAAT box-binding protein and the activating transcription factor/adaptor protein 1 (ATF/AP-1) family also bind to the *ORF62* promoter.[286]

ORF61 Protein

ORF61 encodes a 467-amino acid protein that is expressed shortly after VZV entry and localizes to the nuclei of infected cells[351,396](Fig. 13.5); ORF61 is not detected in the virion tegument. ORF61 protein transactivates putative IE, early, and late promoters in transient expression assays,[291] although not in a T-cell line.[332] When ORF61 is truncated or mutations of *ORF61* promoter elements restrict its expression, VZV replication is severely compromised.[76,446,496] Limiting ORF61 expression by promoter mutations also shows that ORF61 is most important for gE expression. ORF61 dimerization through a domain located at residues 250 to 320 is required for ORF61 regulatory functions and normal replication *in vitro* and in skin xenografts *in vivo*.[444,445]

ORF61 can either repress or enhance activation of other VZV genes by IE4 and IE62, depending on the cell line and transfection conditions.[291,332,446] The ORF61 N terminus contains a RING-finger domain that is required for the transactivating activity of the full-length protein.[437] Carboxyl-terminal truncation mutants of ORF61 that retain the RING-finger domain act as dominant-negative transrepressors and reduce the infectivity of viral DNA. Transient expression of ORF61 enhances the infectivity of VZV DNA,[291] which can be explained by its critical role in dispersing promyelocytic leukemia (PML) nuclear bodies through sumoylating motifs.[443] ORF61 is related to HSV ICP0 and can functionally complement an HSV-1 ICP0 deletion mutant.[289]

IE4

ORF4 encodes the 52-kd essential immediate–early protein IE4,[320,371] which requires

coexpression with *ORF62* for its nuclear localization.[91] IE4 must dimerize for gene activation, and several regions of the protein are required for its transactivation function.[26,287] Mutation of the KYFKC residues that mediate IE4 dimerization is lethal.[371] In transient expression assays, IE4 transactivates some, but not all, putative IE, early or late promoters, and also synergizes with IE62 to transactivate promoters of genes from all three kinetic classes. IE4 activation of target genes occurs at both transcriptional[331] and posttranscriptional levels.[91] IE4 interacts directly with TFIIB and the nuclear factor-κB (NF-κB) p50 and p65 subunits and also binds to an underphosphorylated form of IE62.[320,389] IE4 may function as a viral mRNA export factor through its RNA-binding capacity.[319]

IE4 is the ortholog of HSV-1 ICP27 but the proteins do not complement each other.[74] The IE4 carboxyl portion contains putative zinc-finger domains; several cysteine residues in IE4 are not required for its regulatory activity.[331] and, unlike ICP27, IE4 does not appear to have transrepressing activity.[91,172,332]

IE63

ORF63 encodes a 287-amino acid protein and additional smaller products of 38- and 28-kd.[213] IE63 is phosphorylated predominantly in the carboxy-terminal region by casein kinases I and II, CDK1, and CDK5.[147] Deletion of greater than 90% of both *ORF63* and its duplicate *ORF70* was compatible with very limited VZV replication in melanoma cells, providing IE62 allows an *ORF63* deletion mutant to replicate in U2OS cells.[73,182,387] The carboxy-terminal 70 amino acids of IE63 are dispensable, but further deletion of the carboxy-terminus or replacement of some of the serine or threonine phosphorylation sites of the protein with alanine impairs VZV replication[21,73] and skin infection.[21] IE63 is located primarily in nuclei of infected cells (Fig. 13.5). Phosphorylation of certain amino acids of IE63 is important for its cellular localization when expressed alone[38,73,397] and IE63 nuclear import requires ORF61 in neurons.[438] IE63 binds to IE62 and the two proteins exhibit some colocalization in infected cells; IE63 also binds to the cellular RNA polymerase II[252] and to antisilencing protein 1, interfering with its histone-binding capacity.[6] IE63 is reported to repress expression of VZV promoters in some transient transfection assays,[176,228,252] but IE62 is the only viral gene product that is significantly reduced in cells infected with an IE63-null mutant.[165] IE63 also transactivates the EF-1α promoter in the absence of other viral proteins.[501] IE63 is the ortholog of the HSV-1 $U_S1.5$ protein, which is expressed colinearly with HSV-1 ICP22 (U_S1).[21] IE63 was identified as important for latency in a rodent model.[70,71]

Replication of Viral DNA

Replication Proteins

The minimal repertoire of genes needed for VZV DNA replication is not known although VZV encodes orthologs of each of the seven HSV-1 genes required for origin-of-replication (ori)-dependent replication of viral DNA (Table 13.1).

DNA polymerase

ORF28 encodes the large subunit of the VZV DNA polymerase.[90] Unlike the cellular polymerase, the VZV enzyme is sensitive to phosphonoacetic acid and its activity is enhanced in the presence of ammonium sulfate. *ORF16* is predicted to encode the small subunit processivity factor of the VZV polymerase.

DNA-binding proteins

ORF29 encodes a 130-kd protein that localizes to nuclei of infected cells via a noncanonical NLS[390] (Fig. 13.5). ORF29 binds ssDNA, although the VZV protein binds with lower efficiency and cannot substitute for its HSV-1 ortholog, ICP8.[217] ORF29 binds to the gI promoter[39] and increases or decreases IE62 transactivation of a reporter gene, depending on the cell line.[39] ORF29 protein is secreted from VZV-infected cells and can be endocytosed by neurons.[9] ORF29 is also part of a complex that binds to a sequence in Ori-s, which functions as a negative regulator of VZV DNA replication.[205]

ORF51 encodes the ori-binding protein.[399] The carboxyl portion of ORF51 protein binds *in vitro* to three DNA sequence motifs in the VZV ori with similar affinities. As in the HSV-1 ortholog, UL9, a CGC triplet in the VZV ori, is required for ORF51 binding. ORF51 can substitute for HSV-1 UL9 in an origin-dependent HSV DNA replication assay and can partially complement growth of an HSV-1 UL9-null mutant.[66] VZV DNA binds five other proteins of unknown identity or function, ranging from 21- to 175-kd in size.

Genome Replication

By analogy with HSV, VZV DNA replication is presumed to occur in four stages.[89] First, the linear DNA molecule circularizes shortly after virion entry via the complementary unpaired nucleotides at each 3′ end of the genome, demonstrated by the presence of a fused U_L-U_S joint. The second stage involves replication of the circular genomic template. Isomerization of progeny genomes is thought to occur by homologous recombination between the inverted repeats. Third, replication of the circular molecule generates head-to-tail concatemers, probably by a rolling-circle mechanism (Fig. 13.5). Fourth, these concatemers are cleaved by sequence-specific nucleases to generate linear DNA for packaging into virions. Processing of VZV genomic DNA for encapsidation requires the ORF54 portal protein.[426]

The VZV genome contains AT-rich and GC-rich sequences near the left and right termini, respectively, also found in HSV-1 and implicated in cleavage and packaging of HSV-1 DNA. Because VZV exists predominantly as two isomers, 95% of cleavage appears to occur at one U_L-U_S junction, with cleavage at the other U_L-U_S joint yielding the two minor isomers.[219]

The VZV genome contains duplicate ori_S between ORFs *62* and *63* in the IRS and between ORFs *70* and *71* in the TR_S,[90,398] which are A-T rich and contain three origin-binding protein sites, two of which are important for *ORF62* and *ORF63* expression (Fig. 13.3). Transfection of cells with plasmids containing the VZV ori_S followed by VZV infection results in replication of these plasmids. The VZV genome does not have an ortholog of the HSV-1 ori_L sequence. However, VZV may have another origin of replication since a recombinant with mutations of the ori_S core sequences retained infectivity in melanoma cells.[210]

The VZV ori_S contains a near-perfect 45-bp palindrome with the sequence $(TA)_{17}$ at its center. Mutations of the palindrome impair replicative activity. The VZV ori_S also includes a GA-rich region and three binding sites for the VZV origin-binding protein, ORF51. These sequences are CGTTCGCACTT (also found in both the ori_S and the ori_L of HSV-1)[399] and CATTCGCACTT. Unlike the HSV ori_S and the ori_L, all three VZV ori-binding protein sites are upstream of the palindrome on the same strand and are oriented in the same direction.[65] Dpn1 DNA replication assays indicate that the 45-bp palindrome and the sequence CGTTCGCACTT closest to the palindrome are essential for replication, whereas the sequence CATTCGCACTT contributes additional activity but is not essential.

Viral Enzymes

Thymidine Kinase

ORF36 encodes a viral thymidine kinase (TK) dispensable for VZV replication. Since the VZV enzyme has more deoxycytidine than does TK activity, it is more accurately a deoxypyrimidine kinase. The enzyme is a 70-kd homodimer composed of two 35-kd subunits. It is most active *in vitro* at a higher pH and has broader substrate specificity than its cellular ortholog. VZV TK is more thermostable and more susceptible to inhibition by deoxythymidine triphosphate than is HSV-1 TK. TK phosphorylates and thereby activates acyclovir and its analogs. Most acyclovir-resistant VZV isolates have point mutations in the TK gene near the adenosine triphosphate (ATP) or thymidine-binding sites or have mutations that result in a truncated protein.[373] Differences between the structures of VZV and HSV TK may explain some differences in their substrate activities.[34]

Ribonucleotide reductase

ORFs *18* and *19* encode proteins orthologous to the small and large subunits of HSV-1 ribonucleotide reductase, respectively,[90] and their enzymatic activities are similar. Unlike cellular ribonucleotide reductase, the VZV and HSV-1 enzymes are not inhibited by increased intracellular levels of deoxyribonucleotides.[388] Inhibition of VZV ribonucleotide reductase with small molecules enhances the antiviral activity of acyclovir, presumably by decreasing the intracellular pool of deoxyribonucleoside triphosphates and increasing the concentration of acyclovir triphosphate. Deletion of *ORF19* from the viral genome abolishes viral ribonucleotide reductase activity, impairs the growth of the virus *in vitro*, and potentiates inhibition of replication by acyclovir.[159]

ORF47 and ORF66 protein kinases

As components of the virion tegument, ORF47 and ORF66 are likely to be important for activation of regulatory proteins in the newly infected cell. *ORF47* encodes a 54-kd serine–threonine protein kinase that phosphorylates both acidic and basic proteins, but with a marked preference for acidic amino acids, using both ATP and guanosine triphosphate (GTP) as phosphate donors; it also phosphorylates casein kinase II.[203] The HSV ortholog, UL13, has a similar catalytic domain.[395] ORF47 protein autophosphorylates and also phosphorylates viral proteins ORF32,[349] IE62,[204,302] IE63,[204] gI,[203] and gE[202] but is not required for phosphorylation

of gE, IE62, or IE63 in VZV-infected cells.[160,204] ORF47 binds to IE62 through an N-terminal domain.[32] The N-terminal DYS motif is required for ORF47 kinase activity that, if disrupted, results in nuclear retention of ORF47 and IE62. Deletion of ORF47 does not alter plaque formation[160] but does lead to accelerated gE expression on membranes and cell–cell spread.[203] However, even though plaques appear normal in the absence of ORF47, the protein and its kinase activity are required for efficient VZ virion assembly and transport to cell surfaces.[32] ORF47 is important for T cell and dendritic cell infection *in vitro,*[168] is important for skin infection, and is essential for T-cell tropism *in vivo.*[31,32]

ORF66 encodes a 393-amino acid phosphoprotein expressed in the nucleus, in puncta surrounding nucleoli, and in cytoplasm of infected cells.[395,375] ORF66 is a serine–threonine protein kinase that autophosphorylates[374] and phosphorylates IE62.[214] The ORF66 catalytic domain (residues 93–378) is orthologous to the HSV-1 US3 and other members of this protein kinase superfamily.[106] IE62 phosphorylation by ORF66 determines its late accumulation in the cytoplasm of infected cells, where packaging into virions occurs. Mutagenesis of the glycine 102 residue in a highly conserved, glycine-rich ATP-binding motif in this domain blocks ORF66 kinase function.[375] ORF66 also phosphorylates the cellular nuclear matrix protein, matrin 3, which may modulate RNA processing[109,110] and targets histone deacetylases to promote transcription.[435,436] ORF66 is dispensable for replication *in vitro*[163] and in human skin xenografts in the SCID mouse model; however, the absence of ORF66 or disruption of its kinase activity leads to impaired growth and production of virions in human T cells in xenografts.[282,374,375] VZV infection of primary corneal fibroblasts also requires ORF66 functions.

Other viral enzymes

ORF8 encodes a deoxyuridine 5′-triphosphate nucleotidohydrolase (dUTPase), which hydrolyzes deoxyuridine 5′-triphosphate (dUTP) to deoxyuridine 5′-monophosphate (dUMP) and pyrophosphate.[358] *ORF8* is not required for growth *in vitro* nor is *ORF13*, which encodes the viral thymidylate synthetase.[78,412] *ORF59* encodes the VZV uracil DNA glycosylase that removes uracil residues incorporated into newly synthesized DNA strands. This protein is not necessary for replication in cell culture. VZV-infected cells express a DNase activity encoded by ORF48, the ortholog of HSV-1 UL12.[293]

ORF33 encodes the precursor of the VZV serine protease, which is cleaved autocatalytically at two sites.[118] The mature 31-kd protease is the amino-terminal cleavage product. The active form of the protease is predicted to be a homodimer. The VZV protease crystal structure is similar to that of the cytomegalovirus (CMV) protease.[343] A serine and two histidines constitute the catalytic site of the VZV protease; mutation of either one of these histidines in the protease precursor protein prevents self-cleavage.

ORF17 encodes the ortholog of the virion host shutoff (VHS) protein encoded by HSV-1 UL41. *ORF17* is dispensable for replication, but deletion of this gene yields a temperature-sensitive mutant. ORF17 protein induces RNA cleavage much less effectively than does its HSV-1 ortholog,[368] and the host shutoff function in VZV-infected cells is correspondingly less efficient.

The *ORF9-12* Gene Cluster

ORF9 encodes an essential protein present in the virion tegument that interacts with IE62 and is phosphorylated by ORF47, which supports virion egress.[46,61,237,355,356,413] The ORF9 protein functions in secondary envelopment through interactions with the cellular protein, AP-1, involved in clathrin-coated vesicle transport of proteins from endosomes to the trans-Golgi network (TGN).[237] *ORF9A* encodes the putative 7-kd gN protein located in the membranes of infected cells.[358] Although this protein is not required for replication, blocking ORF9A expression impairs syncytia formation.

ORF10 encodes a 50-kd protein that is incorporated into the viral tegument[216] and localizes to the TGN in infected cells. ORF10 is the ortholog of HSV-1 VP16, but unlike its HSV-1 counterpart, it is dispensable for replication.[62,79] ORF10 complements an HSV VP16 mutant and enhances the infectivity of transfected VZV virion DNA.[290] ORF10 transactivates the *ORF62* promoter, but not the *ORF4* or *ORF61* promoter. ORF10 forms a complex with TAATGARAT-like sequences and Oct1 and HCF to transactivate the ORF62 promoter.[288] ORF10 is important for replication in human skin, but not in T-cell xenografts in SCID mice.[62]

ORF11 is expressed as a 118-kd polypeptide present in the virion tegument and in the nucleus and cytoplasm of infected cells; ORF11 binds to the ORF9 protein.[59] ORF11 alone has little effect on VZV gene transcription, but levels of IE4, IE62, IE63, and gE proteins are reduced if ORF11 is deleted from the viral genome.[60,61] ORF11 functions as an RNA-binding protein with the binding region in the first 22 residues of the protein. RNA binding is conserved among the UL47 alphaherpesvirus orthologs. ORF11 is critical for VZV infection of human skin xenografts, but its RNA-binding function is not required.[60]

ORF12 encodes a predicted tegument protein that affects cell cycle progression by activation of the P13 kinase/Akt pathway.[248] It is dispensable for replication *in vitro;* a spontaneous deletion mutant associated with tissue culture passage has been reported[83] and ORF12 protein is not required for skin tropism.[61]

Nucleocapsid Proteins

Three forms of nucleocapsids are found in VZV-infected cells.[154] Immature B capsids lack viral DNA and contain 32- and 36-kd proteins, presumed to be the mature viral protease and assembly proteins, respectively, present in the nuclear matrix of VZV-infected cells.[132] Mature C capsids contain viral DNA but lack the 32- and 36-kd proteins. Intermediate B/C capsids are thought to contain the VZV genome and the 32- and 36-kd proteins.

ORF40

ORF40 encodes the 155-kd major nucleocapsid protein that localizes to the nuclei of infected cells.

ORF33

ORF33.5, located in the 3′ portion of the *ORF33* gene, encodes the 40-kd precursor of the VZV assembly protein. The mature 37-kd assembly protein is released after cleavage from its

precursor by the VZV protease.[339] The assembly protein is presumed to provide a scaffold for nucleocapsid assembly. When expressed *in vitro*, ORF33.5 forms long, hollow rods that accumulate predominantly in the nuclei of cells.[339]

ORF23

ORF23 encodes a conserved capsid protein, called VP26 (UL35) in other alphaherpesviruses, which is expressed as a late protein[58,351] (Fig. 13.5). Unlike VP26, ORF23 localizes to nuclei through an SRSRVV motif in the carboxy-terminus and mediates nuclear import of ORF40, the major capsid protein. ORF40 is also translocated by ORF33.5. ORF23 is not essential for VZV replication, but deletion disrupts capsid assembly *in vitro.* ORF23-mediated nuclear transport of the major capsid protein is necessary in skin xenografts *in vivo*, and the ORF33.5 interaction with ORF40 does not provide a redundant capacity for this function.

ORF21

ORF21 encodes a 115-kd protein located in the nucleocapsid.[257] The protein localizes to both the nucleus and the cytoplasm of infected cells. ORF21 is essential for VZV replication, and its HSV-1 ortholog, UL37, cannot complement its absence *in vitro.*[471]

Other Putative Late Proteins

ORF35 encodes a protein that localizes to the nuclei of infected cells. A mutant deleted for this gene is impaired for cell–cell spread and for infection of human skin and T-cell xenografts in SCID mice.[175] *ORF44* encodes a nonessential tegument protein that interacts with the ORF49 gene product to support efficient infection.[363] ORF58 is nonessential, but functions have not been defined.[482] Deletion of *ORF64* results in virions that induce extensive cell fusion with large syncytia.[387] *ORF65* encodes a 16-kd virion protein that localizes to the Golgi apparatus of virus-infected cells[77]; it is dispensable for VZV infection of human T cells and skin xenografts in SCID mice.[304]

Glycoproteins

VZV glycoproteins are major constituents of the viral envelope that are also expressed on intracellular membranes and have critical interactions with other viral and cellular proteins during VZV entry, replication, cell–cell spread, and cell–cell fusion.

Glycoprotein B

gB, encoded by *ORF31*, is the most highly conserved of the herpesvirus glycoproteins. In addition to its presumed role in attachment and entry, gB expression along with gH/gL is sufficient to induce cell fusion.[178,310,314,315,404,428,476]

VZV gB has a furin recognition motif at residues 491 to 494 and is cleaved into two polypeptides that are bound together by disulfide residues. Thus, under nonreducing conditions, gB migrates in gels as a 140-kd protein, whereas under reducing conditions, gB resolves as two proteins of 60 and 70 kd. Virion morphology, protein localization, plaque size, and replication

kinetics are not altered by mutations eliminating gB furin cleavage, but furin cleavage is necessary for normal VZV replication in human skin xenografts *in vivo*.[312] gB contains two tyrosine-based motifs in its cytoplasmic domain that are required for endocytosis to the Golgi network[161]; gB associates with clathrin during endocytosis. Sialic acids on gB are implicated in gB-mediated fusion by interaction with MAG.[403] The carboxy-terminal 36 amino acids of gB are required for normal trafficking to the cell surface.[162] gB has both N- and O-linked sugars and is sialylated, sulfated, and palmitylated.[141]

The 2.8Å near atomic resolution of the gB structure in complex with a human neutralizing monoclonal antibody (mAb) identified the critical role of domain IV (DIV) residues for initiation of fusion, based on using structure-guided mutagenesis of gB to define effects on gB/gH-gL fusion and VZV infection in the presence of other viral proteins.[315] (Fig. 13.6) These findings indicate that these DIV residues are accessible in prefusion conformations of gB. The gB N-terminus is also important for fusion.[313] An immunoreceptor tyrosine-based inhibition motif in the gB cytoplasmic domain regulates fusion, which when mutated causes exaggerated cell–cell fusion and severely impaired skin pathogenesis[310] and disrupts the typical transcription of VZV and host cell genes and modifications of the host cell actin cytoskeleton associated with efficient replication.[314] Regulation of cell–cell fusion by the lysine cluster in the gB cytoplasmic domain is also critical for VZV skin infection.[476]

Glycoprotein C

gC, encoded by *ORF14*, is dispensable for growth in cell culture. Because the number of R2 repeats in the gC coding sequence differs, gC varies from 80- to 170-kd. The gC endodomain consists of only six amino acids. gC is heavily glycosylated, with about one-third of its molecular weight resulting from N- and O-linked glycosylation.[141] gC transcription and translation is delayed compared to other VZV glycoproteins, with little VZV gC detected until 72 hours after infection.[142] The quantity of gC transcripts and protein produced also varies depending on the VZV isolate.[218,246] In contrast to cultured cells, skin lesions show abundant gC in a pattern consistent with virion envelope expression (e-Fig. 13.2). VZV gC also enhances the leukocyte inflammatory response.[136]

Glycoprotein E

gE, encoded by *ORF68*, is an 85- to 100-kd protein. Unlike its orthologs, VZV gE is an essential protein[284] and has a unique N terminus of 188 residues necessary for VZV replication.[29] Although gE has been considered to be a late gene product, it is detectable in a Golgi-like cytoplasmic distribution by 4 hours and is expressed extensively on plasma membranes by 9 hours[351] (Fig. 13.5). While gE orthologs are encoded within the US, *ORF68* extends into the repeat regions. gE contains both N- and O-linked sugars, is heavily sialylated, and is modified by myristoylation, palmitoylation, and sulfation.[284] Its monomeric form is phosphorylated at serine and threonine residues by casein kinase II, whereas the homodimeric form of gE is phosphorylated by a tyrosine kinase.[480] gE binds the Fc receptor of human immunoglobulin.[247,367] Expression of gE in epithelial cells induces formation of tight junctions.[277]

After synthesis and maturation in the Golgi apparatus, gE is transported to the cell membrane. The short gE cytoplasmic domain (62 amino acids) has an endocytosis motif, YAGL, a TGN-targeting AYRV tyrosine motif, and an acidic amino acid–rich phosphorylation motif.[202,280] The AYRV motif and the acid patch are required for gE transport.[499] Endocytosis to the TGN requires the YAGL motif, which allows recycling of gE through endosomes back to the cell membrane.[317] Phosphorylation of gE by the ORF47 protein kinase is necessary for endocytosed gE to traffic to the TGN. In cells infected with a mutant unable to express ORF47, gE accumulates on cell membranes.[202,203] gE endocytosis from the plasma membrane is necessary for incorporation into virions.[263] The YAGL endocytosis motif is required for virus replication; the AYRV motif is important for VZV replication in human skin and T-cell xenografts in SCID mice.[280]

Residues in the unique gE N terminus are important for normal gE expression, secondary envelopment and cell-cell spread, and are essential for skin infection.[29] Residues within amino acids 27 to 90 are necessary for gE binding to IDE, normal cell–cell spread *in vitro*,[5,28,29] and virulence in skin xenografts, but not for virus entry into T cells.[28] Nonglycosylated immature gE binds to IDE in the ER. The unique gE residues 51 to 187 are necessary for VZV infection of skin as well as T cells. VZV-MSP is a naturally occurring mutation in the unique gE N terminus, changing the amino acid of codon 150 from aspartic acid to asparagine. The mutant shows altered cellular egress and enhanced cell–cell spread *in vitro* and in skin xenografts.[366]

Correct gE trafficking and maturation requires heterodimerization of gE with gI.[247,276] gE/gI heterodimer formation depends on the cysteine-rich region (amino acids 208–236) also present in gE encoded by other alphaherpesviruses. The capacity of gE to bind to gI is a major determinant of VZV virulence in skin xenografts, indicating that cell–cell fusion and polykaryocyte formation depends on this interaction.[28] Disrupting gE/gI heterodimer formation also results in aberrant VZV infection of dorsal root ganglion (DRG) xenografts, causing severe tissue damage despite impaired cell–cell spread. By contrast, mutations of the gE AYRV *trans*-Golgi localization motif and blocking gE/IDE binding did not alter VZV neurovirulence in DRG xenografts.[484] VZV gE has essential functions in neuropathogenesis.[484]

Glycoprotein I

gI, encoded by *ORF67*, is a 58- to 62-kd glycoprotein that contains N- and O-linked sugars.[284] gI heterodimer formation with gE requires residues 105 to 125 and four highly conserved cysteine residues that are also necessary for gI structure and virion incorporation.[311] gI is not required for VZV replication in cultured human cells but is required in Vero cells. Deleting gI impairs efficient cell–cell spread of virus, adsorption to cells, and syncytia formation *in vitro*. gI is essential for infection of human skin and T-cell xenografts in SCID mice.[75,261,279] Mutations that alter Sp1- or USF-binding sites in the gI promoter reduce gI expression and impair infection of human T-cell and skin xenografts in SCID mice, but not in cultured cells.[174]

The gI cytoplasmic tail is phosphorylated but the phosphorylation sites are not required for VZV skin infection. A threonine residue in the gI endodomain targets gI to the TGN when expressed alone in cultured cells, although gI is more rapidly localized to the TGN in the presence of gE.[4] The carboxy-terminal domain of gI is required for envelopment of VZ virions in the TGN.[439] While gI is also endocytosed from the cell surface and has a methionine–leucine

internalization motif in its cytoplasmic tail, the gE–gI complex undergoes endocytosis more efficiently than does gE or gI alone.[4,318] VZV gI is required for normal maturation of gE and for efficient distribution of gE to the cell surface.

Glycoprotein H

gH, the product of *ORF37*, is a 118-kd glycoprotein that contains N-linked but not O-linked sugars and is sialylated and sulfated.[141,196,283,472] The structure of gH–gL has been resolved to show gH–gL heterodimer formation (Fig. 13.6).[472] This interaction is required for entry, based on the binding of neutralizing antibodies to a site formed by residues of both gH and gL. The gH binding to gL is required for its processing in the Golgi network and transport to the cell surface.[262] Endocytosis of gH results in reduced cell surface expression and decreased cell–cell fusion. gH forms a complex with gE in virus-infected cells and during incorporation into virions.[263,327] Coexpression of gH with either gE or gI allows transport of an immature form of gH to the cell surface, but this form is not fusogenic.[103] The short cytoplasmic tail of gH contains a tyrosine-based motif (YNKI) that mediates clathrin-dependent endocytosis of gH in infected cells.[326] The gH cytoplasmic domain regulates gB/gH–gL mediated cell–cell fusion, which depends on its length rather than sequence, and is necessary for skin infection.[475]

The gH ectodomain has three functional subdomains, DI–DIII, that were defined by site-directed mutagenesis and shown to have specific functions in cell fusion and VZV pathogenesis.[428] The extreme N-terminal residues in DI are important for skin tropism, T-cell entry, and fusion. DII helices and a conserved disulfide bond are essential for gH structure and VZV replication. Disulfide bonds and a bridging strand in DIII are required for the structural stability of this domain and are critical for membrane fusion. The biologic importance of gH DIII function during VZV replication is evident since a naturally occurring compensatory mutation was acquired during VZV replication when the ^{724}CXXC^{727} motif was mutated; this DIII mutation stabilized the bridging strand and rescued both a replication-deficient virus and a lethal cysteine mutation that disrupted the fusion function of gH.[428]

Glycoprotein L

gL, encoded by *ORF60*, is a 20-kd glycoprotein that forms a complex with gH, acting as a chaperone that associates with the immature but not the mature form of gH. gL is thought to be glycosylated with an N-linked oligosaccharide. Whereas gH requires gL for its maturation, gL is fully processed in the absence of gH. When expressed alone or with gH, gL accumulates only in the cytoplasm.[103] gL contains an ER-targeting sequence and is recycled between the ER and the Golgi network.[103] Coexpression of gH and gL supports syncytia formation, whereas expression of either protein alone does not.[103]

Glycoprotein K

gK, encoded by *ORF5*, is a 40-kd glycoprotein containing N-linked sugars and is required for VZV replication.[148,278] Overexpression of gK in a cell line inhibited syncytia formation by wild-type virus. HSV gK cannot complement growth of gK-deleted VZV.

Glycoprotein M and Glycoprotein N

gM, encoded by *ORF50*, is a 435-amino acid membrane glycoprotein.[364,473] *ORF50* has one full-length transcript that produces gM and three alternatively spliced transcripts that are rarely translated *in vitro*.[285] gM is predicted to contain eight transmembrane domains, an N-glycosylation site, and a cysteine residue in the first ectodomain. gM is 42- to 48-kd in infected cells and virus particles; a 37-kd precursor, not yet modified by N-linked oligosaccharides, is present in infected cells. gM localizes to the Golgi and endosomes, where it may be incorporated into the virion envelope. The functions of gM are not defined, although its presence in virus particles suggests a role in viral entry and virion maturation[285] and its trafficking motifs are required for VZV skin tropism.[493] As observed in other herpesviruses, gM forms a complex with gN through a disulfide bond; the interaction with gN is necessary for gM maturation, transport, and virion incorporation. *ORF50* is dispensable, but gM deletion mutants have impaired plaque formation and spread, with vacuoles containing electron-dense material appearing in the cytoplasm.[364] An *ORF50* deletion mutant did not replicate in melanoma cells.[496]

Assembly and Release

Infectious VZV progeny are synthesized as large numbers of cell-free virions and released efficiently from cells infected *in vivo* (see **Pathogenesis and Pathology**), whereas VZV is highly cell associated in cultured cells. Infectious cell-free virus can be recovered by sonicating VZV-infected cells, but yields are low, the particle-to-infectivity ratio is very high (40,000:1),[51] and virions remain attached to cell membrane fragments. VZ virions are usually enclosed in membrane-lined cytoplasmic vacuoles and some may be degraded during transit through the cytoplasm.

Because VZV replication in cultured cells is expected to differ from that in differentiated cells in the human host, any model of assembly and egress derived from *in vitro* observations will be incomplete. However, the current model is that nucleocapsids assemble in the nucleus and transit the inner and outer nuclear membranes for delivery into the cytoplasm in a process that involves envelopment, fusion, and de-envelopment.[125] VZV capsid assembly within the infected cell nucleus has not been well defined but procapsids, partial capsids, and complete capsids accumulate at sites adjacent to replication compartments early in infection.[238] VZV ORF24 and ORF27 are likely to have functions in nuclear egress similar to those of their respective HSV orthologs, UL31 and UL34. The nucleocapsids are thought to undergo secondary envelopment by budding through TGN membranes where the cisternae have been decorated with VZV-encoded glycoproteins with their cytoplasmic tails extending into the cytosol. Tegument proteins adhere to the remodeled cytosolic faces of TGN membranes (Fig. 13.5). The naked nucleocapsids attach to the tegument and invaginate into the cisternae. In cultured cells, these vesicles are usually diverted to prelysosomes, where they are subjected to degrading enzymes (Fig. 13.5). Mannose-6-phosphate side chains render the evolving particles susceptible to binding and uptake by lysosomes bearing the cation-independent mannose-6-phosphate receptor (MPR^{ci}).[67] Cell lines deficient in MPR^{ci} release cell-free VZV more efficiently than other cultured cells, implying that an alternative secretory pathway is operative in some cell types *in vivo* to allow virus egress without lysosomal degradation (Fig. 13.5). Superficial epidermal skin cells, which lack MPR^{ci}, show a pattern of VZV maturation resembling that seen in cells deficient in this receptor.[67]

Syncytia Formation

Cell–cell fusion with formation of large syncytia is a hallmark of VZV replication in cell culture (Fig. 13.7), becoming detectable at about 9 hours after infection of melanoma cells,[351] and involves about 75% of the monolayer by 48 hours, with detachment of fused cells from the surface at about 60 hours. These multinucleated giant cells have enlarged nuclei, abnormal nucleoli, and marginated chromatin. Fusion between nuclear membranes also occurs within syncytia.[448] Syncytia formation is important for VZV pathogenesis in skin, where polykaryocytes are prominent. VZV also induces the fusion of neurons and satellite cells in DRG.[112,354] By contrast, VZV does not cause fusion of T cells; instead, spread in T-cell xenografts is associated with the release of infectious cell-free virions.[281,282] VZV also induces the formation of "viral highways" in which viral particles decorate the surface of infected cells, especially within the syncytia and on filopodia[52] (Fig. 13.7), and an increase in cell surface virions is associated with more rapid cell–cell spread.[366]

The formation of the core fusion complex, consisting of gB, gH, and gL, which is presumed to function in fusion of the viral envelope with the cell surface membrane during entry, is essential for cell fusion and syncytia formation.[315,428,472] The regulation of syncytia formation is required for VZV skin infection, shown by severely impaired pathogenesis and reduced progeny virions when fusion is exaggerated; this regulatory function is mediated by the C-terminal domains of gB and gH (see **Glycoprotein B** and **Glycoprotein H**). This effect was associated with up-regulation of Ras GTPase genes associated with membrane remodeling.[314] The calcineurin pathway contributes to the regulation of gB/gH–gL dependent fusion, as shown by enhanced cell fusion when calcineurin phosphatase activation is blocked.[497] Residues in gH domain III are necessary for cell-cell fusion and virulence in skin xenografts. Formation of typical VZV syncytia also requires gE/gI heterodimerization and functions that depend on the unique gE N terminus.[28,29] Deleting gI (*ORF67*) or reducing its expression by promoter mutations results in a small-plaque phenotype with distorted polykaryocyte formation.[75,261] Syncytial formation is also reduced in the absence of ORF8 and ORF9A proteins.[358] Conversely, typical syncytial formation can be retained *in vitro* even with mutations that severely disrupt VZ virion formation, such as those blocking ORF47 expression or eliminating its kinase activity; the deficiency is evident only by markedly impaired skin infection.[29,31,310]

Replication in Specialized Cells in Culture

VZV replication and gene requirements have been studied *in vitro* using primary human cells and organ cultures that reflect the tropisms of the virus for T cells, skin, and neural cells *in vivo*. Human tonsil T cells are highly permissive for VZV replication[230] (Fig. 13.8), whereas VZV infects T cells at low frequencies in peripheral blood mononuclear cell (PBMC) cultures; infection can be increased by T-cell activation.[225] VZV infection remodels tonsil T cells dramatically to promote their trafficking to skin (see **Pathogenesis and Pathology**) (Fig. 13.9).[380] VZV has only limited capacity to replicate in transformed human B cells.[225] Human

natural killer (NK) cells, in particular the $CD56^{dim}$ subset that predominates in peripheral blood, are highly permissive to productive VZV infection and were more permissive to infection when compared to T cells, NKT cells, and $CD3^{-}CD56^{-}$ lymphocytes[47,48] (Fig. 13.8). VZV infection alters the NK cell surface landscape and functionality[47,48] (see **Modulation of Surface Expression of Cellular Proteins Involved in the Host Response** and **Interference with Intrinsic Antiviral Responses**). Other immune cells that can be productively infected with VZV include immature and mature dendritic cells,[2,168,169,292] plasmacytoid dendritic cells (pDCs), NKT cells, $CD3^{-}CD56^{-}$ lymphocytes, monocytes, macrophages, and B cells[47,169,188,201] (Fig. 13.8).

In skin organ cultures, deleting *ORF 7, 10, 14,* and *47* disrupts VZV infection, whereas deletion of *ORFs 0, 18, 19, 23, 32, 35, 49,* or *68* affects replication in fibroblasts as well.[496] Infected keratinocytes release cell-free virus *in vitro* but infectious virus yields are low, whereas *in vivo* infection yields high titers. VZV modifies host cell gene transcription in differentiated keratinocytes by increasing the expression of the cytokeratin gene encoding *KRT15,* a stem cell marker found at the hair follicle isthmus, and inhibiting the cytokeratin genes *KRT1* and *KRT10,* associated with keratinocyte differentiation.[189]

VZV infects dissociated cells cultured from nervous system tissues, including both neuronal and nonneuronal cells (Schwann cells and astrocytes).[164] VZV also infects neurons and supporting cells in explanted intact ganglia,[138] neurons derived from human embryonic stem cells,[362] and tissue assemblies derived from neural progenitors.[137] A model of latency and reactivation has been developed using neuronal stem cells[269] with detection of small noncoding RNAs during lytic infection.[135] Infection of differentiated neurons in culture with cell-free VZV did not produce cytopathic effects or infectious virus, although VZV DNA, virus-specific transcripts, and protein, including gE, were found several weeks later,[340] and VZV gI is required for spread and virion localization to axons in DRG explants.[68] Virion assembly in neurons requires gC,[142] and in addition to its role in skin, ORF7 functions in virion envelopment in differentiated neurons.[182] While the capacity of vaccine Oka to establish latency was maintained, reactivation was reduced in a neuronal cell model *in vitro.*[361]

VZV Effects on Host Cell Functions

Cell Protein Synthesis, Cell Cycle Changes, and Other Effects

Although *ORF17* encodes an ortholog of the HSV VHS protein, ORF17 is not present in the tegument and has little impact on host protein synthesis.[368] However, VZV infection dysregulates and arrests the cell cycle in fibroblasts (e-Fig. 13.3), an effect characterized by high levels of expression of cyclins A, B1, and D3 without extensive synthesis of cellular DNA.[239,240] Cyclin-dependent kinase (CDK) activity is essential for VZV replication; CDK1 phosphorylates IE62 and is present in virions.[239] VZV replication may be associated with activation of the DNA damage response, leading to cell cycle arrest.[474] VZV may also activate transcription factors and increase cell cycle regulatory proteins through the mitogen-activated protein kinase pathways, extracellular-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and PI3 kinase.[347] JNK activation by VZV contributes to both replication and reactivation in the neuronal model.[231] VZV induces the phosphorylation of CREB in T cells and fibroblasts, which has multifactorial effects on host cell gene expression by binding the coactivator, p300/CBP, and is needed for

cell–cell spread *in vitro* and in skin xenografts.[117] p27, p53, and ATM kinase are other examples of host regulatory proteins induced in infected cells. VZV infection also alters the organization of actin in the cell, with dramatic effects observed when gB-mediated regulation of cell fusion is disrupted.[314]

Inflammasome formation

In response to VZV infection, host cells mount an innate response through pattern recognition receptors and the formation of the nucleotide-binding domain and leucine-rich repeat-containing/pyrin domain–containing 3 (NLRP3) inflammasome. NLRP3 protein recruits the adaptor apoptosis-associated speck-like protein (ASC) and caspase-1, resulting in processing of the proinflammatory cytokine interleukin (IL)-1β by activated caspase-1 and NLRP3 is also up-regulated in VZV-infected skin xenografts *in vivo.*[308]

Interference With Intrinsic Antiviral Responses

Cell signaling

VZV targets the activation of several cellular pathways that support antiviral responses for inhibition. ORF66 interferes with the induction of phosphorylated signal transducer and activator of transcription 1 (STAT1) after exposure to interferon gamma (IFN-*γ*) in VZV-infected T cells and fibroblasts.[374] VZV also interferes with nuclear factor (NF)-*κ*B activation in cultured fibroblasts and in epidermal cells in skin xenografts *in vivo* by rapidly sequestering p50 and p65 in the cytoplasm and by inhibiting degradation of the NF-*κ*B inhibitor, I*κ*B*α*.[186] However, VZV infection of human monocytes induces NF-*κ*B and IL-6 through the Toll-like receptor 2 pathway.[440] VZV also inhibits the expression of STAT 1-*α* and Janus kinase 2 (JAK2) proteins as well as the transcription of IFN regulatory factor I and the major histocompatibility complex (MHC) class II transactivator, mediating IFN-*γ* signal transduction.[3]

In contrast to its inhibition of STAT1, VZV induces STAT3 activation in T cells and fibroblasts, as is also observed in cells infected with the oncogenic herpesviruses Kaposi Sarcoma herpesvirus (KSHV) and Epstein-Barr virus (EBV).[379] STAT3 phosphorylation requires infectious VZV and is a direct rather than a cytokine-mediated effect. STAT3 phosphorylation leads to the induction of the cell protein survivin *in vitro* and in infected skin cells (Fig. 13.9). Inhibition of STAT3 phosphorylation diminishes VZV virulence in skin xenografts and survivin inhibition reduces VZV replication, indicating that constitutive survivin expression in epithelial stem cells that line hair follicles, is important for initiating skin infection. Since STAT1 and STAT3 activation are inversely activated signaling events, VZV-mediated STAT3 activation may enhance replication indirectly by blocking STAT1-mediated innate responses and directly by promoting survival of infected cells through enhanced survivin expression (Fig. 13.9).

Interferon and interferon-regulated responses

As is true of other viruses, IFNs significantly inhibit VZV. The induction of the type I IFN pathway is initiated by IFN-*β* primarily through activation of IFN regulatory factor (IRF)-3, leading to IFN-*α* production. VZV blocks IFN-*β* production efficiently and down-regulates transcription of IRF3-dependent genes, as shown by comparing VZV-infected and uninfected

cells from the same culture.[381] IE62 alone prevents TANK-binding kinase (TBK1)-mediated IRF3 function and IFN-β secretion through a novel mechanism in which IRF3 phosphorylation is blocked. This antiviral activity of IE62 is independent of its function as a transactivating protein. IFN-α triggers production of cell proteins that phosphorylate the alpha subunit of eukaryotic initiation factor 2 (eIF-2α), which blocks translation. VZV can block eIF-2α phosphorylation through an IE63-dependent process, preventing this IFN-α effect,[7] possibly as a redundant mechanism if IE62 interference with IFN-β is incomplete. ORF47 kinase contributes to inhibition of IRF3 activation by altering its phosphorylation and blocking homodimer formation, and ORF61 degrades phosphorylated IRF3 in HEK293 cells[500]; however, these cells do not support productive infection. While IFN-α is an important initial inhibitory response, IFN-γ induces a different pattern of host cell gene expression that is associated with blocking VZV replication in fibroblasts.[382] The downstream mechanisms by which IFN-α and IFN-γ inhibit VZV, which are the IRF-9 and IRF-1 pathways, respectively, account for their differential effects, and again, IE62 functions as a VZV countermeasure by inhibiting IRF-9 transcription. When epithelial cells and fibroblasts are treated with IFN-γ before infection, the transactivating capacity of IE62 is inhibited and the effect is reversed by interfering with JAK/STAT-1 signaling.[383]

VZV can productively infect pDCs and inhibit their ability to produce IFN-α, even when stimulated with a TLR9 agonist.[169] Since VZV infects pDCs in skin, IFN-α production may be impaired *in vivo*. IFN-γ could promote survival of VZV-infected human neurons *in vitro,* which might ensure the efficient establishment of latency *in vivo*[23] and type I IFNs had an inhibitory effect on VZV replication in human induced pluripotent stem cell (iPSC)-derived neurons *in vitro*.[85] VZV infection of DRG in SCID mice resulted in increased production of IFN-α, IFN-γ, and other proinflammatory cytokines.[483]

Promyelocytic leukemia protein nuclear bodies (PML-NBs)

PML-NBs, also known as ND10 bodies, restrict herpesvirus gene expression in newly infected cells and are up-regulated by IFNs. Whereas HSV ICP0 degrades PML protein and PML-NBs, VZV-infected cells do not exhibit PML degradation.[233] Instead, the architecture of PML-NBs is disrupted in VZV-infected cells *in vitro* and in human skin xenografts through an ORF61-mediated effect that depends on small ubiquitin-like modifier (SUMO)-interacting motifs (SIMs) in ORF61.[443] In the absence of SIMs, ORF61 association with PML-NBs is reduced, most PML-NBs remain intact, and VZV skin infection is severely impaired. The ORF61 SUMO-binding capacity is necessary to counteract the intrinsic barrier created when the IFN response in VZV-infected skin induces even higher numbers of PML-NBs in dermal and epidermal cells. Furthermore, incomplete dispersal of PML-NBs by VZV inhibits egress of VZV capsids from the infected-cell nucleus, impairing the synthesis of infectious virus progeny[352,353] This antiviral mechanism has biologic significance, since neurons and satellite cells in human DRG and skin cells infected with VZV *in vivo* contain large PML-NBs that sequester newly assembled nucleocapsids (Fig. 13.9).[353] This function is mediated by the unique carboxy-terminus of PML IV (a splice variant of PML), which interacts with the ORF23 capsid surface protein to trap capsids and inhibit VZV replication. PML-dependent sequestration of nucleocapsids appears to be a common cytoprotective function of these PML-NBs, in which aberrant proteins are sensed and aggregated in neuronal cell nuclei.

Modulation of Surface Expression of Cellular Proteins Involved in the Host Response

VZV down-regulates expression of MHC class I proteins on the surface of infected fibroblasts and T cells, through their retention in the Golgi compartment,[1] although the total amount and rate of synthesis of class I molecules is unchanged in VZV-infected cells. Most of this effect, which blocks CD8+ T cell responses is mediated by ORF66.[1,107] VZV also inhibits IFN-γ induction of MHC class II molecules on the infected cell surface,[3] preventing recognition by VZV-specific CD4+ T cells. Infection of mature dendritic cells (DCs) with VZV results in down-regulation of surface MHC class I, CD80, CD83, and CD86, and inhibits their ability to stimulate proliferation of allogeneic T cells.[292] VZV also down-regulates Fas expression on the surface of DCs.[168] VZV infection of immature DCs fails to up-regulate CD80, CD83, CD86, MHC I and CCR7 which are important for DC maturation and anti-viral responses,[2] and is most likely due to VZV regulation of the NF-κB pathway[186,385] that controls the expression of these immune molecules.

Down-regulation of surface MHC class I by VZV renders infected cells a target for NK cell–mediated killing. Further alteration of the infected cell surface is needed for VZV to prevent recognition and clearance by both cytotoxic T cells and NK cells. Analysis of viral regulation of cell surface ligands for NKG2D, a potent activating receptor expressed ubiquitously on NK cells, revealed that VZV selectively down-regulates expression of ULBP2 and ULBP3 and up-regulates MICA on the surface of infected cells.[49] Furthermore, NK cell activity is not enhanced when NK cells are cocultured with VZV-infected target cells *in vitro*, indicating VZV modulates NK cell–mediated detection and activation.[49]

Profiling of the VZV-infected NK cell surface receptor phenotype by flow cytometry revealed increased expression of the skin homing chemokine receptors, cutaneous lymphocyte–associated antigen (CLA), and chemokine receptor (CCR)4.[47] This remodeling to induce a skin homing phenotype is similar to effects observed on VZV-infected T cells.[380] VZV may use a pan lymphocyte mechanism to hijack lymphocyte trafficking to promote virus spread to the skin. Interestingly, VZV infection of NK cells down-regulates surface expression of CD16, an FcγRIII receptor that enables their function in antibody-dependent cell-mediated cytotoxicity (ADCC).[47] NK cells infiltrating the site of VZV antigen challenge also had significantly reduced CD16 expression,[306] suggesting that the virus may inhibit ADCC function *in vivo*. NK cells also produce proinflammatory cytokines such as tumor necrosis factor (TNF) and IFN-γ that have potent inhibitory effects on VZV replication.[97,382] VZV reduces NK cell secretion of both of these cytokines and VZV infection of NK cells paralyzes their cytotoxic function.[48] Thus, VZV has multiple mechanisms to disarm NK cells.

VZV infection of human monocytes and macrophages *in vitro* down-regulates surface expression of CD14, MHC class II, CD11b, and macrophage colony-stimulating factor (MCSF) receptor expression.[201] In addition, infection impairs dextran-mediated endocytosis by monocytes, suggesting VZV has evolved strategies to modulate the ability of monocytes to take up and present antigen in the context of surface MHC class II. VZV-infected monocytes are also unable to differentiate into macrophages, whereas macrophages were shown to be highly permissive to infection.[201] Thus, VZV encodes an immune evasion strategy to prevent CD4+ T-cell activation.

VZV infection of human PBMCs including NK cells, T cells, NKT cells, B cells, and monocytes has been reported to up-regulate surface programmed cell death ligand 1 (PD-L1) expression,[188] potentially disrupting effective immune responses via the inhibitory signal that is transmitted to PD1. By contrast, VZV down-regulates PD-L1 in infected human brain vascular adventitial fibroblasts, perineural cells, and fetal lung fibroblasts, which may promote persistent vessel inflammation observed in patients with VZV vasculopathy and persistent inflammation in infected lungs.[187]

VZV can up-regulate surface CD59 (a host regulator of complement activation) in infected T cells and DRG, but not skin.[447] This tissue-specific regulation of surface CD59 may provide a mechanism of complement evasion.

Regulation of Apoptosis and Autophagy

VZV regulates apoptosis in a cell type–specific manner. VZV induces apoptosis with chromatin condensation and DNA fragmentation in Vero cells, B cells, T cells, and human fibroblasts, but not in primary human DRG neurons. Conversely, expression of IE63 in sensory neurons inhibits apoptosis induced by withdrawal of nerve growth factor.[164] IE63 interferes with apoptosis in keratinocytes as well as neurons, in association with cytoplasmic accumulation of IE63.[122] Transcriptome profiles indicate a propensity for VZV to up-regulate antiapoptotic genes in neurons and proapoptotic genes in fibroblasts.[267] In VZV-infected T cells, caspase-8 transcripts are reduced, whereas two IRF gene transcripts (ADAR and MxA) are increased. By contrast, caspase-8 transcripts are not reduced in virus-infected fibroblasts or skin cells.[185] VZV ORF66 expression inhibits apoptosis induced by VZV in T cells[374] and is required for efficient growth in corneal epithelial cells, although interference with apoptosis is not the only ORF66 function required in these cells.[111] STAT3 activation by VZV results in up-regulation of survivin in skin, exerting a proviral effect by inhibiting apoptosis.[379] The proapoptotic activity of Bcl-2 interacting mediator of cell death (BIM) was inhibited by its phosphorylation in VZV-infected cells, mediated through the MEK/ERK pathway, which is enhanced by ORF12, whereas without phosphorylation, Bim reduced plaque formation.[249]

Activated cytotoxic T lymphocytes (CTLs) and NK cells secrete granzyme B, which cleaves multiple apoptotic pathway components, resulting in apoptosis of the target cell. VZV ORFs 4 and 62 were identified to contain granzyme B cleavage sites and could be cleaved by granzyme B. However, only ORF4 conferred protection in a NK cell–mediated cytotoxicity assay. Mutation of the ORF4 granzyme B cleavage site did not alter the ability of ORF4 to modulate NK cell cytotoxicity, suggesting a novel ORF4 immunoevasion function independent from the granzyme B cleavage site.[121]

Whereas the HSV-1 neurovirulence protein ICP34.5 inhibits autophagy, VZV lacks an ICP34.5 ortholog. By contrast, VZV induces autophagy-associated proteins and formation of autophagosomes in cultured cells as well as in human keratinocytes that express IE62 in skin lesions (Fig. 13.9).[53,409] Autophagy appears to be a stress response of cells to VZV and the subsequent abundant synthesis of viral glycoproteins.[43] VZV titers are reduced when completion of autophagic flux is inhibited by siRNA against ATG5, and bafilomycin A1 inhibition of autophagy impairs secondary envelopment and trafficking of VZ virions.[132] While engulfment of viral particles within lysosomes (xenophagy) has not been observed, many VZV particles are

transported to the outer cell membrane after secondary envelopment in single-walled vacuoles with properties of late endosomes or amphisomes.[44] Based on the effects of its inhibition, the autophagy pathway is likely to be involved in the initial stress response to VZV and the transport of some progeny virions to the cell surface.

PATHOGENESIS AND PATHOLOGY

In the usual course of VZV infection, the virus exhibits tropism for T cells, cutaneous epithelial cells, and cells of sensory nerve ganglia (Fig. 13.1). VZV can also infect other tissues when cell-associated viremia and viral replication are not controlled by intrinsic or adaptive host immune responses. Under these circumstances, disseminated infection may involve the lungs, liver, central nervous system (CNS), and many other organs. Pathologic changes in these tissues may be caused by replicating virus and, in some instances, by inflammatory or immune-mediated injury. VZV and SVV pathogenesis have similarities consistent with the genetic relatedness of these two primate *Varicelloviruses*.[105,140,170,199,224,256,258] In some cases, the SVV model permits investigations, such as the host cell transcriptome profile triggered by acute lung infection, that are difficult in human infection.[10,11,322] The clinical manifestations of varicella and zoster that are associated with events in VZV pathogenesis and the pathologic changes associated with VZV syndromes are described in **Clinical Features**.

Entry Into the Host

Initial VZV replication is likely to occur in respiratory mucosal epithelial cells (Fig. 13.1). Primary VZV infection (varicella) is presumed to be initiated by inhalation of respiratory droplets containing virus particles or by inoculation of mucosal epithelium with infectious vesicular fluid from an individual with varicella or zoster. Following an incubation period of 10 to 21 days, primary VZV infection results in varicella. The potential for aerosol transmission is suggested by epidemiologic reports, and VZV DNA is detected in air samples from rooms occupied by patients with varicella or disseminated zoster.[372]

T-cell Tropism

Although T-cell tropism appears to be a necessary component of primary VZV infection, the site and mechanisms whereby T cells become infected cannot be defined in the human host. Tonsillar T cells are most permissive for VZV infection, suggesting that spread of VZV from infected mucosal epithelial cells to these T cells initiates cell-associated viremia.[229] Respiratory mucosal epithelial cells line tonsil crypts, penetrating deep into tonsillar tissues that contain many T cells, and migrating T cells traffic across this epithelial cell layer into tonsils. Dendritic cells are also present in mucosal epithelium and may transfer the virus to T cells in regional lymph nodes.[2] Viremia may be amplified during infection as T cells traffic through infected skin and visceral organs, such as the liver. VZV is detected in PBMCs from individuals just before or after the onset of the rash.[17,324] Infected cells are present at low frequency (0.01% to 0.001% of PBMCs)[225] and are usually cleared within 24 to 72 hours after the appearance of the rash. SVV

causes a robust cell-associated viremia that precedes the cutaneous exanthem.[272]

The unexpected capacity of VZV to dramatically remodel the cell surface proteins of T cells and to promote the skin trafficking potential of VZV-infected T cells has been documented using multiparameter single-cell mass cytometry (CYTOF) with 25 surface markers and 16 cell signaling phosphoproteins[380] (Fig. 13.9). VZV increased CD69, PD-1, and CD45RO, creating an effector phenotype, and increased integrins, CD11a and CD28, along with CCR4 and CLA, and decreased CCR7 and CD7, which promotes skin homing. VZV remodeled purified naïve T cells similarly. VZV triggered the cell signaling pathways that result in T-cell responses to cognate antigens, including Zap70 (TCR stimulation via the MHC) and Akt (ligand binding to costimulatory molecules, such as CD28). Thus, reprogramming occurs from within VZV-infected T cells, not by antigen stimulation or cytokine-mediated effects. Instead of selectively infecting tonsil T cells with skin homing properties, VZV takes over the T-cell signaling pathways that normally regulate cell surface proteins during differentiation from naïve to adaptive, antigen-specific memory T cells.[380]

VZV proteins that are required for or contribute to T-cell tropism *in vivo* as identified in T cell–containing xenografts in the SCID mouse model include gI, ORFs 66, 35, and 47 as well as residues 51 to 187 in the unique gE N terminus, the residues required for gE binding to gI and, to a lesser extent, the gE AYRV TGN-targeting motif (Table 13.1). VZV T cell–associated viremia is likely to be facilitated by down-regulation of MHC class I protein, inhibition of apoptosis by ORF66, and STAT3 activation with survivin induction.

Experiments in the SCID mouse model indicate that VZV is transported by infected human T cells to skin xenografts soon after they enter the circulation. However, the spread of VZV in skin is countered by a potent innate immune barrier resulting from constitutive IFN expression and up-regulation of the cellular transactivators STAT1 and NF-κB in epidermal cells, along with the high frequency of PML nuclear bodies in basement membrane cells of the dermis[186,230,443] (Fig. 13.9). Blocking IFN responses accelerates VZV infection in skin dramatically. The long interval between VZV exposure and the appearance of varicella skin lesions appears to reflect the time required for VZV to overcome these robust intrinsic obstacles.

Skin Tropism

During varicella, skin cells become major sites of virus replication (Fig. 13.10). The virus may gain access to cutaneous epithelial cells by migration of intact, infected T cells out of the capillaries into cutaneous tissue, followed by release of virions. Alternatively, infectious virus may move from T cells into capillary endothelial cells. Inclusions and VZV proteins have been observed in capillary endothelial cells and adjacent epithelial cells in VZV lesions.[305] Cells lining the lymphatics of the superficial dermis become dilated and contain intranuclear inclusions, suggesting VZV infection. Cutaneous DCs and Langerhans cells are susceptible to VZV and may contribute to local replication and spread.[2,169]

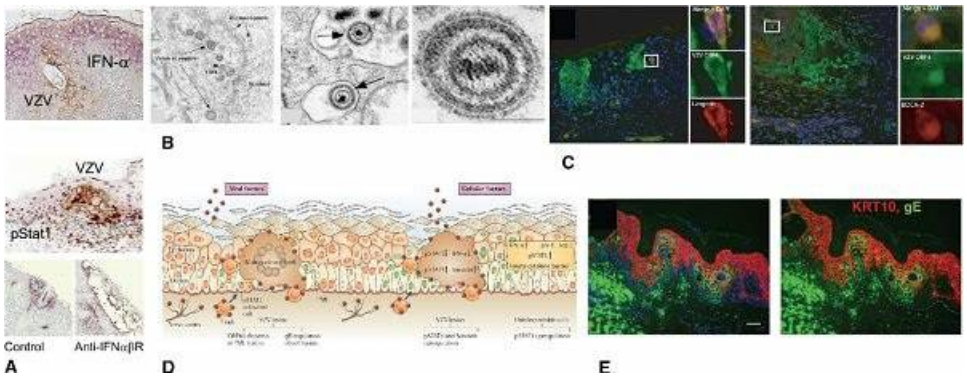

FIGURE 13.10 Varicella–zoster virus (VZV) infection of skin. Formation of epidermal lesions that penetrate the skin surfaces requires 10 to 21 days because of potent innate antiviral responses of epidermal cells. **A:** VZV lesions are formed by cell–cell spread overcoming the interferon barrier (IFN-α and pSTAT) in surrounding uninfected cells; interference with the innate IFN response by treatment of SCID mice with antibody against the IFNα/β receptor results in formation of large skin lesions. **B:** Electron micrograph of the suprabasal epidermis of a varicella skin lesion showing all stages of viral envelopment in infected keratinocytes. Unenveloped nucleocapsids are seen in the nucleus while nucleocapsids are being enveloped (*) by specialized cisternae of the TGN transport vesicles (*arrows*), each containing a single enveloped virion (*left panel*). Accumulating cytokeratin filaments are visible in the cytoplasm of the keratinocytes (*lower left of center panel*). Keratinocytes of the suprabasal layers of the VZV-infected epidermis secrete intact virions to the extracellular space (*arrows in middle panel* indicate two extracellular virions). A virion from a varicella vesicle is illustrated at high magnification and imaged in brightfield; note the spikes on the viral envelope, the complexity of the underlying tegument, and the apparent connections between the nucleocapsid and the tegument (scale bar = 100 nm) (*right panel*). **C:** Sections of varicella and herpes zoster skin lesions were immunofluorescently stained for combinations of DC markers and VZV antigens. Langerhans cell marker langerin (*red staining*) and VZV antigen ORF 4 (*green staining*) (*left panel*) and plasmacytoid dendritic cells with BDCA-2 marker (*red staining*) and VZV ORF4 (*green staining*) *(right panel)* are shown with 4′,6-diamidino-2-phenylindole (DAPI) (*blue staining*). Examples of dual positive cells are boxed and shown at higher magnification as insets. **D:** Schema of skin infection during primary VZV infection. Activation of innate responses (IFN, pStat1, and NF-κB) in uninfected cells is triggered by VZV replication. Within infected cells, VZV activates STAT3 and the antiapoptotic protein survivin. Uninfected T cells that traffic through sites of VZV lesion formation may amplify VZV viremia, and infected dendritic cells may transfer the virus to regional lymph nodes, enhancing T cell–mediated viremia. **E:** Immunofluorescent staining of a human varicella skin biopsy, showing *KRT10* (*red*) expression in the spinous layer; the loss of *KRT10* is seen in VZV-positive areas, shown by gE expression (*green*), scale bars 50 μm. Classic studies of varicella lesions by Tyzzer in 1906[419] showed that the earliest changes consist of vasculitis involving the endothelium of small blood vessels, whereas the emergence of enlarged, multinucleated epithelial cells with intranuclear eosinophilic inclusions is typical of the second, maculopapular stage of the lesions. Progressive degeneration of epithelial cells, coalescence of fluid-filled vacuoles between cells, and destruction of the basement membrane occur as maculopapular lesions evolve into vesicles (Fig. 13.10).

VZ virions are abundant in keratinocytes and in vesicular fluid (Fig. 13.10). Epithelial stem cells lining the hair follicles become infected first, allowing rapid delivery of the virus to the surface as these cells differentiate into keratinocytes. In skin biopsy specimens, early lesions show IE63 in keratinocytes; later, gE, gB, and IE63 are detected in keratinocytes, sebocytes, Langerhans cells, dermal dendrocytes, monocyte–macrophages, and endothelial cells. Viral proteins are also expressed in dermal nerves.[9] Cytokeratin and desmosomal proteins that preserve the epidermal structure are reduced substantially within skin lesions in a pattern associated with skin-blistering disorders.[189] Infiltration of the involved skin sites by inflammatory cells is minimal in the early vesicular phase, whereas later, up-regulation of adhesion molecules on capillary endothelial cells is associated with extensive mononuclear cell migration into the skin lesions. In the final phase, cutaneous lesions progress to ulceration and necrosis.

VZV proteins that are required for skin tropism, as assessed in skin xenografts in the SCID mouse model, include ORFs 10, 11, 31, 35, 47, 61, and 66; gI and particular residues in gI; and specific motifs within gE (Table 13.1). The passage of the Oka virus in tissue culture alters its capacity to infect skin, and analysis using vaccine/parental Oka chimeric viruses indicates that multiple VZV genes are involved in skin tropism.[485]

In addition to viral proteins, VZV skin tropism depends upon the capacity of the virus to up-regulate host cell signaling pathways, including STAT3 and pCREB, and down-regulate IFN-mediated innate defenses[117,379] (Fig. 13.10). Age-related differences have been identified that permit more VZV replication in aging skin.[492] Like VZV, SVV produces a cutaneous rash within 10 to 12 days after close contact with infected animals or following intratracheal inoculation.[272]

Release From the Host

Many cell-free VZ virions are released into vesicular fluid of skin lesions, which facilitates transmission by direct contact. VZV differs from other human herpesviruses in that infectious virus can be released into respiratory secretions and spread to susceptible persons by airborne transmission.[372] Viral DNA can be detected by PCR in specimens obtained from respiratory sites in the late stage of the incubation period and during the first few days of rash.[17,123] VZV DNA can also be detected in saliva during and after zoster, but it is not known whether infectious particles are present.[298] Compared to HSV-1, VZV DNA is rarely found in oral secretions in the absence of symptoms even in patients with HIV infection.[424]

Virulence

Naturally circulating strains of VZV do not exhibit intrinsic differences in virulence, as judged by the clinical consequences of primary VZV infection. Nonetheless, circulating strains of VZV do differ in their genome sequences, allowing assignment to clades (Fig. 13.4). The enhanced growth of the naturally occurring VZV–MSP variant in skin xenografts in SCID mice suggests that a single amino acid change in gE can alter pathogenesis.[366] VZV TK-negative viruses have been isolated from patients given prolonged acyclovir therapy, but altered pathogenicity has not been described. VZV isolates from three patients with encephalitis did not have distinctive genetic characteristics.[41] A study of Oka vaccine viruses isolated from skin revealed the same DNA sequence (a clonal isolate), whereas virus isolated from lungs contained mixed DNA sequences but with no identifiable changes related to tropism.[346] In addition, viruses isolated from skin lesions after vaccination have been found to have *ORF62* genes that encode amino acids characteristic of the parent strain rather than the substitutions identified in the vaccine, suggesting that a natural selection for these residues occurs during replication in the human host.[345] As demonstrated in the SCID mouse model, many VZV genes and promoter regulatory elements contribute to VZV cell tropism and virulence (Table 13.1).

Latency

VZV gains access to sensory ganglia, either hematogenously or by retrograde neural transport from mucocutaneous lesions during primary infection, where it establishes latency. The importance of cell-associated viremia in the delivery of the varicelloviruses to sensory ganglia is supported by VZV detection at these sites before rash has appeared and in nonhuman primates infected with SVV, and the occurrence of two episodes of zoster due to distinct strains in one individual[42,258] Alphaherpesvirus latency is characterized by the presence of viral DNA in ganglionic neurons (Fig. 13.11), limited viral gene transcription, and the potential for reactivation. VZV becomes latent in neurons in cranial nerve, dorsal root, and autonomic ganglia along the human neuraxis.[171,200,260,441] Based on autopsy studies, the prevalence of VZV latency in the population varies from 63% to 100%[84,335]; in the largest study, VZV DNA was found in 94% of 414 trigeminal ganglia.[173] Use of precise laser capture microdissection and PCR revealed VZV DNA in 4.1% of neurons and in less than 0.1% of satellite cells.[441]

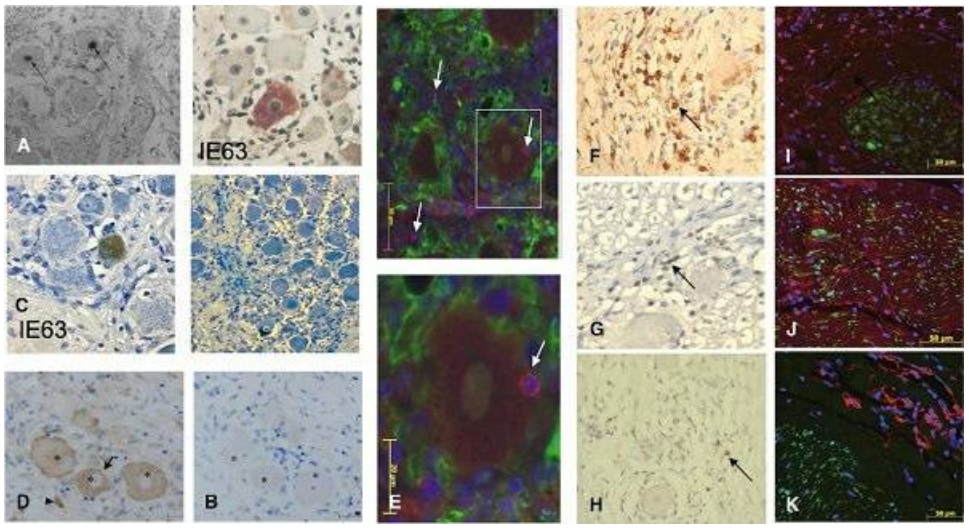

FIGURE 13.11 Varicella–zoster virus infection of human sensory ganglia. **A:** Detection of VZV DNA by *in situ* hybridization in the nucleus of a neuron (*arrow*) in sensory ganglion section obtained postmortem from a patient without signs of zoster. **B:** Immunohistochemical detection of IE63 protein in neuron cytoplasm (*arrow*) in a thoracic ganglion section using rabbit anti-VZV ORF63. **C:** Immunohistochemical detection of IE63 protein in dorsal root ganglion sequential sections using rabbit preimmune IgG antibody (*left panel*) and matched high-titer rabbit anti-IE63 IgG at magnifications ×100 (*right panel*) and ×200 (*lower panel*). **D:** Immunohistochemical detection of CXCL10 in dorsal root ganglia from a patient with zoster rash at time of death. The ganglion innervating the site of the rash contained CXCL10-positive neurons (*arrow*) and infiltrating cells (*arrowhead, left panel*). *Right panel* shows isotype control staining of the consecutive section. Stars indicate the same cells. **E:** Immunofluorescence detection of CXCR3 (*red*) and S100b (*green*) and counterstained with DAPI (*blue*) in the same ganglia as in **(F).** Nonneuronal CXCR3-positive cells were observed throughout the reactivated lumbar DRG (*arrows*), with some CXCR3-positive cells juxtaposed to neurons (*boxed region, upper panel*); higher-power magnification of the inset box (*lower panel*). **F-H:**Immunohistochemical detection of immune cell subsets: CD8-positive T cells, (*arrow*) **(F)** T-cell intracellular antigen (TIA)-positive cells, (*arrow*) **(G)** and granzyme B positive (*arrow*) **(H)** in DRG from a patient with zoster rash at time of death. **I–K:** Immunofluorescence detection of immune cell subsets (*red*) and S100b (*green*) and counterstained with DAPI (*blue*) in ganglia from a postherpetic neuralgia–affected patient years following zoster rash resolution. **I:** shows CD4-positive staining (red), **J:** CD8-positive staining (red), and **K:** CD20-positive staining. Latent VZV DNA assumes a circular or concatemeric form[69] and is present at a frequency of 2 to 9 genome copies in 1% to 7% of neurons, which corresponds to a virus burden of 30 to 3,500 copies per 100 ng of ganglionic DNA.[84,165,200,335,441] The wide range of genome copy number in latently infected ganglia may reflect variability in the extent of cell-associated viremia and that the number of cutaneous lesions in primary VZV infection can range from a few to many hundreds.[357] Episodes of VZV reactivation or possibly reinfection may also increase the virus burden in latently infected ganglia.

The use of deep sequencing to evaluate trigeminal ganglia obtained less than 9 hours postmortem demonstrates that VZV gene expression is highly restricted during latency[94,321] in contrast to earlier reports of transcripts mapping to many *ORFs* when only less precise methods were available, including *in situ* hybridization, PCR amplification of cDNA libraries,[82,84] and multiplex PCR of mRNA.[299] By deep sequencing, gene expression was limited to *ORF63* and a transcript antisense to *ORF61* in trigeminal ganglia. Notably, the antisense transcript suppressed *ORF61* expression in cotransfection; isoforms of this latency-associated transcript that expressed a viral protein were identified in lytic infection and in zoster lesions. By contrast, a different isoform is expressed in latency, designated the VZV latency-associated transcript (VLT), that does not encode a protein.[94] VZV transcripts are also detected in enteric neurons that may indicate persistent gene expression or its triggering by surgical removal of intestinal tissues.[124]

Whereas the VLT was detected in 90% of early postmortem ganglia, ORF63 was also present in 63%. In earlier studies, *ORF63* transcripts in individual ganglia were found to vary more than 2,000-fold, ranging from 1 to 2,785 copies per 10,000 copies of GAPDH transcript,[84] and *ORF63* transcripts were detected in 17 of 28 ganglia, with as many as 29,000 copies per 1 μg of input mRNA. The consistent detection of *ORF63* transcripts in high abundance is not understood. Deep sequencing of RNA extracted from human trigeminal ganglia positive for VZV and HSV-1 DNA revealed microRNAs (miRNAs), the small noncoding RNA molecules that can alter transcript stability and translation, mapping to the HSV-1 genome but not the VZV genome.[420] Some of the small noncoding RNAs in VZV-infected neurons may be consistent with miRNA structures.[135]

Chromatin remodeling appears to contribute to the restricted pattern of latent VZV gene transcription based on chromatin immunoprecipitation (ChIP) assays.[120] Like HSV-1 DNA, histones are associated with VZV DNA at all stages of the viral life cycle, but the histone composition differs during productive infection and latency. Acetylated histone H3K9(Ac), indicative of a euchromatic (transcriptionally active) state, is associated with the *ORF62* and *ORF63* promoters during both latent infection in human ganglia and lytic infection of human melanoma (MeWo) cells. Neither *ORF14* (glycoprotein C) nor *ORF36* (thymidine kinase) is transcribed or associated with H3K9(Ac) during latent infection. An IE63 interaction with human antisilencing function 1 protein interferes with its capacity to bind histones h3.1 and

h3.3.[6]

Some VZV protein expression may be detected in autopsy ganglia from patients with no evidence of zoster. IE63 was first identified in rare ganglion neurons by Mahalingam et al.[259] (Fig. 13.11). Detection of IE62, IE63,[251] ORF66,[82] and proteins encoded by *ORFs 4*, *21*, and *29* was also described in early studies and restriction of IE62 and IE63 to the cytoplasm of neurons was proposed as a mechanism by which latency is maintained. However, ascites-derived monoclonal antibodies and rabbit antisera may contain endogenous antibodies to human blood group A determinants, including antibodies to VZV IE62, gE, and ORF40 capsid protein that produce a cytoplasmic Golgi-like pattern of staining in neurons of blood group A subjects (~30% to 40% prevalence).[490] IE63 expression was confirmed as being rare when ganglion sections were stained with anti-IE63 rabbit antiserum and with preimmune serum to control for blood group A reactivity[259,491] (Fig. 13.11). Detection of VZV proteins in a few neurons from autopsy ganglia is likely to reflect early or abortive reactivation.

Investigations of VZV tropism for human neural cells *in vivo* have used the SCID mouse model, in which human DRG is xenografted under the mouse kidney capsule and maintained ≥20 weeks until neuronal subtype heterogeneity is established before infection. In this model, a limited lytic infection of DRG occurs in the first 14 days (Fig. 13.12). VZ virions are detected in neurons and satellite cells, and infectious virus is produced[354,486,488] and is accompanied by both proinflammatory host factors and IFNs and neuroprotective responses. Peripherin+ nociceptive and RT97+ mechanoreceptive neurons are infected by VZV via axonal transport and contiguous spread from satellite glial cells, but RT97+ neurons are nonpermissive for replication.[483] By 1 month, infectious virus is no longer released from cells, virion assembly ceases, and VZV genome copy numbers are reduced. *ORF63* and less consistently *ORF62* continue to be transcribed but gB expression is silenced. This transition from lytic to persistent infection indicates that VZV latency can be established in human neurons in the absence of adaptive immunity, since SCID mice do not generate antigen-specific T cell or humoral immunity. VZV neurotropism was also shown by intraventricular inoculation of SCID mice.[22]

Like VZV, SVV establishes latent infection in ganglionic neurons at multiple levels of the neuraxis, but not in lung or liver.[199,322] SVV DNA, viral gene transcripts, and CD4+ and CD8+ T cells are detected in ganglia 3 days before the rash, supporting viremia as a route of access to sites of latency during acute infection; notably, VZV gene transcription declined within only 7 days after inoculation, accompanied by dramatic innate immune responses within the ganglia.[10] VZV neurotropism has also been investigated in rodent and guinea pig models.[64,70] Inoculation of cotton rats by injections adjacent to the spine and sensory ganglia with VZV mutants showed that *ORFs 1, 2, 10, 13, 14, 17, 21, 32, 47, 57, 61, 66*, and *67* were dispensable for VZV DNA persistence in ganglion tissues, whereas *ORF 4, 63*, and *66* mutants were impaired. VZV persists in the enteric neurons in the guinea pig model, as does SVV in nonhuman primates.[124,255,322]

Reactivation

The factors that trigger VZV reactivation from latency in infected neurons *in vivo* are unknown. In an *in vitro* model, inhibition of nerve growth factor induces reactivation of VZV and HSV from latently infected human neurons.[361] Three possible outcomes of reactivation are abortive infection restricted to the ganglia; transport of virus particles to skin but with lesion formation blocked by innate and adaptive immunity; and cutaneous lesion formation, manifested as zoster (see **Clinical Features**)[166] (Fig. 13.10 and e-Fig. 13.4).

The pathology of VZV reactivation in ganglia is characterized by inflammation and hemorrhagic necrosis with associated neuritis, localized leptomeningitis, unilateral segmental myelitis, and degeneration of related motor and sensory roots.[158] Demyelination is seen in areas with mononuclear cell infiltration and microglial proliferation. Intranuclear inclusions, viral

DNA and proteins (Fig. 13.12), and viral particles are found in acutely infected ganglia.[63,112,129] Infectious VZV has been isolated from human ganglia only of patients with active zoster.[336] Immune cell subsets have been identified in ganglia during active VZV reactivation, with a predominance of CD4+ and CD8+ T cells[392] while ganglia obtained 1 to 5 months after zoster had an immune infiltrate composed of noncytolytic granzyme B-negative T cells and macrophages.[139] VZV-infected cells have been detected in subependymal microvessels in fatal zoster cases. VZV reactivation may be followed by vasculopathy affecting large and small vessels with resultant cortical and subcortical infarction and mixed necrotic and demyelinative lesions, particularly in deep white matter and periventricular ependyma.

The lytic phase of VZV infection of DRG xenografts in SCID mice can be considered a model of events that occur during VZV reactivation[354] (Fig. 13.12). Both neurons and satellite cells are productively infected.[486,488] Importantly, VZV induces cell–cell fusion between neurons and satellite cells and spread from satellite cells to adjacent uninfected satellite cells. Infection of these cells surrounding neuronal cell bodies facilitates access of the virus to other neuronal cell bodies. Similar cell–cell fusion has been observed in ganglia obtained at autopsy from patients with zoster.[112] During VZV reactivation, amplification by spread to other neuronal cell bodies within the ganglia presumably allows delivery of virus particles from many neurons along axons to the skin in the affected dermatome. VZV damage to both satellite cells and neurons in the ganglia helps to account for the neurologic consequences that are rare during HSV reactivation.

SVV also reactivates in a dermatomal distribution either spontaneously or after drug- or radiation-induced immunosuppression, or CD4+ T-cell depletion.[258,415] SVV glycoproteins are detected in zoster skin lesions, lungs, and multiple ganglia of most immunosuppressed monkeys, but not in control animals. Reactivation is associated with SVV infection of macrophages, dendritic cells, and T cells of lymph nodes, indicating dissemination.[414]

Postherpetic neuralgia (PHN) is a chronic pain syndrome that is common after VZV reactivation (see **Clinical Features**), and has been suggested to reflect an altered excitability of ganglionic or spinal cord neurons. PHN has been associated with diffuse and focal infiltration of ganglia by chronic inflammatory cells[450] (e-Fig. 13.4), and CD4+ T cells, CD8+ T cells, and CD20+ B cells have been reported to persist in ganglia years after zoster (Fig. 13.11).[406] VZV DNA has been detected in PBMCs of patients with PHN.[421]

Reinfection

Reinfection with VZV appears to be rare based on clinical criteria, although genotyping evidence of recombination demonstrates that it can occur.[42] Second episodes of varicella have been documented,[127] but confirmation of true reinfection with VZV as opposed to incorrect diagnosis of a previous vesicular rash is difficult. In a cohort of adults who developed varicella despite a reported previous episode, none had VZV antibodies in sera obtained before the acute illness, suggesting that the earlier exanthem was not caused by VZV.[433] Most immunocompromised patients who have had prior VZV infection and who develop signs suggestive of a second episode of varicella likely have generalized, atypical reactivation without dermatomal involvement although reinfection may occur. Immunologic evidence of reinfection based on increases in antibody and cellular immunity to VZV when immune subjects have close contact with an infected person is indirect since enhancement of adaptive immunity can occur without

any viral replication, as observed when immune individuals receive inactivated varicella vaccine. Subclinical reinfection can occur despite vaccine-induced immunity since vaccinated individuals can develop zoster due to wild-type VZV.[123]

IMMUNE RESPONSE

Immune Control of Primary VZV Infection

Both the innate and adaptive arms of the immune response are required to resolve primary VZV infection. In addition to local antiviral responses mediated by epidermal cells (Fig. 13.10), NK cells are crucial as evident from case studies reporting severe, often fatal, varicella in patients with NK cell deficiency and dysfunction.[113] In immunocompetent hosts, NK cells are likely to be key responders, as suggested by increased frequencies of NK cells during active infection.[411] NK cells from nonimmune individuals lyse VZV-infected fibroblasts and also produce granulysin, which has antiviral activity.[156] In addition, NK cells are rapidly recruited to sites of VZV antigen challenge in previously exposed hosts.[306]

IFN-α is detected in serum at the onset of varicella and may limit early viral replication, as suggested by its clinical efficacy in modifying the severity of varicella in immunocompromised children and by the association of more severe varicella in adults with reduced serum IFN-α.[14,434] The importance of IFNs is also underscored by acute, severe varicella in patients who have primary immunodeficiencies affecting IFN signaling pathways.[309]

The innate response to primary VZV infection also appears to involve invariant natural killer T cells (iNKT) and antigen presentation to these unusual T cells by CD1, a nonclassical MHC class I molecule, as suggested by disseminated infection after administration of varicella vaccine virus in a child who had deficient iNKT cells and CD1 expression but no other evidence of a primary immunodeficiency disorder.[25]

The initial stages of primary VZV infection before and in the first few days of rash evoke little or no adaptive immunity, as measured by antibody production or assessment of T cells that recognize VZV antigens. Nevertheless, although the virus can evade induction of and recognition by CD4+ and CD8+ T cells transiently, replication becomes contained when VZV-specific immunity is induced[12] (Fig. 13.13). Antibodies can be detected in low concentrations in some individuals at the onset of the varicella rash and are usually present within 3 days. Antibodies to VZV proteins neutralize VZV replication, either directly or with complement, and also function in ADCC.[157,195,377] IgG, IgM, and IgA antibodies are directed against many viral proteins[13] and the breadth of the VZV B-cell repertoire has been shown in identical twins.[442] However, the humoral immune response appears to have little role in controlling primary VZV infection, since children with agammaglobulinemia have uncomplicated varicella. Among healthy children, the early detection of high levels of circulating VZV-specific IgG or IgM antibodies does not predict disease severity. Moreover, children with T-cell immunodeficiencies may develop fulminant varicella, despite VZV antibody responses.[13]

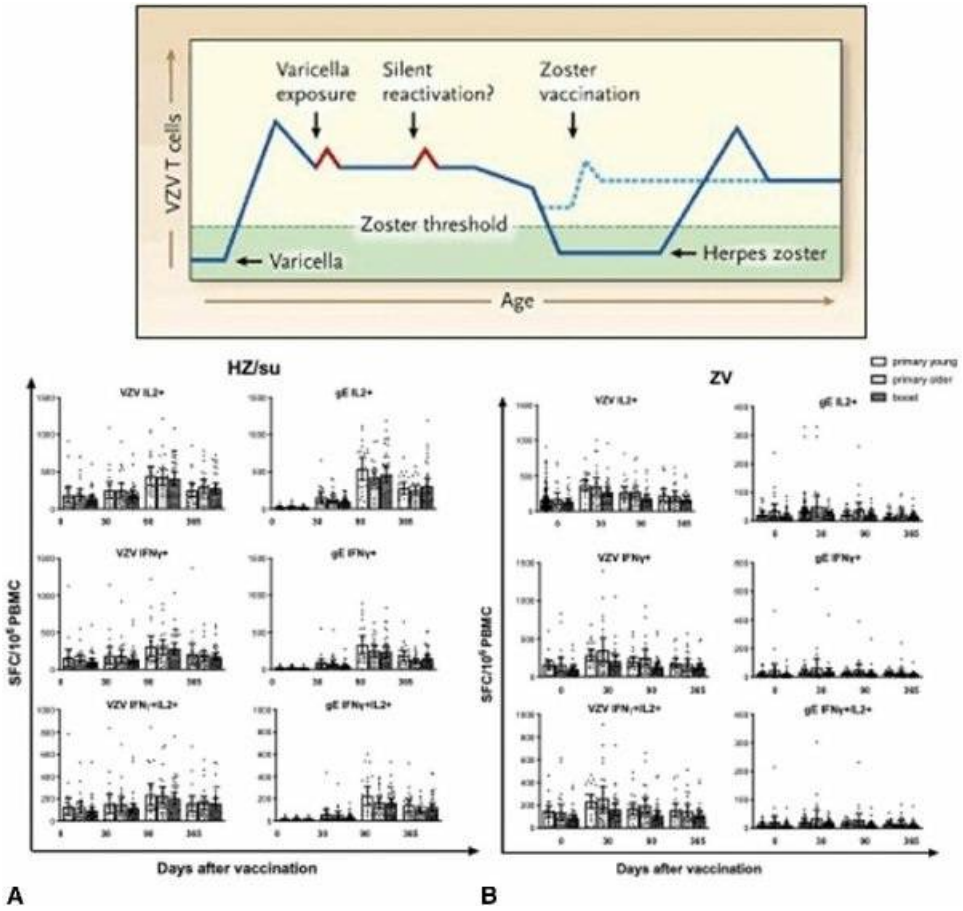

FIGURE 13.13 The immune response to varicella–zoster virus (VZV) infection. Upper panel: Schematic of VZV T-cell immunity. Varicella is the primary infection caused by VZV, and its resolution is associated with the induction of VZV-specific memory T cells (*blue line*); varicella vaccine also induces memory T cells. Memory immunity to VZV may be boosted periodically by exposure to varicella or silent reactivation from latency (*red peaks*). VZV-specific memory T cells decline with age. The decline below a threshold (*dashed green line*) correlates with an increased risk of zoster. The occurrence of zoster, in turn, is associated with an increase in VZV-specific T cells. Administration of zoster vaccine to older persons may prevent VZV-specific T cells from dropping below the threshold for zoster occurrence (*dashed blue line*). (From Arvin A. Aging, immunity, and the varicella-zoster virus. *N Engl J Med* 2005;352(22):2266–2267. Copyright © 2005 Massachusetts Medical Society. live attenuated zoster vaccine. (From Weinberg A, Kroehl ME, Johnson MJ, et al. Comparative immune responses to licensed herpes zoster vaccines. *J Infect Dis* 2018;218(suppl_2):S81–S87. Reproduced by permission of Oxford University Press.)

The critical role of VZV-specific cell-mediated immunity in primary VZV infection is supported by correlations between the induction of virus-specific T cells and disease outcome.[12] Cellular immunity appears to be important for terminating viremia and limiting virus replication at localized cutaneous sites. Healthy children who had T cells that recognized VZV antigens within 24 to 72 hours experienced milder varicella.[13] T-cell proliferation in response to VZV antigen is accompanied by the production of many cytokines, including IL-2 and IFN-γ, which amplify the initial antiviral response.[179] Robust cellular immunity is elicited even when the varicella rash consists of fewer than 10 lesions. Conversely, lymphopenia and failure to develop VZV-specific T-cell proliferation in immunocompromised children correlate with persistent viremia and risk of visceral dissemination.[13] Children with immunosuppression due to underlying diseases or interventions or those with primary cellular immunodeficiency diseases experienced progressive and often fatal varicella before the availability of antiviral drugs. A similar pattern of acquisition of cell-mediated immunity and resolution of viremia and rash is observed in SVV infection.

Overall, this pattern of virus–host interaction initially favors the virus because cutaneous viral replication allows VZV transmission to other susceptible individuals, while the host is favored thereafter through the protection from illness on subsequent exposures afforded by memory B and T cells that recognize VZV antigens.

Memory Immunity

Memory immunity to VZV is required to prevent symptomatic reinfection with exogenous virus and to prevent or minimize the severity of symptomatic VZV reactivations. The extent to which memory immunity contributes to the preservation of viral latency in neurons is not known. IgG antibodies that bind to viral glycoproteins and many other VZV polypeptides and VZV-specific IgA antibodies are maintained, likely functioning as the first line of defense against reinfection.

Cell-mediated immunity to VZV proteins including gB, gC, gE, gH, gI, and the immediate early proteins IE62 and IE63, persists for years in the immunocompetent host.[12,16,365] Healthy VZV-immune adults have circulating T cells that recognize an average of 7 of 10 IE62 peptides and 6 of 10 gE peptides. Such individuals also have T cells that exhibit class I and class II MHC-restricted lysis of target cells expressing VZV antigens.[99,384] CTLs that recognize IE62 protein or gE are present at equivalent precursor frequencies in both the CD4+ and CD8+ memory T-cell populations.[16] VZV gC, gI, ORF4 protein, and ORF10 protein are also CTL targets.[12,15] VZV-specific memory T cells circulate at low frequencies of about 5 per 100,000 PBMCs in immune adults, and memory CD4+ and CD8+ CTLs specific for individual VZV proteins circulate at frequencies of about 1 per 150,000 PBMCs. Intracellular cytokine detection assays showed that the mean percentage of VZV-specific CD4+ T cells based on IFN-γ or TNF-α production was about 0.12%.[19] Immune subjects also have persistent delayed-type hypersensitivity (DTH) responses to VZV skin test antigens.

Mechanisms by which memory immunity to VZV is maintained may include exposure to

VZV through close contact with an infected person, since enhanced VZV T-cell proliferation, DTH, and VZV IgG antibodies often follow such contacts, as well as endogenous reexposure to VZV antigens by subclinical reactivations (Fig. 13.13). Repeated antigenic stimulation may also result if subclinical VZV reactivations lead to viral transfer to skin or mucosal sites of replication without progressing to zoster. This possibility is supported by the recovery of cell-mediated immunity to VZV in bone marrow transplant recipients who had no clinical episodes of zoster but had subclinical reactivations detectable by PCR.[467] It is not known whether conditions necessary for CD4+ and CD8+ T-cell recognition of neurons harboring VZV are present during latency; if so, VZV immunity may be maintained by intermittent local expression of viral proteins during abortive reactivations. However, viral peptides can only be detected by T cells when present in MHC complexes, and class I MHC requires IFN-γ exposure for up-regulation on neurons. Attempts to analyze local T-cell responses during latency have been hampered by the lack of a marker for cells harboring VZV genomes.[259,491]

Long-lived memory NK cells have been suggested to play a role in antiherpesvirus immunity. Cytotoxic NK cells with a tissue resident phenotype were recruited to skin sites of VZV test antigen challenge in previously exposed hosts. This NK cell-mediated recall response, decades after initial virus exposure, indicates NK cells may contribute to a long-lived memory response to VZV.[306]

Immunity and Reactivation

T cells are present in ganglia obtained postmortem from latently infected individuals, but the extent to which VZV-specific T cells provide surveillance for early stages of reactivation in ganglionic neurons is unknown. Diminished T-cell responses to VZV antigens in older and immunocompromised individuals correlate with enhanced susceptibility to zoster.[12,243] The restoration of VZV T-cell immunity and the reduced risk of zoster in immunocompromised and elderly individuals given live attenuated and gE subunit VZV vaccines have confirmed this hypothesis[87,323] (Fig. 13.13). Age-related immunosenescence is also associated with a decrease in DTH responses to VZV antigens. The decrease in VZV-specific immunity in skin of older individuals is unlikely to be due to a defect in CD4+ T resident memory (Trm) cells, as VZV-specific CD4+ T cells were shown to be functionally competent and not altered by aging. Rather, it has been proposed that other modulatory factors in the skin such as increased PD1 receptor signaling or skin resident regulatory T cells may inhibit immune responses in the skin of older aged individuals.[430] A study of peripheral blood from zoster patients revealed that the numbers of CD3+ and CD8+ T cells decreased during aging and PHN. NK cell numbers were also reduced in older aged zoster patients compared to the middle age patient group, which may reflect NK cells being important following VZV reactivation in older age zoster patients.[454]

Zoster in young children after intrauterine or early postnatal varicella and the short interval between primary and recurrent VZV infections in HIV-infected children probably reflects suboptimal induction of VZV cell-mediated immunity.[20,96] Severe and prolonged suppression of VZV-specific cellular immunity also creates the highest risk for zoster, viremia, and dissemination. Depletion of CD4+ T cells alone was sufficient to permit the reactivation of latent SVV.[415] By contrast, susceptibility to VZV reactivation is not associated with decreasing titers of VZV IgG antibodies, even in immunocompromised patients.[453]

Upon VZV reactivation, VZV T-cell responses increase promptly, peaking at a responder

cell frequency of about 10 per 100,000 PBMC at 6 weeks. The resolution of rash is also accompanied by local production of IFN-α in lesions. When reactivation was mimicked using a VZV skin test, VZV-specific central memory CD4+ T cells accumulated and proliferated at the site, as did regulatory T cells.[431] While information is limited, autopsy studies indicate that an extensive inflammatory response, including CD4+ T cells, CD8+ T cells, and NK cells, persists in ganglia for several months after zoster with or without PHN.[139] Up-regulation of CXCL10 occurs in ganglia during reactivation, and lymphocytes that express the CXCR3 receptor for CXCL10 are prominent among infiltrating cells (Fig. 13.11).[391] A persistent inflammatory response including CD4+ T cells, CD8+ T cells, and B cells was observed in ganglia of a patient with PHN.[406] Enhanced VZV T-cell immunity persists for at least 3 years after zoster and may explain why second episodes of zoster are rare except in immunocompromised patients.

EPIDEMIOLOGY

Incidence and Prevalence

VZV is a ubiquitous human pathogen with a worldwide geographic distribution. The annual incidence of varicella in the United States was equivalent to the annual birth rate (~4 million) before varicella vaccine was introduced in 1995, and the prevalence of anti-VZV IgG antibodies indicated that up to 99% of adults had been infected.[211] Universal varicella vaccine in the United States has dramatically reduced the annual epidemics.[266] By 20 to 29 years of age, only about 5% of individuals remain susceptible in geographic areas with temperate climates, in the absence of vaccination programs. In tropical regions, only about half of individuals younger than 24 years of age have had varicella. The varicella attack rate is very high among susceptible adults who emigrate from tropical areas to temperate zones.

Given the high incidence of varicella, most adults are at risk for VZV reactivation and one-third will develop zoster. In the United States, approximately 1 million cases of zoster are diagnosed annually, two-thirds of which occur in individuals older than 50 years and 9 in 10 are immunocompetent.[481] Hope-Simpson[166] observed that the incidence rose to 7.8 cases per 1,000 people older than 60 years of age, compared with 2.5 per 1,000 people 20 to 50 years of age. The risk is as high as 50% among those who reach 85 years of age. Since the risk of zoster increases with age, and the population over age 65 is expected to be 72 million in 2030, zoster and its attendant serious neurologic complications will continue to be a significant health burden.

Zoster incidence rates are equivalent between men and women but are lower in black than in white Americans. Zoster is particularly frequent among patients with leukemia, Hodgkin's and non-Hodgkin's lymphoma, small cell carcinoma of the lung, and after bone marrow transplantation (>25%) and renal transplantation (15%). HIV infection increases the risk for zoster by 15- to 25-fold regardless of age.[133] Although cancer is correlated with a higher risk of zoster, zoster in healthy individuals is not associated with an increased risk for malignancy. Patients with systemic lupus erythematosus are more susceptible. Zoster is rare in childhood, but infection *in utero*, varicella during the first year of life, and varicella in adults are associated with higher risks.[20,334]

Epidemic Patterns

While varicella cases appear to initiate most annual epidemics, episodes of zoster provide a source of reintroduction and transmission to susceptible individuals, who then develop varicella. Genotyping demonstrates the cocirculation of several VZV strains during a single varicella outbreak, indicating multiple sources of the virus.[92] Before varicella vaccination was introduced, most susceptible children became infected during annual epidemics due to efficient VZV transmission by the respiratory route and contact with high titers of infectious virus in skin lesions. The attack rate for previously uninfected household or day care center contacts exposed to varicella was about 90%, compared to 12% to 33% for more casual exposures such as school classrooms. VZV appears to be transmitted less efficiently in tropical climates although high population density may offset this pattern. Zoster is not seasonal because it originates from the reactivation of endogenous latent virus. Some reports have suggested that exposures to varicella can precipitate episodes of zoster, but there is no known mechanism by which reexposure would trigger reactivation. While zoster vaccines are available, uptake has been limited, leaving many older adults at risk for zoster.

Morbidity and Mortality

The high prevalence of VZV infection means that almost all individuals experience some VZV-related morbidity, absent vaccination. The risk for severe morbidity or mortality during primary or recurrent VZV infection depends on host factors rather than virulence characteristics of the infecting virus strain.

Varicella complications resulted in hospitalization rates of 11,000 per year in the United States (2.2 to 4.3/1,000 cases) before varicella vaccine was introduced.[265] Serious complications are least common among children 1 to 9 years of age and are 6 to 15 times higher among adults. Case fatality rates are 10 and 24 times higher in infants (6.7/100,000 cases) and adults (17.1/100,000 cases), respectively, than in children 1 to 4 years of age (0.7/100,000).[303] Serious complications are usually secondary bacterial infections, varicella pneumonia in adults, or neurologic syndromes.[115,144] CNS morbidity is higher among patients younger than 5 years and older than 20 years of age.[183] Among adults requiring intensive care, half required mechanical ventilation for an average duration of 14 days and mortality was 24% despite acyclovir therapy.[275] Before effective antiviral drugs were available, 32% to 50% of children with malignancy developed disseminated infection; varicella pneumonia occurred in 20% of cases, and the mortality rate was 7% to 17%.[114]

Varicella has been reported to occur in 0.7 to 2 per 1,000 pregnancies, with a predicted maternal mortality rate of 0.5 per 1,000 cases[108] and a risk of congenital varicella syndrome. Rarely, the pregnancy may terminate by spontaneous abortion, fetal demise, or premature delivery. The incidence of congenital varicella syndrome was 0.4% when maternal varicella occurred from 0 to 12 weeks of gestation, compared with 2% for infection from 13 to 20 weeks of gestation.[108] The virus appears to be transmitted to the fetus during the second and third trimester of maternal varicella with about the same frequency as in the first trimester, but a study found no infants with congenital varicella syndrome or other morbidity at birth if the mother had varicella between 25 and 36 weeks of gestation.[108] Infants are at risk for neonatal varicella when maternal varicella occurs at the end of gestation, with an attack rate of about 20% unless

antibody prophylaxis is given, and a 30% mortality rate without antiviral therapy. Zoster is not unusual in pregnancy but it does not cause significant maternal or fetal morbidity.[108]

One in ten individuals with zoster experiences at least one zoster-related nonpain complication, while one in four experience zoster-related pain that persists 30 days or more.[481] The frequency of PHN is higher in older patients, increasing from 3% to 4% in those between 30 and 49 years of age to 21%, 29%, and 34% in patients 60 to 69, 70 to 79, and more than 80 years of age, respectively.[12,466] Data from the United States indicate a risk of PHN of 1.38 cases per 1,000 person-years in healthy adults older than 60 years.[323] The incidence of zoster-associated CNS disease, most of which are cases of VZV vasculopathy, ranges from 0.2% to 0.5%, with risk factors including older age and cranial nerve involvement during the acute zoster episode. Cerebral angiitis following zoster has a case-fatality rate as high as 20%. Immunosuppressive therapy for malignancy increases the morbidity and mortality associated with zoster, although the risk for fatal infection is less than 1%.

CLINICAL FEATURES

Varicella

Varicella follows an incubation period that ranges from 10 to 21 days. Prodromal symptoms of fever, malaise, headache, and abdominal pain often precede the appearance of the rash by 24 to 48 hours. Fever, irritability, lethargy, and anorexia are prominent during the 24 to 72 hours after the first cutaneous lesions are noted; respiratory symptoms and vomiting are unusual. Body temperature usually rises to less than 101.5°F but can be as high as 106°F. The varicella exanthem typically begins on the scalp, face, or trunk. The cutaneous lesions consist of erythematous macules that evolve within several hours to form a clear, fluid-filled vesicle surrounded by an irregular erythema margin, the classic “dew drop on a rose petal” (Fig. 13.1). Lesions in the maculopapular or vesicular stages are usually pruritic. After 24 to 48 hours, the vesicular fluid becomes turbid and crusting begins. Later crops of lesions form on the trunk and extremities and can resolve without progressing to form vesicles. Lesions of the mucous membranes of the oropharynx, conjunctivae, and vagina are common. In the final phase, the crusted lesions are sloughed as new epithelial cells are generated at the lesion site. Varicella vesicles are common on eyelids and conjunctivae, but eye disease is unusual.

New varicella lesions emerge for 3 to 6 days, with the total number of lesions ranging from less than 10 to 2,000; most children have fewer than 300 lesions. True subclinical varicella is rare.[357] Children who develop varicella after household exposure to an index case are more likely to have more severe varicella, presumably due to a higher inoculum.[102,357] Skin damage such as eczema or sunburn exacerbates the severity of the exanthem. Hypopigmentation of the skin at sites of varicella lesions often persists for weeks, but extensive scarring is unusual. Low polymorphonuclear leukocyte and lymphocyte counts during the first 72 hours of rash are followed by lymphocytosis[45]; slight elevations of liver function tests are common.

Staphylococcus aureus and *Streptococcus pyogenes* (group A *β*-hemolytic streptococcus) cause secondary bacterial infection of skin lesions, cellulitis, bacterial lymphadenitis, or

subcutaneous abscesses[45,88,115,328] (e-Fig. 13.5). Varicella gangrenosa, a form of necrotizing fasciitis, is a life-threatening infection usually caused by *S. pyogenes.*[494] Bacteremia, usually caused by *S. aureus* or *S. pyogenes*, can lead to acute bacterial sepsis or focal infection such as pneumonia, arthritis, or osteomyelitis.

Varicella pneumonia in otherwise healthy adults presents with fever, cough, tachypnea, and dyspnea beginning about 3 days (range 1 to 6 days) after the onset of rash and may be associated with cyanosis, pleuritic chest pain, or hemoptysis (e-Fig. 13.6). Varicella pneumonia is often transient, resolving completely within 24 to 72 hours, but interstitial pneumonitis with severe hypoxemia progresses rapidly to cause respiratory failure in severe cases.[275] Varicella pneumonia is associated with active infection of the epithelial cells of the pulmonary alveoli. Infection induces mononuclear cell infiltration of the alveolar septa and edema of alveolar septal cells, along with the accumulation of exudate, formation of hyaline membranes, and cellular desquamation into the alveolar spaces, which inhibit oxygen transfer. Desquamated cells in the alveoli and bronchiolar epithelial cells contain eosinophilic intranuclear inclusions and virions. Fatal varicella pneumonia is more common in smokers and is characterized by focal necrosis.

Varicella hepatitis, a rare complication, is associated with extensive replication in the liver, lysis of hepatocytes, and inflammation. Aspirin is contraindicated in children with varicella because it predisposes to liver damage (Reye syndrome).

Varicella encephalitis or cerebellar ataxia usually occurs within 2 to 8 days.[183,253,378,432] Patients with encephalitis typically have sudden onset of seizures and altered sensorium, whereas those with cerebellar disease show irritability, nystagmus, and gait and speech disturbances. Some patients have fever, headache, and meningismus only, without altered consciousness or seizures. The cerebrospinal fluid (CSF) usually shows a mild lymphocytic pleocytosis (<100 cells/mm^3) and a slight-to-moderate protein level (<200 mg) with normal glucose. Encephalitic symptoms usually resolve rapidly (within 24 to 72 hours); ataxia can persist for days to weeks. A few cases of optic neuritis, transverse myelitis, and Guillain-Barré syndrome have been associated with varicella.[183]

Varicella encephalitis is observed most often in immunocompromised patients who have persistent viremia, suggesting a role for direct viral invasion of CNS tissue in some cases. The histopathology of brain tissue from rare cases of fatal varicella encephalitis demonstrates vasculitis of large and small vessels, demyelination, axonal damage, perivascular infiltration with mononuclear cells, microglial proliferation, and neuronal degeneration; however, histologic abnormalities are often minimal. Recovery is associated with astrocytosis surrounding affected areas.[50] In other cases, varicella-related neurologic syndromes resolve rapidly and completely, which may indicate a predominantly inflammatory or immune-mediated pathogenesis. The observation that cerebellar ataxia and encephalitis can occur during the pre-eruptive phase of varicella may indicate early transfer of VZV to neural tissues, triggering local inflammatory responses.[432] CNS disease may also result from ischemic arteriopathies; one-third of these cases in children are associated with varicella.[40]

Acute thrombocytopenia is a complication of varicella that causes petechiae and purpuric skin lesions, hemorrhage into the varicella vesicles, epistaxis, hematuria, and gastrointestinal bleeding. Hemorrhagic complications are usually transient. Purpura fulminans, caused by arterial thrombosis and hemorrhagic gangrene, is a rare but life-threatening complication. Thrombocytopenia may occur from 1 to 2 weeks or longer after varicella, as a result of direct

infection of bone marrow megakaryocytes or immune-mediated processes. Platelet survival may also be reduced as a result of endothelial cell damage caused by vasculitis or transient hypersplenism, or as part of the syndrome of intravascular coagulopathy. As a postinfectious complication, thrombocytopenia may be associated with increased production but shortened platelet survival due to antiplatelet antibodies.

Varicella nephritis causes hematuria, proteinuria, diffuse edema, and decreased renal function, with or without hypertension. A few cases of nephrotic syndrome and hemolytic-uremic syndrome have been reported in children with varicella. Varicella arthritis is rare; it resolves spontaneously within 3 to 5 days with no residual joint disease. Other unusual complications of varicella include myocarditis, pericarditis, pancreatitis, and orchitis. Adrenal infection, characterized by focal necrosis, is common in fatal disseminated varicella. Renal pathology can occur, with hypercellularity of the glomeruli, epithelial proliferation, focal necrosis, and interstitial inflammation.

Varicella in High-Risk Populations

Varicella vesicles in immunocompromised children are usually larger and more numerous, and new lesion formation often continues for at least 7 days, with an average time to lesion crusting of 14 days. In one series, all of the deaths from varicella in children with leukemia occurred within 3 days after the diagnosis of varicella pneumonia.[114] Varicella hepatitis and thrombocytopenia lead to coagulopathy; hemorrhage into lesions is a sign of severe varicella, as is severe abdominal or back pain. Encephalitis is rarely the immediate cause of death. Disseminated VZV infection in children with cancer has also produced myocarditis, nephritis, pancreatitis, necrotizing splenitis, esophagitis, and enterocolitis. Neutropenia enhances susceptibility to secondary bacterial infections. Children who acquire varicella after organ transplantation are also at risk for progressive VZV infection. Children on long-term, low-dose steroid therapy for asthma are not usually at risk for serious varicella, but fatal varicella has been described in patients receiving higher doses of prednisone during the incubation period.

Untreated varicella can be fatal in children with SCID or T-cell disorders, including adenosine deaminase or nucleoside phosphorylase deficiency and cartilage hair hypoplasia and NK cell deficiencies.[113] Varicella can also be severe in children with Wiskott-Aldrich syndrome, ataxia telangiectasia, and other primary immunodeficiencies. Children with HIV infection may have unusual hyperkeratotic lesions and new lesion formation for weeks or months.[96,143]

Placental infection with chronic villitis has been described after maternal varicella in pregnancy. VZV can be transmitted to the fetus and, in rare instances, causes congenital varicella syndrome (e-Fig. 13.7). Infants with congenital varicella syndrome have unusual cutaneous defects, with cicatricial skin scars, atrophy of an extremity, microcephaly, seizures, mental retardation, intrauterine growth retardation, and other sequelae, including chorioretinitis, microophthalmia, and cataracts.[108] Varicella embryopathy exemplifies the consequences of VZV infection of spinal ganglion cells and damage to the developing autonomic nervous system. Severe microcephaly with cortical atrophy and calcification follows intrauterine encephalitis and necrosis of brain parenchyma.

Infants acquire varicella in the newborn period due to maternal varicella. Those whose lesions are present at birth or within the first 5 days of life are not at risk for dissemination, probably because of transplacental transfer of maternal IgG antibodies to VZV. Those who are

born within 4 days before, or 2 days after, the onset of maternal varicella may develop progressive varicella with hepatitis, pneumonia, and coagulopathy.

Zoster

Zoster is characterized by pain and a vesicular eruption on an erythematous base in one or several dermatomes (Fig. 13.1 and e-Fig.13.4). Rash and pain usually develop within a few days of each other, although pain may precede the rash by 7 days or longer. The initial cutaneous lesions often appear in groups at one or several sites anteriorly and posteriorly within each affected dermatome; discrete vesicles resembling varicella lesions may merge to form larger, fluid-filled lesions as the exanthem evolves. Skin lesions resolve within 1 to 2 weeks, while complete cessation of pain usually takes 4 to 6 weeks. A few disseminated cutaneous lesions occasionally accompany the localized dermatomal infection even in the normal host, and VZV DNA may persist in peripheral blood up to 6 months after resolution of zoster.[344] Many patients with uncomplicated zoster have a CSF pleocytosis and elevated protein. VZV can be isolated from CSF and detected by PCR.[63,146] VZV reactivation in the immunocompromised host often causes a more extensive dermatomal rash and cell-associated viremia, which allows VZV dissemination to lungs, liver, CNS, and other organs. Dissemination can occur without rash, suggesting that T cells can become infected while trafficking through the infected ganglia. Patients with HIV infection may have chronic hyperkeratotic skin lesions (e-Fig. 13.8). Antibody-based therapies for immune-mediated diseases such as multiple sclerosis may increase risks of VZV infection.[469] Second episodes of zoster may occur, as documented in five zoster vaccine study participants from whom the same VZV strain was recovered at intervals of 12 to 28 months between reactivations.[150]

Because VZV becomes latent in any ganglion, zoster can develop in any dermatome. The trunk from T3 to L2, which is innervated by twelve pairs of ganglia, is the most frequently involved (e-Table 13.1), followed by the face and the extremities. The face, which is the second most common site, is supplied by afferent fibers only from the two trigeminal ganglia; these are the most frequently latently infected ganglia,[299] as is the case for HSV-1. In the classic study by Hope-Simpson,[166] about half of the cases involve the thoracic dermatomes, particularly T5 to T12. Lumbosacral dermatome disease was observed in 16% of these patients, predominantly in the L1 to L2 distribution. HSV reactivations occur in this region but are patchy rather than dermatomal (e-Fig. 13.4).

Zoster affects the head in approximately 19% of cases, with 97% in the trigeminal distribution.[166] In patients with trigeminal zoster, the ophthalmic division of the fifth nerve is most frequently affected (e-Fig. 13.9). The seventh cranial nerve ganglion is the next most commonly affected. Weakness of facial muscles is usually associated with lesions in the ear (Ramsay Hunt syndrome; geniculate zoster). Commonly associated with geniculate zoster are eighth-nerve deficit, fifth-nerve zoster or zoster of the occiput and neck,[223] ophthalmoplegia, and multiple lower cranial nerve palsies. Importantly, multiple forms of VZV reactivation in a trigeminal and facial distribution as well as polyneuritis cranialis may occur in the absence of rash.

PHN, the most common neurologic complication of zoster, is often defined clinically as pain that persists for at least 3 months after resolution of zoster rash.[447] Age is the most important factor in predicting the development of PHN. Genetic factors may play a role.[273] Pain is usually

constant, severe, stabbing or burning, and frequently associated with allodynia (increased sensitivity to light touch). The incidence of PHN appears to be slightly higher in women[167] and after zoster involving the trigeminal ganglia. VZV reactivation can also produce chronic radicular pain without rash (zoster sine herpete) as well as other zoster-related neurologic and ocular disorders in the absence of rash.

Zoster paresis (weakness) is manifest by arm weakness, which may extend to the brachial plexus, or diaphragmatic paralysis after cervical distribution zoster, by leg weakness after lumbar or sacral distribution zoster, and by urinary retention after sacral distribution zoster. Magnetic resonance imaging (MRI) reveals involvement not only of the posterior horn and posterior roots but also of the anterior roots and anterior horn at the spinal level corresponding to the clinical deficit. The prognosis of zoster paresis varies, with near-complete recovery in the majority of cases.

VZV reactivation may also present as meningitis or meningoencephalitis. Encephalitis was associated with VZV infection and extensive fusion of astrocytes and astrocyte gliosis in the recovery phase. Many reported cases of VZV encephalitis may actually be VZV vasculopathy. Reports of VZV meningitis, meningoradiculitis, and cerebellitis (gait ataxia and tremor predominated), all in the absence of rash and confirmed by the detection of VZV DNA or anti-VZV antibody in CSF, reveal that VZV is not an uncommon cause of aseptic meningitis. CNS infections in adults have been associated with genetic disorders of DNA sensing due to mutations in the RNA polymerase III gene.[55]

VZV produces several ocular disorders, including both acute retinal necrosis (ARN) and progressive outer retinal necrosis (PORN)[192] (e-Fig. 13.10). ARN patients have periorbital pain and floaters with hazy vision and loss of peripheral vision. PORN presents with sudden painless loss of vision, floaters, and constricted visual fields with resultant retinal detachment. Diffuse retinal hemorrhages and whitening with macular involvement bilaterally are characteristic findings (e-Fig. 13.10). Although PORN can also be caused by HSV and cytomegalovirus, most cases in AIDS and other immunocompromised patients are due to VZV. PORN may be preceded by retrobulbar optic neuritis and aseptic meningitis, central retinal artery occlusion, or ophthalmic-distribution zoster and may occur together with multifocal vasculopathy or myelitis. Optic neuritis after zoster may be bilateral. Reports of visual loss in association with pain on eye movement and clinical findings of papillitis and central scotomata or optic atrophy weeks after VZV infection suggest an immunologic pathogenesis in some cases. The third nerve is affected more frequently than the sixth as a cause of zoster ophthalmoplegia. Combinations of third, fourth, and sixth nerve palsies are not unusual. Like optic neuritis, ophthalmoplegia may appear weeks to months after cutaneous signs.

VZV infection of cerebral arteries (VZV vasculopathy) is a serious complication of VZV reactivation, which causes both ischemic and hemorrhagic stroke.[297] In adults with zoster, the risk of stroke was increased by 30% within the following year[193] and 4.5-fold when zoster was in the ophthalmic distribution of the trigeminal nerve. VZV vasculopathy can present as headache, mental status changes, and focal neurologic deficits. Lesions at gray-white matter junctions are seen on brain imaging (e-Fig. 13.10). In more than two-thirds of patients, angiography reveals focal arterial stenosis and occlusion, aneurysm, or hemorrhage. Angiography showed involvement of both large and small arteries in 50% of 23 cases, small arteries in 37%, and large arteries alone in only 13%. Deep white matter lesions often predominate and are ischemic or demyelinating (e-Fig. 13.10). Vascular pathology ranges from neointimal proliferation to

necrosis with and without inflammation. Infected cerebral arteries contain multinucleated giant cells, Cowdry A inclusion bodies, herpesvirus particles detected by electron microscopy, as well as VZV DNA and viral proteins. Reactivated VZV may also travel along ganglionic afferent fibers to the adventitia of cerebral arteries. Elements of VZV vasculopathy that may contribute to stroke include a thickened arterial intima composed of myofibroblasts and cells of medial smooth muscle origin, a disrupted internal elastic lamina, and decreased numbers of smooth muscle cells.[297] Most recently, VZV has been associated with vasculopathy involving extracranial arteries, including some cases of giant cell arteritis (GCA) of the temporal arteries based on VZV antigen detection and VZV DNA by PCR in biopsy tissues.[130,300] When VZV is detected, GCA is attributed to axonal transport of the virus to infect the adventitia, associated with the formation of multinucleated giant cells, transmural inflammation, and medial smooth muscle damage. Nevertheless, VZV protein expression has not been detected in other biopsy studies,[386,425] indicating that GCA has other etiologies.

VZV myelopathy, also called postinfectious myelitis, usually presents days to weeks after zoster as a self-limiting, monophasic spastic paraparesis, with or without sensory features and loss of sphincter function. The CSF usually contains a mild mononuclear pleocytosis, with a normal or slightly elevated protein. Rarely, VZV myelitis recurs. VZV myelopathy may also be an insidious, progressive, and sometimes fatal myelitis, usually in immunocompromised individuals, especially those with AIDS. MRI reveals longitudinal serpiginous enhancing lesions (e-Fig. 13.10). Pathologic and virologic analyses of the spinal cord from fatal cases have shown VZV invasion of the parenchyma and spread to adjacent nerve roots. Importantly, VZV myelitis may develop without rash. VZV-induced vasculopathy can also produce spinal cord infarction.

Zoster sine herpete is chronic radicular pain without rash, which has been virologically confirmed by detection of VZV DNA in CSF,[128] by detection of VZV DNA in blood mononuclear cells (MNCs) and anti-VZV IgG antibody in CSF, or by reduced serum/CSF ratios of anti-VZV IgG indicative of intrathecal synthesis.[35] Persistent radicular pain without rash was caused by a chronic active VZV ganglionitis of the trigeminal ganglion (e-Fig. 13.10). PORN severe unremitting eye pain, third cranial nerve palsies, retinal periphlebitis, uveitis, iridocyclitis, and disciform keratitis can occur without a zoster rash.

DIAGNOSIS

Differential Diagnosis

Varicella must be differentiated from vesicular rashes caused by enteroviruses or *S. aureus*, scabies, drug reactions, contact dermatitis, or, rarely, rickettsial pox or disseminated HSV infection. The clinical diagnosis of zoster can be difficult when acute pain and paresthesias precede the cutaneous eruption; the pain can be sufficiently severe to mimic myocardial infarction, cholecystitis, appendicitis, and other conditions. Localized contact dermatitis is the most common alternative etiology. A recurrent vesicular rash in lumbosacral dermatomes is usually HSV infection.

Laboratory Diagnosis

Laboratory techniques are most useful to guide decisions about antiviral treatment for VZV infection, especially for high-risk patients and for the differential diagnosis of neurologic disorders. The most sensitive method to identify VZV in any tissue is detection of viral DNA by PCR, although PCR may have false-positive results[241]; VZV proteins can be identified by immunohistochemical analysis of cells from cutaneous lesions prior to crusting. Infectious virus can be isolated from lesion specimens in tissue culture but cultures are often negative, especially if the specimen is not processed rapidly or the lesions are later stage. Assays for VZV IgG antibodies are most useful for determining the immune status of individuals whose clinical history of varicella is equivocal. The fluorescent-antibody membrane antigen assay (FAMA) is the most sensitive and specific method and the only method documented to predict susceptibility but is only available in research labs. Most commercial enzyme immunoassay methods have high specificity, generating few false-positive results, but 10% to 15% of immune individuals may be misidentified as susceptible. These commercial assays often do not detect antibody in recipients of the varicella vaccine, even though they have a protective immune response. Commercial VZV IgM antibody assays often lack specificity and should not be used as the only evidence of VZV-related disease.

If VZV is considered a potential cause of a neurologic disorder without rash, CSF and blood MNCs should be tested for VZV DNA by PCR and CSF for anti-VZV antibody.[131] VZV DNA is most likely to be found in patients with acute meningoencephalitis and cerebellitis and in some patients with VZV vasculopathy and myelitis. VZV vasculopathy is difficult to diagnose because many patients do not have a preceding zoster rash or CSF pleocytosis; VZV DNA PCR analysis of CSF is only 30% sensitive. Intrathecal synthesis of anti-VZV IgG antibodies is considered superior to CSF PCR for diagnosis of VZV vasculopathy, recurrent VZV myelopathy, and zoster sine herpete.

TREATMENT

While human leukocyte interferon and vidarabine were the first antiviral treatments with clinical benefit,[14,271] acyclovir and related nucleoside analog prodrugs are more effective and safer for treating both varicella and zoster.[24,33,104,123,222,250,271,418,465] Valacyclovir is a valine ester derivative of acyclovir that is de-esterified by hepatic enzymes to yield acyclovir. Famciclovir is a diacetyl derivative of penciclovir, a guanosine analog, which is enzymatically converted to penciclovir by intestinal and hepatic enzymes. These prodrugs are better absorbed from the gastrointestinal tract, allowing higher serum levels of drug after oral administration.

Molecular proof of the pivotal role of the VZV TK in the action of acyclovir and penciclovir has come from both the cloning and stable expression of the gene in TK-deficient cells and from sequencing of the VZV gene in acyclovir-resistant viral mutants.[373] Missense mutations in the TK ATP– or nucleoside-binding sites, and mutations clustered between these two sites confer acyclovir resistance. Mutations leading to expression of truncated VZV TK protein also result in drug-resistant viruses. Rarely, acyclovir resistance can be conferred by mutations in the VZV DNA polymerase. VZV strains that are resistant to both acyclovir and penciclovir retain

sensitivity to the pyrophosphate analog, foscarnet. Cidofovir, an acyclic nucleoside phosphonate, is also active against acyclovir-resistant VZV strains and is an alternative to foscarnet.

Sorivudine (1-β-D-arabinofuranosyl-E-[2-bromo-vinyl]uracil) is an oral drug with potent *in vitro* activity against VZV and is effective *in vivo* in healthy adults with varicella and HIV-infected patients with zoster, but it is not licensed in the United States because of toxicity resulting from interaction with 5-fluorouracil.[36,134] However, the marginal benefit of this drug over acyclovir in HIV-infected patients with zoster suggests that early administration is more important than potency of the antiviral drug. Whereas all of the licensed antiviral drugs that inhibit VZV replication act on the viral DNA polymerase, other as yet unapproved compounds have different targets. A thiourea compound inhibits VZV by interfering with VZV ORF54 portal protein and encapsidation of viral DNA.[426] Roscovitine, an inhibitor of CDKs, also inhibits VZV replication in cultured cells.[410] Brincidofovir, the prodrug of cidofovir, has activity against acyclovir-resistant VZV.[295] New agents that target host cell proteins and restrict VZV replication *in vitro* and in human tissue xenografts have also been identified.[359]

Varicella

Early acyclovir therapy prevents progressive varicella and visceral dissemination by ensuring that cell-associated viremia is terminated, even if the host response is impaired. In addition, early therapy minimizes cutaneous disease and may therefore reduce the risk of secondary bacterial infections. Immunocompromised patients who have pneumonia, hepatitis, thrombocytopenia, or encephalitis, and adults with varicella pneumonia including pregnant women, require immediate treatment with intravenous acyclovir. Oral acyclovir ameliorates varicella in healthy children, adolescents, and adults when administered within 24 hours after the appearance of the initial cutaneous lesions.[8,102] Acyclovir therapy does not prevent the host from mounting an effective immune response to VZV, consistent with the concept that limited viral replication provides sufficient antigenic stimulation to induce VZV memory immunity.

Zoster

Acyclovir and the related drugs are beneficial therapies for zoster in healthy and immunocompromised patients. Among healthy individuals, treatment initiated within 72 hours reduces the period of continued new lesions in the involved dermatome and the time to complete healing. Antiviral treatment is especially important in immunocompromised patients because of their risk of disseminated disease and for adults with ophthalmic zoster because of their risk for developing acute uveitis and chronic keratitis. Acute neuropathic pain is reduced by early treatment with acyclovir, valacyclovir, or famciclovir; these drugs do not affect PHN. The benefits of antiviral therapy for acute rather than chronic pain suggest that different mechanisms may contribute to these two components of zoster-related pain.

Acyclovir is usually given intravenously to immunocompromised patients who are at high risk for disseminated zoster; less severely immunocompromised patients are given oral valacyclovir or famciclovir. Treatment reduces the duration of new lesion formation, acute pain, and time to complete healing; some benefit is observed even when therapy is delayed for more than 72 hours in persons still developing new lesions.[24,465] Relapse of zoster occurs in some immunocompromised patients despite antiviral treatment[177] although most respond to a second

course of acyclovir, indicating that relapse usually reflects an inadequate host response rather than antiviral resistance.[177]

While not life-threatening, PHN is disabling and difficult to treat. Neuroleptic drugs and various analgesics are used to alleviate pain, but no universally accepted treatment exists. Drugs include gabapentin; pregabalin; tricyclic antidepressants such as amitriptyline, nortriptyline, maprotiline, and desipramine; and levorphanol, topical lidocaine, and rarely opiates.[184]

Patients with VZV vasculopathy can be treated with intravenous acyclovir and prednisone. Steroids are also used to treat patients with myelopathy, although some improve spontaneously. PORN is treated with intravenous acyclovir and steroids followed by oral acyclovir, or with intravitreal injections of foscarnet and oral acyclovir. Retinopathy may persist or recur despite acyclovir treatment.

PREVENTION

In most circumstances, preventing VZV transmission to susceptible individuals is difficult because patients with varicella may be contagious for 24 to 48 hours before the onset of their rash. Infection control practices, including caring for infected patients in isolation rooms with filtered air systems, are essential in hospitals that treat patients for whom varicella might be life-threatening.[145,372]

Passive Antibody Prophylaxis

VZV-specific antibodies interfere with the initial phases of VZV replication *in vivo*, as shown by the reduced varicella attack rate in individuals given VZV immunoglobulin prophylaxis shortly after exposure.[357] Passive antibodies may limit replication at initial sites of inoculation or may block or diminish cell-associated viremia or the early phase of VZV infection of epidermal cells. Anti-gH antibodies have neutralizing activity and may be important for this effect, as suggested by the restricted skin infection in SCID mice given anti-gH antibody at the time of VZV inoculation.[429]

VZV antibody prophylaxis is recommended for individuals with risk factors for serious varicella and exposure to a person with acute varicella or zoster.[8,56] Varicella zoster immunoglobulin (VariZIG)[56,101,274] or high-dose intravenous immunoglobulin should be given within 96 hours after exposure[8] although some benefit may occur with later administration.[242] Prophylaxis does not eliminate the possibility of varicella, especially with household exposure,[274] which may require antiviral therapy if the patient is at high risk. Passive antibody administration does not reduce the risk for VZV reactivation or alter the severity of varicella or zoster when given after the onset of illness.[394]

Antiviral Prophylaxis

Acyclovir given during the incubation period following exposure of susceptible individuals to VZV can prevent disease but the benefit of using acyclovir for prophylaxis has not been

compared directly with acyclovir treatment of individuals in whom the varicella rash has just erupted. Daily oral acyclovir for 12 to 24 months can diminish the risk of zoster in bone marrow transplant recipients, but zoster may occur when prophylaxis is discontinued and drug-resistant VZV mutants may emerge. The alternative is prompt initiation of acyclovir for VZV reactivation.

VACCINES AND VACCINE IMMUNITY

Varicella

The live attenuated varicella vaccine is the first human herpesvirus vaccine licensed for clinical use and is recommended for routine vaccination of infants and susceptible older children and adults in the United States.[8,408,422] The vaccine virus was derived from a clinical isolate of VZV, the Oka strain, which was propagated in guinea pig embryo fibroblasts and then in WI38 human fibroblasts. In contrast to the outcome in susceptible children inoculated with infectious VZV from vesicular fluid,[37] tissue culture propagation appears to attenuate the virus so that vaccine containing as much as 17,000 plaque-forming units (pfu) per dose of infectious virus induces immunity to VZV but rarely produces clinical symptoms.[455] Attenuation is achieved even though varicella vaccine stocks contain mixtures of VZV genomes with varying mutations.[93,376] Comparing the parent Oka and vaccine Oka viruses in the SCID mouse model indicated that passage in fibroblasts reduces the ability of the virus to replicate efficiently in human skin, although T-cell tropism and neurotropism are not affected.[281,486] Less than 5% of children develop skin lesions after vaccination with Oka-derived vaccines; however, the vaccine Oka strain of VZV can be transmitted from these individuals.[236,264] (e-Fig. 13.11). Whether the virus remains attenuated after transmission is not known because of the low frequency of secondary cases.

In prelicensure trials, the live attenuated (Oka-Merck strain) vaccine was administered to more than 7,000 children and more than 1,600 healthy, susceptible adults.[232,463] In clinical trials, a single dose of vaccine containing 1,000 to 3,000 pfu of attenuated Oka virus induced seroconversion rates of more than 90% in children 12 years of age and younger and afforded complete protection against disease in about 85% of exposures. On exposure to varicella, some previously vaccinated children experience breakthrough infection, but the resulting disease usually remains mild, with fewer than 50 cutaneous lesions and no fever. Modified disease severity is consistent with priming of the host response by immunization.

The varicella vaccine also induces VZV-specific cellular immunity,[296,452,487] which is likely to be essential for its long-term protective efficacy.[99,384] Varicella immunization elicits T cells that proliferate and produce lymphokines in response to stimulation with the IE62 protein and the viral glycoproteins[19,31] and induces cytotoxic T cells that can lyse cells expressing VZV proteins.[179,384] The VZV-specific T-cell response is detectable within 10 to 14 days in most individuals,[19] whereas IgG antibodies to VZV were detected in only 40% of children tested at 2 weeks. This early T-cell response may account for the efficacy of vaccination when given immediately after exposure.[18] Varicella vaccine is also immunogenic when administered

concurrently with measles–mumps–rubella (MMR) vaccines or as a quadrivalent MMR-V vaccine.[221]

Achieving high VZV IgG seroconversion rates in susceptible adolescents and adults requires two doses of the vaccine administered at an interval of at least 4 weeks,[126,296] consistent with the diminished host response to primary VZV infection and more severe varicella in adults. However, cellular immunity to VZV in adults given two doses of vaccine was significantly lower compared with children who received a single dose of vaccine, and VZV-specific T-cell proliferation correlated with lower IFN-γ responses.[179,296] Adults are also more likely than children to have transient local rash, and waning VZV antibody titers. Nevertheless, immunizing susceptible adults is important to protect against their risk of developing severe varicella.[123]

The persistence of VZV memory immunity after immunization has been difficult to assess because the continued circulation of wild-type VZV may boost vaccine-acquired immunity through exogenous exposure. However, VZV IgG and T-cell responses have been documented in 94% to 100% of varicella vaccine recipients for 7 to 10 years after vaccination, and protection has been sustained in most vaccinees.[126,232,303,423] In postlicensure surveillance done before vaccine coverage rates were high, no change in the frequency of breakthrough varicella or severity of symptoms with time after vaccination was found; however, those with low or undetectable VZV IgG titers 6 weeks after immunization were four times more likely to experience varicella.

Although the incidence of varicella is dramatically lower in all age groups in the United States, the widespread use of the varicella vaccine has meant that as many as half of the cases of varicella in well-vaccinated populations are in immunized children. Because the wild-type virus is transmissible from cases of breakthrough varicella, community outbreaks can be sustained. Prelicensure studies showed that a two-dose regimen induces higher humoral and cellular immune responses in children evaluated just after vaccination and after 1 year.[296,449] The observations of the enhanced host response to two doses, along with the surveillance data on breakthrough infections, have led to the use of a two-dose regimen in children as well as in adolescents and adults.[8] Varicella immunization using a two-dose regimen of MMR-V also enhances the primary immune response to the varicella component.

The Oka-Merck varicella vaccine has been given to children with acute leukemia in remission, reducing the attack rate after household exposure to 13%.[126] Seroconversion in these patients is associated with a high degree of protection after two doses of vaccine. Cell-mediated immunity is elicited less reliably in leukemic children given varicella vaccine, consistent with the often diminished T-cell proliferation to VZV antigens after natural varicella in immunocompromised children. Because it contains infectious virus, varicella vaccine must be given to these children with careful attention to the status of their underlying disease and immunosuppressive therapy regimens. Vaccine-related rashes occurred at about 1 month after immunization in approximately 50% of children with leukemia in remission. Rashes occurred at the site of inoculation but also as widely scattered vesicles, indicating that the vaccine virus remains capable of causing cell-associated viremia. This experience is consistent with retention of vaccine Oka tropism for T cells in the SCID mouse model. In healthy children, the limited replication of the vaccine virus at the site of subcutaneous inoculation likely allows time for induction of adaptive VZV-specific immunity before viremia can occur, whereas vaccine virus may escape from infected epithelial cells into T cells, causing viremia and varicella-like

symptoms in some immunocompromised children. When children with leukemia developed rash, the vaccine virus was transmitted to their healthy, susceptible siblings, but the contacts had mild illness or asymptomatic seroconversion. The vaccine virus was not transmitted unless the immunocompromised child had rash indicating that no significant replication of the vaccine virus occurred at respiratory sites.[416] Detection by PCR of VZV in oropharyngeal secretions from children given varicella vaccine has been reported, but infectious virus has not been recovered. Immunizing susceptible, healthy household contacts of high-risk children may also reduce the risk of household exposure.[98]

Reactivation of the vaccine strain of VZV has been described in healthy vaccine recipients; however, analysis of the incidence of zoster in leukemic children who had vaccine-induced immunity and in those with past natural infection showed that the vaccine virus reactivated significantly less often than wild-type VZV.[151] Whether this observation indicates that the vaccine virus is less likely to establish latency or has less potential to cause symptomatic reactivation is not known. VZV-specific T-cell responses were higher in leukemic children who had been vaccinated but did not experience recurrent VZV compared with children who developed zoster. Vaccinated individuals can also develop zoster through subclinical infection with wild-type VZV despite vaccine-induced immunity.[149] Information about the prevalence of vaccine or wild-type VZV in neurons after immunization is limited, but VZV was detected by PCR in ganglia from children who died from trauma or nonimmunocompromising conditions.[123] As annual varicella epidemics diminish due to universal childhood vaccination programs, opportunities for superinfection with wild-type VZV will be minimal. If exogenous exposures are important for maintaining memory immunity in individuals with naturally acquired infection, then zoster could become more common in highly vaccinated populations, but accumulating evidence argues against this possible outcome.[152,153,191,470]

Zoster

The development of the varicella vaccine raised the possibility that vaccination might also be effective for reducing the risk of zoster associated with waning immunity in the elderly.[323] A high-potency preparation of the live attenuated VZV vaccine containing about 14-fold more attenuated Oka virus than the varicella vaccine reduced the burden of zoster illness in healthy adults aged 60 years and older,[323] when both incidence and severity of disease were considered together, by 61.1% ($p < 0.001$) over a median follow-up period of 3 years. The incidence of PHN was reduced by 66.5% ($p < 0.001$) and zoster incidence decreased by 51.3% ($p < 0.001$).

Administration of the live attenuated zoster vaccine induced memory B-cell responses composed of IgG and IgA antibody-secreting cells. A majority of antibodies produced were VZV–gE specific. However, the most potent neutralizing antibodies produced were gH specific, complement independent, and restricted cell–cell spread *in vitro* and may be important in controlling viral spread following VZV reactivation.[429] By contrast, most of the gE-specific antibodies did not neutralize, required complement, and could not restrict cell–cell spread.[405] VZV-specific responder cell frequencies increased from 1 per 68,000 to 1 per 40,000 in healthy adults over 55 years of age given the live attenuated vaccine, which was equivalent to the VZV responder cell numbers in naturally immune individuals aged 35 to 40 years.[243] VZV DNA was detected in saliva but transmission has not been reported. Evidence that baseline immunity to VZV and the number of regulatory T cells prior to vaccination can predict the effect of age on

zoster vaccine immunogenicity suggests their importance in modulating responses.[458] Notably, CD4+ T-cell responses to VZV showed enhanced breadth after vaccination[234] and diversification of the VZV-specific T-cell receptor repertoire.[341]

Older individuals given the live attenuated zoster vaccine had diminished CD4+ and CD8+ T-cell responses[456,460]; a second dose boosted the responses.[459] A decline in the immunogenicity of the vaccine was observed in recipients every decade over the age of 50 years. Furthermore, older adults had higher proportions of VZV-specific T cells exhibiting markers of senescence and exhaustion, which may result in reduced effector responses to VZV challenge. Another study of older individuals revealed reduced generation of long-lived memory T-cell responses, which was likely due to reduced T-cell survival after the peak response to zoster vaccination.[342]

To avoid risks associated with infectious virus, a heat-inactivated preparation of varicella vaccine was given to patients receiving autologous bone marrow transplantation; recovery of VZV T-cell immunity was accelerated and zoster was less common in vaccinated transplant recipients as compared with unvaccinated controls.[155,350] The efficacy of peritransplantation vaccination of these patients with inactivated VZV vaccine was later demonstrated in placebo-controlled studies, indicating that their immunocompromised status does not block vaccine-induced immunity effective against zoster.[294,468]

Most recently, a zoster vaccine consisting of recombinant glycoprotein E with the ASO1 adjuvant had an even greater impact on clinical illness due to VZV reactivation than the live attenuated zoster vaccine, showed equivalent efficacy across all older age groups, and is now preferred for zoster prevention[57,87,235,325] (e-Fig. 13.10). Compared to the live attenuated vaccine, the recombinant gE vaccine induced a marked increase in gE-specific CD4+ T-cell frequencies and showed no age-related differences in numbers of responder T cells or cytokine production.[342] T-cell responses were higher to either vaccine in recipients when baseline responses were higher and VZV-specific IFN-γ and IL-2/IFN-γ dual positive CD4+ T-cell frequencies were equivalent, but the gE recombinant vaccine elicited higher IL-2 CD4+ T-cell frequencies as well as higher gE-specific T-cell responses.[457] These differences in immunogenicity may account for its enhanced efficacy regardless of age and the longer duration of protection compared to the live attenuated vaccine. This gE subunit vaccine is also safe for administration, immunogenic, and protective against zoster in immunocompromised patients.[88]

PERSPECTIVE

Advanced sequencing to understand the molecular evolution of the VZV genome, the capacity to map functional domains of viral proteins using structure-based discovery and targeted mutagenesis of the VZV genome, single-cell proteomics to probe VZV–host cell interactions, and use of state-of-the-art methods to document innate and adaptive immune responses in VZV-infected tissues have generated many new insights over the past decade. New approaches to probing the mechanisms by which VZV achieves tropism for human lymphocytes and myeloid lineage cells, skin epithelial and dermal cells, and neuronal cell subtypes will not only advance the understanding of the interplay of VZV with host cells but will also guide studies of other alpha herpesviruses in the human cell context. Notably, our knowledge of the complexities of

VZV latency and reactivation as well as the molecular mechanisms underpinning postherpetic neuralgia remains limited. These and other questions about VZV pathogenesis will require multiparameter systems biology tools, since the processes involve many overlapping modifications of the host cell, rather than representing a single “mechanism.” While exceptional progress has been made with the licensure of antiviral therapies and vaccines to prevent VZV infections, more cost-effective interventions are needed to reduce the global burden of VZV disease.

ACKNOWLEDGMENTS

The authors and editors wish to acknowledge the invaluable contributions of the late Don Gilden to the field of VZV research and clinical care and to this chapter in the previous edition of Fields Virology.

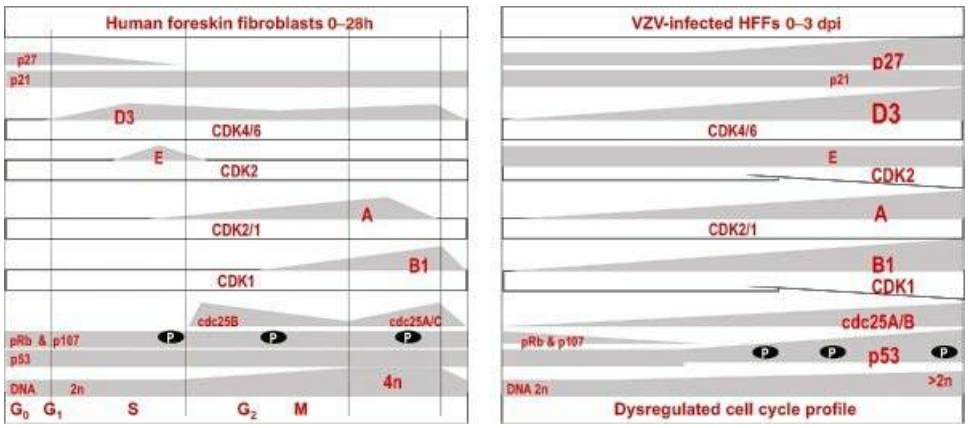
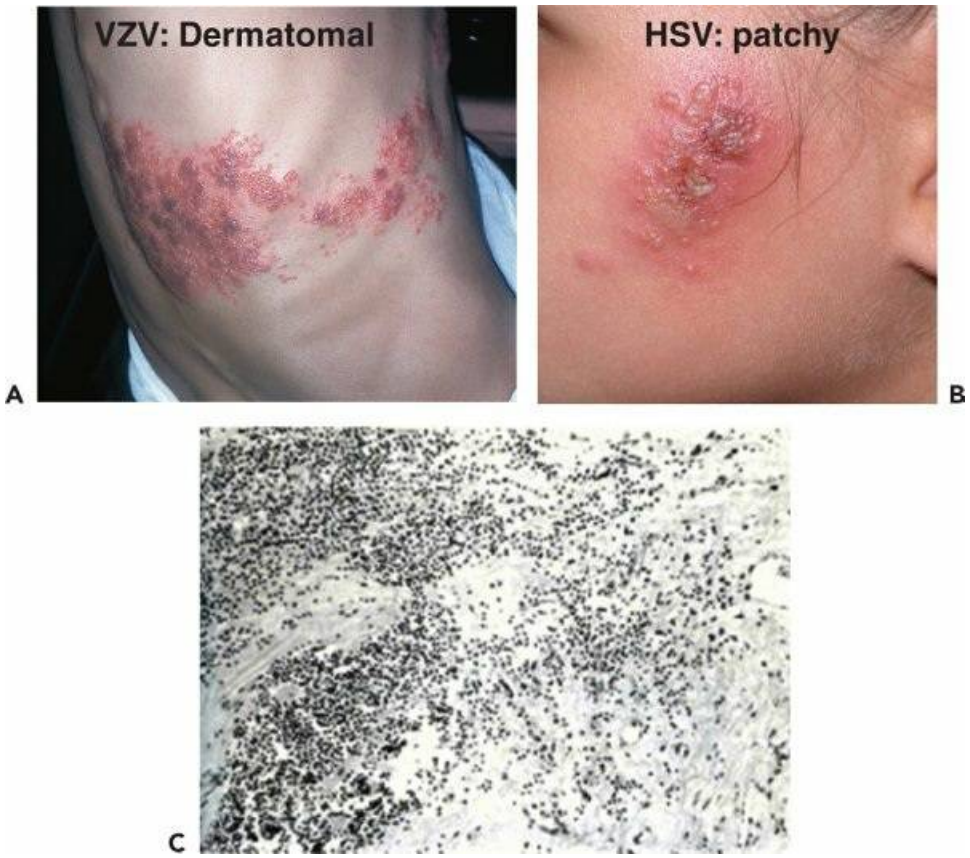
CHAPTER 13



Varicella–Zoster Virus

e-FIGURE 13.1 Model for synergistic activation by IE62, Mediator, and cellular transcriptional activators. IE62 and a cellular factor that binds to a specific upstream site (illustrated here by Sp1) recruit Mediator to promoters. High levels of promoter activation result from the recruitment of Mediator and its stabilization at the promoter by both IE62 and Sp1. IE62 interacts with DNA (*solid line*), MED25, TBP/TFIID, and the general transcription factor TFIIB (not shown). The *dashed line* indicates the potential direct interaction between IE62 and Sp1. Because IE62 does not require a specific binding site, it could position itself along the DNA and interact with activators whose sites could be variably placed relative to the TATA box. (From Ruyechan WT. Roles of cellular transcription factors in VZV replication. *Curr Top Microbiol Immunol* 2010;342:43–65, with permission.)



e-FIGURE 13.2 Extensive expression of glycoprotein C in a human skin vesicle not seen in cultured cells. Detection of abundant VZV gC within a biopsy of a human zoster vesicle. A section of a vesicle biopsy was immunolabeled with mouse anti-gC monoclonal antibody linked with the Alexa 488 fluorescent antibody and imaged by confocal microscopy. (Adapted from Grose C, Carpenter JE, Jackson W, et al. Overview of varicella-zoster virus glycoproteins gC, gH and gL. *Curr Top Microbiol Immunol* 2010;342:113–128, with permission.)

e-FIGURE 13.3 Cell cycle profiles of normal and VZV-infected human foreskin fibroblasts (HFFs). Cell cycle regulatory proteins and DNA synthesis are shown as *shaded boxes*; CDKs are *open boxes*. Their relative abundance is indicated by the area and font size. *P* in a *black circle* denotes phosphorylation. Quiescent HFFs are in G0 phase and express basal levels of CKI proteins p27 and p21, which bind to cyclins and suppress their activity. When stimulated to enter the cell cycle, p27 levels drop and cyclin D3 levels rise, leading to increased CDK4 and CDK6 activity. CDK4/6 phosphorylate pRb and p107, enabling cyclin E expression that causes a burst of

CDK2 activity to drive cells into S phase. Increased levels of cdc25B and cyclin A in S phase activate first CDK2–cyclin A and then CDK1–cyclin A. Cyclin B accumulates in S phase and complexes with CDK1, but peak activity occurs in late G2 phase when cdc25A and cdc25C remove inhibitory phosphates on CDK1. The pocket proteins pRb and p107 continue to be phosphorylated during the entire cell cycle, p53 is inactive unless activated by checkpoint control proteins, and DNA synthesis proceeds to reach 4n by the end of S phase. In contrast to normal HFFs, VZV-infected cells have a dysregulated cell cycle profile. The levels of p27, cyclin D3, cyclin A, cyclin B1, cdc25A, cdc25B, and phospho-p53 are elevated. Levels of CDK1 and CDK2 are approximately threefold greater than in uninfected cells, corresponding with high kinase activity. Levels of p21 remain constant, while elevated cyclin E levels persist longer than expected. The pocket proteins are undetectable and the amount of DNA is slightly greater than 2n. The dysregulated cell cycle profile in VZV-infected HFFs most closely resembles arrested G2 phase, although the abundance of p27 and absence of cdc25C are atypical. (From Moffat JF, Greenblatt RJ. Effects of varicella-zoster virus on cell cycle regulatory pathways. *Curr Top Microbiol Immunol* 2010;342:67–77, with permission.)

Perspective

HISTORY

A novel herpesvirus was discovered in 1986 in patients with lymphoproliferative disorders.[212] Initially named human B-lymphotropic virus, it was later found mainly to infect and replicate in lymphocytes of the T-cell lineage, and renamed human herpesvirus 6 (HHV-6). Subsequently, based on their sequences and biological properties, HHV-6 strains were classified into two distinct groups, which are now known as human herpesvirus 6A (HHV-6A; species *Human betaherpesvirus 6A*) and human herpesvirus 6B (HHV-6B; species *Human betaherpesvirus 6B*). HHV-6B is the major causative agent of exanthema subitum (ES; also known as roseola)[282]; HHV-6A has been associated with spontaneous abortion and Hashimoto thyroiditis, but the etiologic proof is not yet definitive.

Human herpesvirus 7 (HHV-7; species *Human betaherpesvirus 7*) was isolated in 1990 from

a healthy individual whose T cells were stimulated with antibodies against CD3 and then incubated with interleukin-2 (IL-2).[70] The virus is a second causative agent of ES[240] and has been associated with febrile convulsions in young children.[272] HHV-6B and HHV-7 are ubiquitous, with more than 80% of adults having antibodies to both viruses.[3,4,21,26,45,135,271]

INFECTIOUS AGENT

Classification

HHV-6A, HHV-6B, and HHV-7 share many properties with other herpesviruses, including virion structure, genomic architecture and genetic features, high prevalence in their natural host, and the ability to establish latent infections in the host. Their lytic replication cycles (Fig. 14.1) are generally similar to that for other herpesviruses. They belong to the *Roseolovirus* genus of the betaherpesvirus subfamily, and are characterized by replication in T lymphocytes (although they can also infect other cell types), high prevalence, and association with febrile rash illness. As betaherpesviruses, roseoloviruses are related to cytomegaloviruses (CMV), including having genetically colinear genomes, encoding several subfamily-specific genes, and having protracted replication cycles. Other roseoloviruses have been identified in chimpanzees,[138] mandrills,[137] pigs,[48] and mice,[48,196] and as an endogenous virus in a Philippine tarsier.[14]

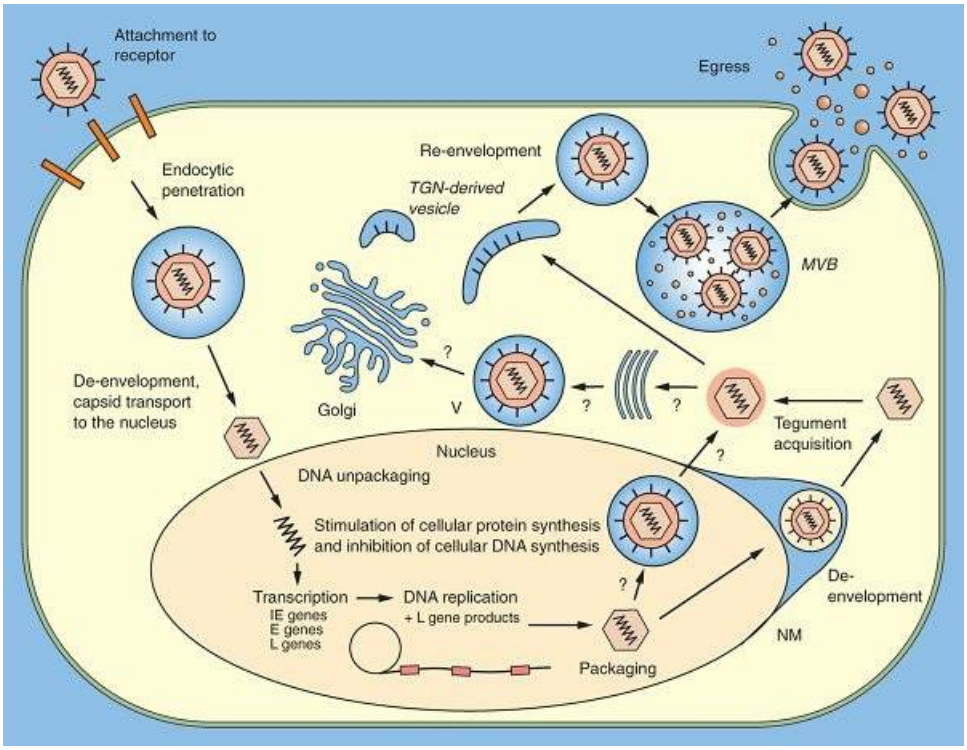

FIGURE 14.1 Stages of replication. A single receptor is shown, although it is likely that the virus employs multiple receptors to enable entry into a wide range of cell

types. AL, annulate lamellae; G, Golgi complex; HS, heparan sulfate; Nu, nucleus; NM, nuclear membrane; R, receptor (CD46 for HHV-6A and HHV-6B, CD4 for HHV-7); V, vacuole, MVB (multivesicular body).

The human roseoloviruses are closely related, yet molecularly and biologically distinct viruses that differ with respect to their genome sequences, cell tropisms, interactions with cells and signaling pathways of the immune system, and epidemiology.[1,4,21,26,52,110,135]

Propagation and *In Vitro* Cell Tropism

HHV-6A and HHV-6B infect a variety of cultured human cells, such as T cells (preferentially mature CD4+), natural killer (NK) cells, *γ/δ* T lymphocytes, primary fetal astrocytes and dendritic cells, olfactory ensheathing cells (HHV-6A but not HHV-6B), and peripheral blood mononuclear cells (PBMC). Cell lines derived from megakaryocytes and glioblastomas, as well as neural, epithelial, and fibroblastic cells can also support limited HHV-6 replication.[26,45] Fresh isolates can be adapted to grow in continuous T-cell lines, such as HSB-2 and J-JHAN for HHV-6A, and Molt-3 and MT-4 for HHV-6B, but the genetic changes required for adaptation have not been characterized.

HHV-6A has a greater capacity than HHV-6B for replication in cultured cells of neuronal origin.[46] In primary astrocytes, HHV-6A establishes a productive lytic infection, whereas HHV-6B produces little cytopathic effect and only small amounts of viral nucleic acids, proteins, or infectious progeny, and establishes a long-term, low-level persistent infection.[53] After the course of 30 days in an oligodendrocyte cell line, HHV-6A transitioned from a lytic state to a quiescent infection that may represent latency (reactivation was not demonstrated), whereas HHV-6B infection was nonproductive and did not persist.[5] In some cultured cells, the HHV-6 genome integrates into a host cell telomere (chromosomally integrated, or ciHHV-6), establishing a quiescent form of persistence that may represent a form of latency.[10]

In contrast, HHV-7 has a narrow *in vitro* cell tropism, thus far being restricted to primary phytohemagglutinin (PHA)-stimulated CD4+ T cells obtained from umbilical cords or PBMC, and an immature continuous T-lymphoblastoid cell line, SupT-1.[21] HHV-6A, HHV-6B, and HHV-7 induce similar cytopathic effects, characterized by ballooning refractile cells (Fig. 14.2).

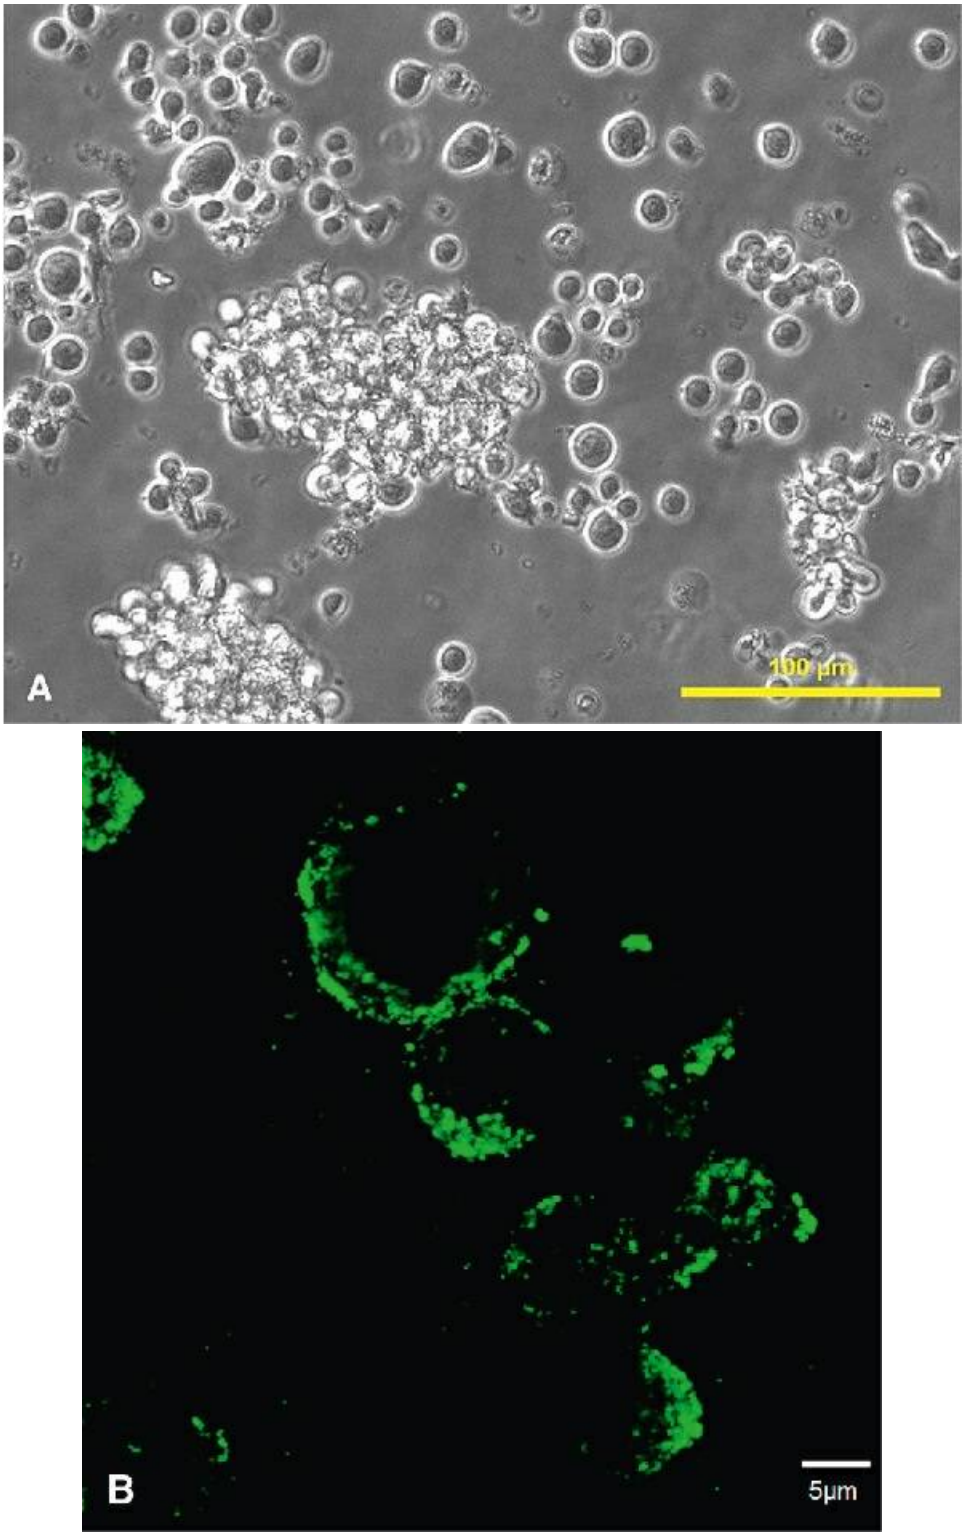

FIGURE 14.2 Cytopathic effects induced in cord blood mononuclear cells (CBMCs) by HHV-6B. A: Balloon-like cells are seen in CBMCs at 1 day post infection. **B:** CMBCs at 3 days post infection were stained by IFA using monoclonal antibody for HHV-6B gB. Similar cytopathic effects and staining are seen for HHV-6A, HHV-6B, and HHV-7.

Virion Structure

Roseoloviruses share the standard features of herpesvirus virions: an icosahedral capsid 90 to 110 nm in diameter that contains the 145-kb (HHV-7) and up to 170-kb (HHV-6B) double-stranded DNA (dsDNA) genome, a tegument that surrounds the capsid, and a lipid bilayer envelope studded with virus-specified membrane proteins and glycoproteins; enveloped extracellular virions are 160 to 200 nm in diameter[19,20,126,287] (Fig. 14.3).

HHV-6B capsids have atomic-level structural properties shared with evolutionary relatives that range from tailed bacteriophage (caudoviruses) to herpesviruses.[298] The HHV-6B pU11 tegument protein is a homolog of human cytomegalovirus (HCMV) pp150/pUL32, which forms a capsid-associated tegument complex (CATC) that appears to strengthen HCMV capsids to enable stable accommodation of the 236 kb HCMV genome, which is nearly 50% longer than the HHV-6B genome. Dimers of pU11 also form CATCs, but their reduced number and the nature of their interaction with the capsid suggest less need for the level of reinforcement provided by the HCMV CATC. By thin-section electron microscopy (EM), HHV-6 teguments are smooth and fill the space between the capsid and envelope, whereas HHV-7 teguments have an electron lucent space between the tegument and envelope. Immunoelectron microscopy revealed that HHV-7 pU14 is present at the outer periphery of the tegument.[232]

Mature HHV-6B virions consist of at least 29 polypeptides, including 6 in the envelope

fraction and cellular p53.[26,239] As described below in the Entry section, envelope glycoproteins include gB, and the gH/gL/gQ1, gH/gL/gQ1/gQ2, and gQ1/gQ2 complexes.

Genome Structure and Organization

Genomic Architecture

As packaged in nucleocapsids, roseolovirus genomes are composed of a central unique segment (U) bracketed by a pair of direct repeat structures, DR_L and DR_R (Fig. 14.4; e-Fig. 14.1; Table 14.1).[52,135,145,161] Some forms of HHV-6 intracellular replicative intermediates do not have duplicated DR segments; the unit form of these concatemeric or circular genomes consists of one copy of the U segment and a single DR.[23] From left to right, HHV-6 DRs consist of 25 to 29 base pairs (bp) of unique sequence, a conserved pac1 (cleavage and packaging) element, an array of heterogeneous telomere-related repeats based on the sequence TA(A/G)(C/G)(C/T)C that span about 300 bp in laboratory-passaged strains and up to 3 kb in low passage viruses, about 7 kb of unique sequence that encodes a handful of genes, an array of telomeric repeat sequences similar to sequences present at the telomeres of vertebrate chromosomes (R-TRS, [TAACCC]n), a conserved pac2 element, and 16 to 18 bp of unique sequence (Fig. 14.4, e-Fig. 14.1, and e-Fig. 14.2). The HHV-7 R-TRS is more heterogeneous than for HHV-6 (e-Fig. 14.2).[210] Despite the differences, HHV-7 cleavage and packaging signals are recognized and processed during HHV-6 infections, and vice versa.[149] Other repeat arrays (R0 to R3) are located in the U segment of each of the viruses[52,80,110,164,182] (Table 14.1 and Fig. 14.4 and e-Fig. 14.1). Compared with other herpesviruses, some of which have G+C contents exceeding 60%, roseoloviruses have relatively low G+C contents (Table 14.1).

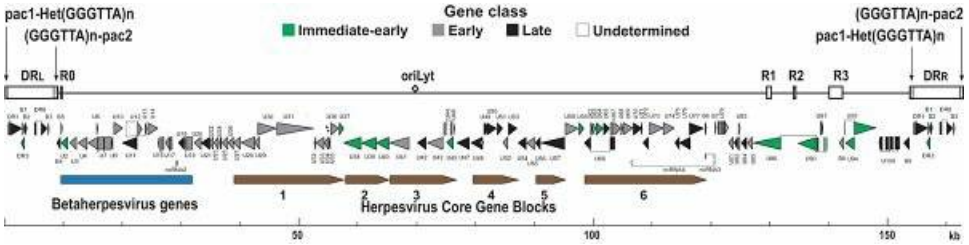

FIGURE 14.4 HHV-6B genomic and genetic architecture. The diagram is based on information from.[37,52,60,80,85,88,110,164,182] The positions and arrangements of the major internal repeat elements, the origin of replication (*oriLyt*), and the structure of the direct repeat (*DR*) termini are shown for frame (ORF) sizes, orientation, and location are indicated. ORF found in HHV-6B and not in HHV-6A are designated with "B" prefixes. Small upstream ORFs are indicated with small triangles at the N-termini of the associated large ORFs. Only a subset of known mRNA splicing events is represented. The orientation and order of the six conserved herpesvirus core gene blocks are indicated, as is the block of genes (U2 to U19) found only in betaherpesviruses.

TABLE 14.1 Properties of roseolovirus genomes

	HHV-6A	HHV-6B	HHV-7
%(G+C)			
DR	58	59	53
U	41	41	34
Overall	43	43	36
Length (kb)			
DR	8	8.1–13	5.8–10
U	143	145	133
Total	159	161–170	145–153
Repeat arrays (copy number and length)			
DR			
L-TRS[a]	42 × 6*h* bp	50 × 6*h* bp	20–663 × 6*h* bp
R-TRS	59 × 6 bp	78 × 6 bp	106–148 × 6*h* bp
R0	NP	13 × 14 bp	NP
R1	51 × 12 bp	54 × 12 bp	NP
R2A (HHV-7 R1)	2 × 17–18 bp	5 × 17–18 bp	2 × 84 bp plus 2 partial 64 bp[b]
R2B	1,233 bp[c]	8 × 12 bp	NP
R3 (HHV-7 R2)	28 × ~105	24–26 × ~104 bp	15–16 × 105 bp

[a]Left-terminal resolution site (L-TRS) and right-terminal resolution site (R-TRS) designate the TRS arrays near the left and right ends of direct repeat (DR), respectively.

[b]In human herpesvirus (HHV)-7(RK), the arrangement is 3 × 84 bp plus 68 bp partial repeat.

[c]HHV-6A R2 is composed of TpG dinucleotide repeats spanning 1,233 bp.

h, heterogeneous versions of repeat element; NP, not present.

Determination and analysis of the complete nucleotide sequence of human herpesvirus 7. *J Virol* 1996;70:5975–5989.

The mammalian telomere-like sequences have no role in nuclear retention of viral DNA, efficiency of DNA replication, or packaging-associated DNA cleavage.[27,47] Like the similar sequences required for integration of Marek disease virus genomes into telomeres of its host cells,[119] these sequences are involved in site-specific integration of HHV-6 genomes into telomeres of host chromosomes during establishment of ciHHV-6. In ciHHV-6,[10] the virus genome is typically linked to the host chromosome with the TRS array at the DR_R end of the genome joined to the chromosomal TRS (with loss of the viral *pac2* sequence) (Fig. 14.5). A TRS is added to the imperfect telomeric repeat present at the distal end of the virus genome (with loss of *pac*1).

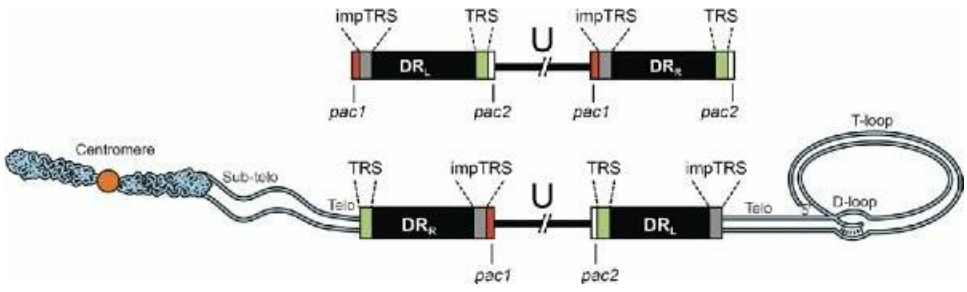

FIGURE 14.5 Structure of HHV-6 genomes when integrated at chromosomal

telomeres.

About 1% of humans inherit ciHHV-6 via their parental germ line,[44,118,198,257] which results in every nucleated cell harboring at least one complete HHV-6A or HHV-6B genome. In most individuals with inherited ciHHV-6 (iciHHV-6), a single chromosome is targeted, but some individuals have iciHHV-6 on chromosomes acquired from both of their parents. Persistent lineages of iciHHV-6A or iciHHV-6B have sporadically emerged in human populations over a period of thousands of years.[13,146,197,251,297] iciHHV-6A and iciHHV-6B genomes have the potential to reactivate to lytic replication with pathogenic potential.[56,277]

Although HHV-7 also has telomeric sequences, its chromosomal integration is much less common; it has not been observed to integrate into the host germ line.[203]

Genetic Structure and Genetic Relationships

Recent application of modern genome sequencing methods, coupled with deep RNA sequencing and proteomics analyses, has had multiple impacts, including more accurate genome sequences, increasing availability of genome sequences from many strains from numerous international sources, and information that demonstrates wide variation in forms and degrees of gene expression. These include pervasive RNA splicing, including over long ranges, as well as the presence of long RNAs that do not have long open reading frames comparable to the canonical protein-coding regions, but in fact abundantly express short proteins.[60,85,88] Some mRNAs that express canonical proteins contain upstream short open reading frames whose translation can modulate translation of the longer downstream ORF.[60] Maximal utility of this new information will be dependent on development of updated annotations that connect to informative sequence feature displays and to canonical literature and gene names.[85]

Protein-coding open reading frames (ORF) are present on both strands of the genome, with little overlap among adjacent ORF (Fig. 14.4 and e-Fig. 14.1). The HHV-7 genome is more compactly arranged than for HHV-6A or HHV-6B, with a similar genetic complement being encoded in a U segment that is 12 kb shorter than for HHV-6A or HHV-6B (Table 14.1). In addition to the repeat arrays, two genomic regions have no long open reading frames with obvious protein coding capacity: the region between U41 and U42 that harbors the origin of lytic DNA replication (oriLyt), and the region between U77 and U79. RNA sequencing and coupled proteomics analyses recently revealed the presence of abundant long RNAs transcribed from these regions, including mRNAs that express small proteins.[60]

Many of the genes encoded in the central portion of roseolovirus genomes are conserved among the alpha-, beta-, and gammaherpesvirus[52,80,135,164,182] (Table 14.2; Fig. 14.4; e-Fig. 14.1; and Chapter 8). A betaherpesvirus-specific gene cluster is located to the left of the core genes. Clusters of genes unique to roseoloviruses flank the core genes.

TABLE 14.2 HHV-6A, HHV-6B, and HHV-7 genes of known or implied functions and their HCMV homologs

Based on information in.[37,52,60,80,85,88,110,164,182] Kinetic class assignments are based on.[85]
HHV, human herpesvirus; HCMV, human cytomegalovirus; ORF, open reading frame; IE, immediate early; E, early; L, late.

Over the conserved domains, roseoloviruses are genetically colinear with CMV, but CMV encode many genes without roseolovirus counterparts. Between HHV-6 and HHV-7, amino acid sequence identities range from 22% to 75%, most being approximately 50%. HHV-6A and HHV-6B have 90% overall nucleotide sequence identity; the 66-kb segment that spans U32 to U77 is highly conserved (95% identity), whereas the 27-kb segment spanning U86 to U100 is only 72% identical.[52]

Intraspecies sequence variation is very low. Across a 120-kb segment spanning HHV-6B genes U2 to R2, pairwise identities were greater than 99.9% across a set that included 61 clinical specimens from Japan, Uganda, and the United States, plus 64 iciHHV-6B specimens from

Seattle[88]; comparable results have been seen for HHV-6A. Other than repeat copy number differences, HHV-7 strains JI and RK differ by only 179 bp (0.1%) over their genomes.

Roseoloviruses differ somewhat from each other in their genetic complement, with several small differences in coding capacity and splicing patterns between HHV-6A and HHV-6B.[60,88] DR3, U6, U22, U83, and U94 are encoded by HHV-6A and HHV-6B, but not HHV-7. HHV-7 encodes a duplicated gene (U55A and U55B) that is encoded as a single copy by HHV-6A and HHV-6B. Relative to HCMV, genes unique to roseoloviruses include U20, U21, U23, U24, U24A, U26, and U100.

Although no amino acid sequence similarity has been identified, the general layout and splicing patterns of two HCMV immediate-early (IE) regions are conserved in the roseoloviruses. Thus, the roseolovirus IE-B domain that spans U17 to U19 corresponds to the HCMV UL36 to U38 IE locus, and the IE-A domain spanning U86 to U90 corresponds to the HCMV major IE locus.[160,182]

Every betaherpesvirus encodes several members of a family of duplicated and diverged genes that are related to HCMV US22 and are referred to as the US22 gene family.[182] For HCMV, some US22 family members are transcribed as IE genes and encode transactivating functions. In the roseoloviruses, DR2, DR6/7, U2, U3, U5, U7 (U5/7 in HHV-7), U8, U17/16, U25, and U95 are all members of this gene family. At least four of the HHV-6A US22 homologs encode transcriptional transactivators (DR6, U3, U16, and U25).

Roseoloviruses have been the subject of little genetic experimentation. Replacement of the HHV-6B U3-U7 gene cluster with a selection marker demonstrated that these genes are not essential for virus replication or latency in cultured cells.[131] HHV-6A genomes have been cloned as bacterial artificial chromosomes (BACs), which have been used in studies of viral glycoproteins[244] and the function of the telomeric repeats[267,268] and to identify a role for an HHV-6A-encoded microRNA in regulation of lytic infection.[186]

Stages of Replication

Entry

Differences in receptor recognition likely contribute to the distinct cellular tropisms of HHV-6A and HHV-6B.

A cellular receptor for HHV-6A,[215] CD46, is also a member of the regulator of complement fixation family and is expressed on the surface of all nucleated human cells. The short consensus repeats 2 and 3 of the CD46 ectodomain are required for HHV-6 receptor activity.[87] HHV-6A but not HHV-6B can mediate fusion from without (FFWO; fusion that does not require viral protein synthesis) in a variety of human cells,[174] an activity that is dependent on CD46 expression. CD46 isoforms that are alternative splice variants also may impact HHV-6 infection.[95]

Human CD134 is a cellular receptor of HHV-6B,[248] but not HHV-6A. CD134 is a member of the TNF receptor superfamily, which is a type I transmembrane protein, and a co-stimulator for T-cell activation. Compared with the ubiquitous expression of CD46, CD134 is mainly expressed on activated primary T cells. Another cellular protein, GP96, is important for both

HHV-6A and HHV-6B entry.[154,204]

HHV-7 uses CD4 as a receptor, although the virus can infect cells that do not express detectable CD4.[21]

On the virus side, two HHV-7 glycoproteins have been identified as being able to bind cell surface proteoglycans heparan and heparan sulfate: gB, and the spliced glycoprotein encoded by U100.[45] Other virion proteins are likely involved in receptor interactions or entry, such as the gH/gL complex, which, along with products of U100, is a target for complement-independent neutralization. gQ1, a spliced product of the U97, 98, 99, and 100 ORFs, is unique to roseoloviruses.[246] The gene is expressed via complex splicing, producing a number of envelope-associated polypeptides. The HHV-6 gH/gL complex associates with the 80-kDa virion envelope form of gQ1 (gQ-80K; gQ1). A different small transcript from U97 gene encodes an unrelated protein of 37 kDa (gQ-37K; gQ2) that interacts with the gH/gL/gQ1 complex in infected cells and virions.[6]

Interaction of the virion with the CD46 or CD134 receptor is via the HHV-6A or HHV-6B gH/gL/gQ1/gQ2 complex (Fig. 14.6).[6,176,214,247,249] HHV-6A gQ1/gQ2 is critical for the CD46 interaction.[114] A short amino sequence in HHV-6A gQ1 (494aa-497aa) is important for HHV-6A gH/gL/gQ1/gQ2 complex function.[156] HHV-6B gQ1/gQ2 complex is sufficient for CD134 binding[249] while all four components of HHV-6A gH/gL/gQ1/gQ2 complex are required for CD46 binding.[242]

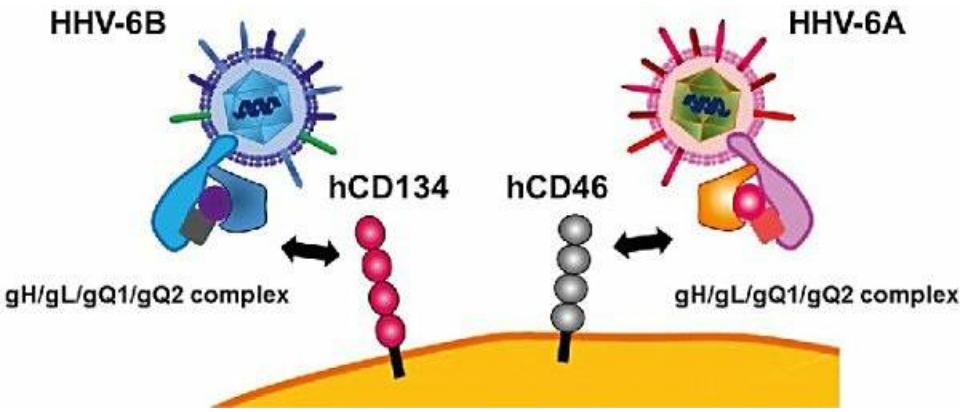

FIGURE 14.6 Virion–receptor interactions. HHV-6A and HHV-6B recognize distinct cellular receptors. The HHV-6A gH/gL/gQ1/gQ2 complex binds human CD46 and the HHV-6B complex binds human CD134.

An amino acid residue in HHV-6B gQ1 (E127) is important for CD134 binding.[247] The ectodomain of CD134 contains four cysteine-rich domains (CRD) and a stalk domain. CRD2 is needed for HHV-6B complex binding, and 2 amino acid residues (K79 and W86) within CRD2 are key for its interaction with the HHV-6B complex, and the positive charge of K79 could associate with the negative charge of E127 of HHV-6B gQ1 and contribute to the interaction.[247,249]

HHV-6A and HHV-6B U47 are positional homologs of HCMV glycoprotein O (gO) gene.

Both HHV-6 gOs are components of gH/gL-associated envelope complexes, but they are not CD46 ligands and likely play different roles than gH/gL/gQ1/gQ2.[171] gQ and gO have much greater sequence divergence between HHV-6A and HHV-6B than do other glycoproteins (76.8% and 72.1% identity, respectively), suggesting that they contribute to the biological differences between these viruses.

Lipid rafts are critical for HHV-6 entry. Depletion of cholesterol from virion and cell membranes inhibits virus infection, and HHV-6A binding to cells triggers rapid redistribution of CD46 to lipid rafts.[173,243] Envelope glycoproteins are enriched in raft fractions, and raft components are incorporated into virions.[121]

Transcription

Herpesvirus genes generally belong to one of two main categories: latent or lytic. There are three general kinetic classes of lytic genes: immediate-early (IE; expression not dependent on *de novo* protein synthesis) genes that provide functions for regulation of gene expression, early (E; expression dependent on IE gene expression) genes that encode proteins needed for replication of the virus genome, and late (L; expression is dependent on viral DNA synthesis) genes that encode virion proteins.

Roseolovirus gene expression follows the general herpesvirus program. For HHV-6B, 8 genes are expressed as IE, 44 as Early, and 44 as Late, and 4 were biphasic[85] (Table 14.2). HHV-6A and HHV-6B U83 and U89/90 are well established as IE genes. For both loci, multiple differently regulated transcripts are expressed (e-Fig. 14.3). The U83 IE transcript is spliced and expresses a truncated version of the chemokine encoded by U83, whereas the full-length transcript is expressed as a late gene. U42 encodes a homolog of the HSV IE gene α27 and HCMV UL69, which is regulated as an E gene; HHV-6B U42 is not transcribed in the absence of *de novo* protein synthesis; thus, its regulation is similar to that of its HCMV counterpart. Expression of the U90 IE gene rose to more than 10 copies per cell within 8 hours, whereas a structural gene transcript (U11) took 16 hours to reach comparable levels[205]; at 72 hours after infection, U11 was expressed at several hundred copies per cell. Transcripts of the gene needed for initiation of DNA replication (U73) and the parvovirus ns1/rep homolog (U94) were expressed at much lower levels (<10 copies/cell).

Recent studies that employed deep RNA sequencing and proteomics have made it clear that, as for other herpesviruses, HHV-6A and HHV-6B transcription is very complex.[60,85,88] Important features include abundant mRNA, numerous splice isoforms that can be differentially regulated and can express diverse forms of related proteins. Some mRNAs include small ORFs that are likely to be involved in regulation of larger downstream canonical ORFs that have long been recognized. Some regions of the genomes are spanned by long RNAs that at first glance seemed to be noncoding because of the absence of long ORFs, but proteomics analyses and studies of ribosomal occupancy have made it clear that some small ORFs are indeed expressed as proteins. Much work will be required to develop frameworks for understanding the biological activities enabled by these complex forms and patterns of gene expression.

The HHV-6 R3 repeat element (R2 in HHV-7) is a potential IE enhancer. R3 is located about 300 bp upstream of the oppositely oriented U89/90 and U95 genes; it is present in more than 25 copies per genome (Table 14.1) and contains potential transcription factor-binding sites (nuclear factor kappaB [NF-κB] and AP2 in HHV-6A; PEA3 and AP2 in HHV-6B; and PEA3 in HHV-

7). U95 has amino acid sequence similarity with the murine CMV (MCMV) IE2 gene and is a member of the HCMV US22 gene family. Deletion of three R3 units decreases promoter activity 15-fold, and NF-κB family members p50 and c-Rel bind to NF-κB sites in R3.[179] The HHV-6 major immediate early gene (U90-89) promoter (MIEp) is highly active in T cells; its activity is reduced in the absence of intron 1. The NF-κB-binding site in the R3 repeat is critical for this activity.[162]

Promoters of the genes encoding the HHV-6A DNA polymerase (U38) and its processivity factor (U27) were active in infected, but not in uninfected, cells; thus, they have virally responsive elements. The U38 promoter is TATA-less, and its activity is dependent on a palindromic activating transcription factor (ATF)/CREB-binding site.

Four latency-associated transcripts from the IE1/IE2 locus are oriented in the same direction as the IE1/IE2 genes and share their protein-coding regions with IE1/IE2, but have latency-specific transcription initiation sites and exons.[132] In addition, transcripts from the U94 gene (a homolog of the parvovirus ns1/rep gene) have been detected in primary PBMC that were polymerase chain reaction (PCR) positive for HHV-6 DNA, and negative for other lytic gene transcripts.[211] If a role for U94 in HHV-6 latency is identified, this would constitute a significant biologic difference from HHV-7 because HHV-7 does not encode a U94 homolog. While neither human nor murine CMV encodes a U94 homolog,[263] hints as to U94 function may come from studies of rat CMV, which encodes a U94 homolog that binds single- and dsDNA and is not essential for virus replication.[40]

MicroRNAs (miRNAs) play important roles in biological processes. HHV-6B expresses 4 miRNAs: hhv6b-miR-Ro6-1, hhv6b-miR-Ro6-2, hhv6b-miR-Ro6-3, and hhv6b-miR-Ro6-4, which are encoded at two loci within the genome (in both DRL and DRR) and are encoded in antisense orientation relative to predicted HHV-6B specific genes.[260] There is a report that the maximum levels of hhv6b-miR-Ro6-1, hhv6b-miR-Ro6-2, hhv6b-miR-Ro6-3, and hhv6b-miR-Ro6-4 in serum of patients with the drug-induced hypersensitivity syndrome/drug reaction (DIHS/ DRESS) were significantly higher than in those with maculopapular eruption (MPE) and healthy controls and the serum levels of hhv6b-miR-Ro6-2 were associated with the severity of skin lesions, indicating that the detection of their miRNAs in DIHS/ DRESS may reflect the HHV-6B reactivation.[169] HHV-6A-encoded miR-U86 is involved in regulation of viral lytic replication.[186] Numerous additional HHV-6A and HHV-6B miRNAs were recently identified whose functions have not been studied.[60]

Translation and Transport

Several HHV-6A and HHV-6B genes (e.g., U36 and U48; Fig. 14.4) were recently found to have short translated upstream ORFs near the 5′ end of mRNAs that express larger proteins from downstream ORFs.[60] Ribosomal interactions with upstream short ORFs regulate translation of downstream ORFs, and the small peptides can have independent biological activities.[61,76]

HHV-6A and HHV-6B U51 encode a G-protein–coupled receptor homolog that is expressed on the surfaces of transfected T-cell lines but in other cell lines accumulates intracellularly without being transported to the cell surface,[166] suggesting the presence of a cell-specific transport or processing function.

Virally Encoded Transcription Regulators

Roseoloviruses encode genes that regulate transcription of viral and cellular genes. These include products of HHV-6A IE-A and IE-B loci, DR6, U3, U27, and U94. Positive regulatory effects have been seen by transfection or infection in a variety of cell types on heterologous viral promoters, including the HIV-1 and human T-cell lymphoma 1 (HTLV-1) LTR, Epstein-Barr virus (EBV) latent membrane protein 1 (LMP-1) and EBV nuclear antigen 2 (EBNA-2), HSV gD, human papillomaviruses 16 and 18, and the adenovirus E3 and E4 genes.[26,45] In addition, negative regulatory effects have been observed on cellular promoters for p53, H-ras, and CXCR4, along with mixed effects on the CD4 promoter (positive by HHV-6A and negative by HHV-7).[66] Up-regulation of the HIV-1 LTR is variously dependent on the presence of the NF-kB, AP-1, trans-acting response (TAR), and SP1 sites, whereas its suppression by U94 is independent of NF-kB and SP1 but dependent on the TAR element.

Functions of Immediate-Early Gene Products

Human herpesvirus 6 IE-A consists of two genetic units, IE1 and IE2, corresponding to U90-U89 and U90-U86/87, respectively.[83,195] IE2 proteins with molecular masses of 100, 85, and 55 kDa are detectable 3 days after infection, whereas IE1 proteins of greater than 170 kDa are detectable within 8 hours. IE2 is expressed via differential splicing and alternative translation initiation. IE2 proteins show a mixed cytoplasmic and nuclear localization pattern. At earlier times (8 to 48 hours after infection), it is present as intranuclear granules, whereas at later time points (72 to 120 hours after infection), IE2 coalesces into a few large immunoreactive patches. IE2 can induce the transcription of a complex promoter, such as the HIV-LTR, as well as simpler promoters, whose expression is driven by a unique set of responsive elements (*cis*-acting replication element [CRE], nuclear factor of activated T cells [NFAT], NF-κB).[86] Moreover, minimal promoters having a single TATA box or no defined eukaryotic regulatory elements can be activated by IE2, suggesting that it plays an important role in initiating the expression of several HHV-6 genes as a promiscuous transactivator.[256] HHV-6 IE2 interacts with the heterogeneous nuclear ribonucleoprotein K (hnRNP K) and the beta subunit of casein kinase 2 (CK2β).[229] IE2 localizes at cellular telomeres and viral replication compartments during infection (PMID 32320442). U95 interacts with the mitochondrial GRIM-19 protein that promotes cell death induced by IFN-β and retinoic acid.[286] Short-term HHV-6B infection of MT-4 T-lymphocytic cells induced syncytial formation, resulted in decreased mitochondrial membrane potential, and led to progressively pronounced ultrastructural changes, such as mitochondrial swelling, myelin-like figures, and a loss of cristae. The high affinity between U95 and GRIM-19 may be closely linked to the detrimental effect of HHV-6B infection on mitochondria.

The C-terminal domain of the IE2 protein is conserved among betaherpesviruses and important for the transactivation function. Structural analysis of this domain revealed a homo-dimeric form reminiscent of the DNA-binding domains of EBV EBNA1 and KSHV LANA, presenting a putative DNA-binding site that may interact with transcription factors.[184]

IE1 of HHV-6A and HHV-6B stably interact with PML bodies (also known as ND10 or nuclear promyelocytic leukemia protein [PML] oncogenic domains [POD]).[83,231] Remarkably, PML bodies remain structurally intact and associate with the IE1 protein throughout lytic HHV-6

infection, unlike other herpesviruses, which trigger PML-body dispersal. IE1 is covalently modified by conjugation to the small ubiquitin-like proteins, SUMO-1-3.[82,83,231] Recent work indicates that PML plays an important in IE1 SUMOylation.[41]

HHV-6A U16 is encoded in the IE-B region of the genome. The protein-coding region of one transcript is generated by in-frame splicing of ORF U17 and U16, and another includes ORFs U16 and U15. A third differentially spliced complementary DNA (cDNA) (U16+) was identified by 5′ rapid amplification of cDNA ends. These transcripts arise from at least two transcription initiation sites; the U17/U16 spliced transcript is expressed under IE conditions, and a multiply spliced gene product encoded by U16 is expressed as a late gene. The U17/U16 and the U16+ gene products can transactivate the HIV LTR.[68]

Replication of Genome

Nucleotide metabolism

Roseoloviruses encode several enzymes that have roles in nucleotide metabolism and provide the precursors needed for nucleic acid synthesis: ribonucleotide reductase (pU28), a phosphotransferase (pU69), alkaline exonuclease (pU70), and uracil-DNA glycosylase (pU81), but do not encode a thymidylate synthase or thymidine kinase. Roseolovirus ribonucleotide reductases consist of a single subunit homologous to the large subunit of two-subunit enzymes.

Initiation and elongation

Roseolovirus lytic DNA replication is initiated at an oriLyt that is similar to alphaherpesvirus oriLyts and markedly different from the oriLyts of CMV and gammaherpesviruses.[107,133,148,210] The oriLyts are located between the 5′ end of U41 and the 3′ end of U42. The minimal oriLyt segment is about 300 bp long, and a fully functional oriLyt is about 800 bp long. Multiple tandem iterations of the origin sequence enable more efficient replication of plasmids in transient replication assays, and confer a replication advantage on virus genomes.[50] A critical element near the center of oriLyt consists of two palindromically arranged sequences, OBP-1 and OBP-2, that are recognized by the origin-binding protein (OBP) encoded in roseoloviruses by U73 (a homolog of HSV-1 UL9). The core OBP sites flank an AT-rich sequence of about 30 bp (e-Fig. 14.4). Several positions within the OBP binding sites are conserved among the viruses that encode OBP homologs, whereas others differ in a manner that provides viral specificity. Replication efficiency is also affected by the sequence and composition of the AT-rich spacer. HHV-6A and HHV-6B are able to support replication of each other's oriLyt. Plasmids containing the HHV-6 oriLyt, however, were replicated in HHV-7-infected cells, but not vice versa, suggesting that oriLyt sequences and binding specificities differ between the viruses. It is thus surprising that the HHV-6 OBP binds strongly to the HHV-7 OBP binding sites, but the HHV-7 OBP binds strongly to only one of the HHV-6 OBP sites.[134]

In addition to OBP, roseoloviruses encode homologs of the six other virally encoded proteins needed for replication of plasmids containing an HSV oriLyt. They include the major DNA-binding protein (pU41), the DNA polymerase (pU38) and its processivity factor (pU27), and three gene products that constitute the helicase–primase complex (pU43, pU74, and pU77). In an *in vitro* DNA synthesis system that employed the single-stranded M13 genome as a template, the HHV-6A DNA polymerase alone synthesized molecules shorter than 100 nucleotides.[144]

Addition of the polymerase processivity factor homolog encoded by U27 (p41), led to synthesis of molecules greater than 7,200 nucleotides in length, similar to the processivity increase produced by its homologs in other herpesviruses. The N-terminal portion of the processivity factor was required for this activity.

Genome packaging and cleavage

About 5% of genomes contained in nucleocapsids are circularized, creating a juxtaposition of direct repeat right (DRR) and direct repeat left (DRL) that results in assembly of a complete cleavage and packaging signal. The structure of such circular genomes is as follows: DRR-(TRS)n-pac2-N16–18-junction-N25–29-pac1-het(TRS)n-DRL.[47,52,79,210,223,252] Some heterogeneity is seen in the sequences of concatemeric junctions, with 1 to 8 bp of additional, possibly untemplated, DNA being inserted into some molecules.[52,223] Circularized molecules provide the template for rolling-circle replication, which leads to production of concatemers of nascent DNA suitable for packaging into capsids.[210] In the model of Frenkel and Roffman,[69] concatemers are cleaved between properly juxtaposed pac1 and pac2 sequences after a headful threshold has been reached during packaging, leading to unit-length packaged genomes. Relatively few multimeric concatemers are generated during replication, and compared with HSV, HHV-6 replication intermediates are not highly branched, suggesting less frequent homologous recombination among replicating molecules, or effects due to the presence of three oriLyts in every HSV genomes, versus one for roseoloviruses.[228]

Identification of the oriLyt and cleavage and packaging signals allowed development of amplicon systems based on HHV-6 and HHV-7[24,47] that feature T-cell replication, oriLyt, and cleavage-packaging signals and can be used for expression of foreign genes. They have potential use as gene therapy vectors.

Virion Assembly and Release

Roseolovirus virion maturation and egress appear to involve a process of successive envelopment, de-envelopment, and re-envelopment steps during nuclear egress and acquisition of the final envelope (Fig. 14.1). DNA replication and capsid assembly take place in the nucleus; nascent capsids that contain DNA appear about 3 days after infection.[20,22] A feature that is likely to be a result of the envelopment–development process is the presence of abundant nonenveloped, tegumented nucleocapsids in the cytoplasm. In some studies, particles with neither tegument nor envelope were observed in the cytoplasm[20,258]; teguments appeared to be acquired cytoplasmically in pools of electron-dense material. Membrane-bound nuclear structures that appear to be cytoplasmic invaginations (tegusomes) have been proposed as sites of tegument acquisition,[209] but given the relatively low frequency with which they are observed, this is not the major pathway. Because viral glycoproteins gB, gH-gL, and gQ1 are absent from the plasma membrane, envelopment or egress by budding directly from the plasma membrane are not likely. These glycoproteins are concentrated in cytoplasmic structures known as *annulate lamellae*,[258] which may correspond to the endosome- and TGN-related intracellular membranes where final envelopment of virions occurs.[173] HHV-6 virions collect in multivesicular bodies (MVB) that contain numerous mature virions and small exosomal vesicles.[173] MVB membranes can fuse with the plasma membrane, resulting in the release of mature virions and exosomal particles. In addition to exocytosis, mature virions can be released by cell lysis.[258]

Functions of Other Virally Encoded Gene Products

The U3-U7 gene cluster is not essential for virus replication or latency in cultured cells.[131]

U11 encodes the roseolovirus homologs of HCMV tegument protein, pp150: p100 (HHV-6A), 101K (HHV-6B), and phosphoprotein p86 (HHV-7).[181,201,232] HHV-6A U11 is incorporated into teguments in association with the product of the U14 gene (pU14); U11 is essential for virus propagation.[158]

pU14 localizes in the nucleus at early phase of infection and then relocates to the cytoplasm where it functions as a tegument protein. In the early phase, pU14 induces cell cycle arrest in G2/M phase by associating with EDD in the nucleus.[172] The substitution or deletion of 3 amino acids (L424, E425, and V426) of U14 abolishes its binding with another tegument protein, U11,[158] and results in a defect in viral maturation.[175,269] The importance of these amino acids for U14 function is suggested by its structure, in which a β hairpin contributes to the dimer interaction and likely contributes to interactions with other proteins.[269]

HHV-6B U19 can inhibit p53-dependent signaling following gamma irradiation[127] and also bind to the p53-regulating protein HDM2.[128]

The HHV-6A U21-24 gene cluster is dispensable for virus replication.[115] HHV-6A U23 is a membrane protein expressed at late phase of infection locating at the trans-Golgi network (TGN),[98] although its function is still unknown.

The gB (encoded by U39) is a conserved herpesvirus glycoprotein that is found on virions of most herpesviruses, including roseoloviruses. It has roles in attachment and penetration and is a target for complement-independent neutralization. The primary HHV-6A gB translation product of about 112 kDa is proteolytically cleaved to form disulfide-bond–linked subunits of 64 kDa and 58 kDa; for HHV-6B and HHV-7, the corresponding products were approximately 102, 59, and 50 kDa, and 112, 63, and 51 kDa, respectively. As with the gB of other herpesviruses, the extracellular domain of HHV-7 gB binds to cell surface heparan sulfate proteoglycans, indicating a role in adsorption of the virion to cells.[224] The deletion of gB cytoplasmic tail (CTD) impairs the intracellular transport of gB protein to the TGN, showing that CTD is critical for gB transportation.[157] Domain II of gB is expected to be exposed to the solvent in the trimeric form. A neutralizing monoclonal antibody targets a linear epitope on the domain II, indicating its functional importance.[266]

HHV-6 U42 is a homolog of HCMV UL69. Like pUL69, pU42 homodimerizes and shuttles from between the nucleus and cytoplasm, but pU42 does not interact with the cellular DExD/H-box helicases UAP56 and URH49, and thus does not export mRNA.[300]

As for other herpesviruses, the conserved virion glycoproteins gH and gL (encoded by ORFs U48 and U82, respectively), heterodimerize and together have roles in membrane fusion associated with both virus entry and cell-to-cell spread.[246] As mentioned, the HHV-6 gH/gL complex forms independent envelope complexes with either gQ1/gQ2 or gO.[30,171] HHV-6A gQ1 and gQ2 are essential for HHV-6A replication[242,244] while HHV-6A gO is not essential.[245]

The proteinase required for capsid maturation, DNA packaging, and virus assembly is encoded by U53. The HHV-6 proteinase, like its homologs in other herpesviruses, is translated as a precursor molecule that is autolytically processed at two sites (the release and maturation

sites) to produce the mature proteinase and assembly proteins. As in the other herpesviruses, the processing sites consist of an Ala-Ser sequence. In contrast to the other herpesviruses, roseoloviruses lack an internal autocatalytic cleavage site (Ala-Ala instead of Ala-Ser), which results in their proteinase being a single-chain enzyme.[254]

HHV-6 U69 gene product (pU69) is the presumed functional homologue of HCMV UL97-encoded kinase (pUL97), which converts ganciclovir to its monophosphate metabolite in HCMV-infected cells.[45] The efficiency of ganciclovir phosphorylation in HHV-6-infected cells, and by vaccinia virus–expressed pU69, however, is relatively poor.

Viral DNA replication was reduced 50-fold, and cytopathic effects were also inhibited in T cells stably expressing short interfering RNA (siRNA) specific for the HHV-6 G-protein–coupled receptor (GPCR) homolog encoded by U51, suggesting that HHV-6 U51 is a positive regulator of virus replication.[299]

HHV-6 gM (encoded by U72) is a type III membrane protein with 7 membrane-spanning domains and a C-terminal cytoplasmic tail, and interacts with gN (encoded by U46) to form a complex for transport to the TGN.[120] Finally, the complex is incorporated into mature virions and essential for virus production.[120] The gM/gN complex interacts with the v-SNARE, VAMP3, which is incorporated into virions.[98]

The Rep68 protein of adeno-associated virus type 2 (AAV-2) is a site-specific adenosine triphosphate–dependent endonuclease and helicase and is involved in site-specific integration of the viral genome into the host genome (see Chapter 06—parvovirus chapter). Rep68's HHV-6A homolog, U94, can serve as a helper for AAV-2 replication, and can complement a point mutant of AAV-2 rep.[253] As summarized by Caselli et al.[30] (a) HHV-6 U94 transcripts have been detected in PBMC during latency; (b) activities associated with U94 include suppression of H-ras and bovine papillomavirus 1 (BPV-1) transformation and transcription from the H-ras and HIV-1 LTR promoters, the ability to bind to ssDNA and to human TATA-binding protein, the ability to inhibit the replication of HHV-6 and other betaherpesviruses (HHV-7 and HCMV), but not HSV, and (c) HHV-7 does not encode a U94 homolog, although rat CMV does. The activities of U94 in the regulation of HHV-6 replication have implications for co-reactivations and latency of human betaherpesviruses. U94 is also able to hydrolyze ATP to ADP and has a 3′ to 5′ exonuclease activity on dsDNA, and compromises the integrity of synthetic telomeric D-loop through exonuclease attack at the 3′end of the invading strand, suggesting a possible role in genome integration.[259] In addition, expression of U94 in cultured endothelial cells inhibits the formation of capillary-like structures, reduces cell migration, and blocks angiogenesis.[29] U94 is dispensable for HHV-6A chromosomal integration.[267]

U41 and U70, which enhance dsDNA break repair, were also dispensable.[275]

HHV-6B direct repeat 6 (DR6) expresses a nuclear protein that interacts with the U27-encoded viral DNA polymerase processivity factor, p41, and can induce p53-independent cell cycle arrest in G2/M.[216] HHV-6A lineages that spontaneously lost the genomic segment spanning DR1 through the first exon of DR6 appear to have a growth advantage in at least some cell lines.[25]

Fate of Host Cell

Roseolovirus infection has profound effects on host cells, including margination of chromatin, shutoff of host cell DNA synthesis, generalized stimulation of host cell protein synthesis, and development of the classic cytopathic effect of ballooning, refractile, multinucleated giant cells, as has been reviewed elsewhere.[26,45] For at least HHV-7, the multinucleated cells develop not by fusion of cells into syncytia but by polyploidization that is linked to dysregulation of cdc2 and cyclin B. This leads to an accumulation of cells in the G2 to M phase of the cell cycle, with nuclei continuing to reproduce in the absence of cell division.[219] Cytokines can be induced, including interferon-alpha (IFN-α), interleukin-1β, interleukin-15, CC chemokines, tumor necrosis factor alpha (TNF-α), and the G-protein-coupled peptide receptor, EB1. In addition, HHV-6A and HHV-6B can inhibit the proliferative responses of PBMC to antigens and mitogens.[64,102]

HHV-6 infection induces cell surface expression of CD4, which then renders NK cells susceptible to HIV-1 infection. HHV-6A, but neither HHV-6B nor HHV-7, down-regulates cell surface expression of CD3; HHV-7 sharply down-regulates CD4.[21,26,91]

HHV-6B infection induces a p53-independent G2 cell cycle arrest in human cord blood mononuclear cells that is mediated by the pDR6 viral protein.[217] HHV-6B infections of T-cell lines led to G1/S and G2/M arrests concomitant with an increased level and enhanced DNA-binding activity of p53. HHV-6B induces phosphorylation of p53 at Ser15 and Ser20 by casein kinase 1,[155] suggesting that viral suppression of T-cell proliferation links to p53 phosphorylation and accumulation. Interactions of HHV-6B pU19 with the p53-regulating protein HDM2 result in decreased p53 ubiquitination and increased levels of p53 in HHV-6-infected cells.[128] p53 mainly localizes in the cytoplasm of HHV-6-infected cells, but it translocates into the nucleus of mock-infected cells. Infected cells are resistant to UV-induced apoptosis, suggesting that HHV-6 has a mechanism for retaining p53 within the cytoplasm, providing protection from apoptosis. Since HHV-6 gene expression is enhanced in the absence of active p53,[193] p53 induction may be a cellular response to the invading pathogen. p53 interacts also with the HHV-6B U14 tegument protein, and is incorporated into viral particles.[239]

In ways that have parallels to manipulation of cellular metabolism by other herpesviruses, HHV-6A replication is enhanced by its ability to modulate infected cell metabolism in ways that result in enhanced glycolysis that is linked to increased glucose uptake, glucose consumption, and lactate production[278]; this activity is linked to viral activation of AKT-mTORC signaling.

Some parallels have emerged in studies of apoptosis induction during infections with HHV-6 and HHV-7. In fresh umbilical cord blood lymphocytes, infected cells are apoptotic,[20,106] whereas in cell lines, infected cells die by necrotic lysis and apoptosis is triggered in apparently uninfected or nonproductively infected cells.[108,221] For HHV-7, the induction and release of TRAIL by infected cells is likely responsible for apoptosis induction in uninfected bystander cells.[222] During *in vivo* primary HHV-6B infections, apoptosis was detected in 15% to 20% of circulating PBMC.[284] HHV-7 replication was enhanced in cells expressing high levels of the apoptosis suppressor, Bcl-2.[220]

HHV-6 attachment and/or entry in the absence of de novo protein synthesis can induce expression of the human endogenous retrovirus K18-encoded superantigen.[36]

In HHV-6-infected immature monocyte-derived dendritic cells, viral early and late antigens are expressed, and nucleocapsids containing a DNA core are observed, but few virions are

detected in the cytoplasm. In co-cultures, HHV-6 can be transmitted from these cells to stimulated CD4+ T cells, suggesting that DCs may be the one of the first cell populations targeted by the virus and may transmit the virus to T cells.[238]

HHV-6 infection of monocytes/macrophages results in the establishment of latency with expression of latency-associated transcripts overlapping the IE locus encoding the U86-U90 genes. Latent HHV-6 can be reactivated by stimulating cells with phorbol esters.[131] Whether latently infected cells carry episomes or integrated viral genomes remains to be determined.

PATHOGENESIS AND PATHOLOGY

Detailed referencing of historical literature in this area is available in several comprehensive reviews.[4,26,65,271]

Transmission

HHV-6B and HHV-7 are ubiquitous viruses infecting most individuals during the first 2 to 3 years of life. Horizontal infection accounts for the majority of transmission events, likely via saliva and respiratory secretions (Fig. 14.7). Studies have demonstrated that family saliva-sharing behaviors are associated with earlier acquisition of HHV-6B and older siblings are associated with earlier acquisition of both HHV-6B and HHV-7.[139,208,296]

Given the young age of primary HHV-6B infection, most organ transplant recipients have acquired the virus prior to transplantation; however, the transplanted organ may be a source of HHV-6B primary infection in very young patients (Fig. 14.7).[291]

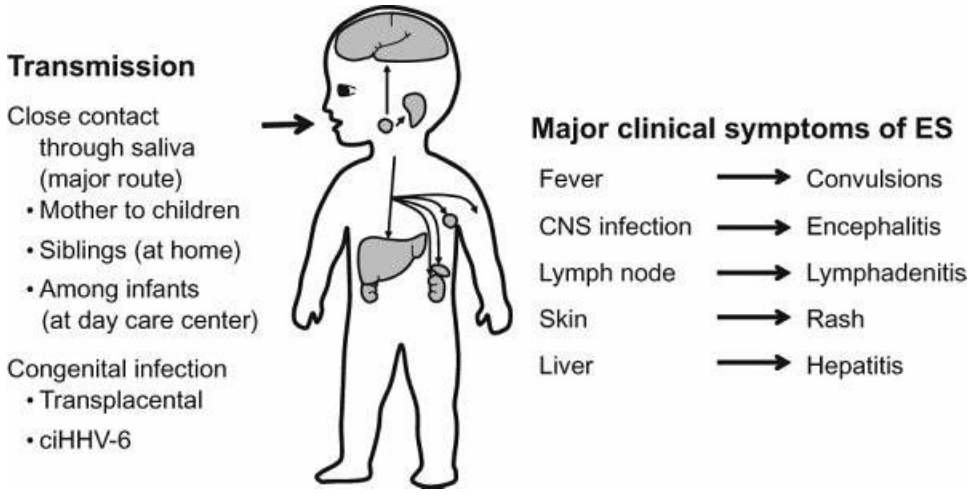

FIGURE 14.7 Pathogenesis of HHV-6B primary infection.

While most HHV-6B infections occur via horizontal routes, approximately 1% of the population acquires HHV-6A or B as inherited chromosomally integrated virus via the germ

line.[118,198] In such individuals, an intact HHV-6A/B genome is integrated at the telomere of a chromosome, with copies of that chromosome being present in every cell in the body. While HHV-6A/B DNA has been detected in fetuses and in blood of neonates, indicating that intrauterine transmission is possible, most cases of congenital transmission of HHV-6A/B can be attributed either to genetic transmission of iciHHV-6A/B from either or both parents or to transplacental transmission of virus from mothers with iciHHV-6A/B.[93]

Primary Infection

Site of Primary Replication

Human herpesvirus 6B and HHV-7 possibly initiate infection through respiratory pathways, including lymphocyte-rich tonsils and olfactory ensheathing cells present in the nasal cavity. The high prevalence of the virus in the olfactory bulb suggests that a route of CNS entry might be via olfactory ensheathing glial cells present in the nasal cavity.[97]

Cell and Tissue Tropism

The *in vivo* host tissue range of HHV-6A/B includes lymphoid and endothelial cells, as well as cells present in the liver, central nervous system tissues, and salivary glands.[26,45]

In vivo, HHV-7 infects CD4+ T lymphocytes (believed to be the site of latent infection), and salivary gland epithelial cells (a site of productive infection and viral shedding).[21] In addition, cells expressing an HHV-7 structural antigen were detectable in lungs, skin, and mammary glands, and at reduced frequencies in liver, kidney, and tonsils; this antigen was not detected in large intestine, spleen, or brain.[124] In a recent tissue level study of the human virome, HHV-7 was detected in 37% of 203 specimens.[136]

Persistence

Human herpesvirus 6 DNA and antigens can be detected in saliva, nasal secretions, brain, lung, bone marrow progenitors, and PBMC. HHV-6 DNA was detected mainly in the monocyte fraction of PBMC from patients convalescing from ES and from healthy adults, and appears to establish latency in monocytes or macrophages and CD34-positive progenitor cells.[7,130,149] As described above, latency-associated transcripts have been detected from the IE region and U94. In a prospective study, 89% of children from 1 to 12 years of age were PCR positive for HHV-6 at least one time point, with 1.2% of specimens being positive for reverse transcription PCR (RT-PCR), indicating active infection[33]; this activity was not associated with illness.

The HHV-6 variants differ with respect to their absolute and relative frequencies of detection in PBMC and cerebrospinal fluid (CSF). Of over 1,000 HHV-6 PCR-positive PBMC specimens, 2.5% were positive for HHV-6A and 99% for HHV-6B (some were positive for both). Of 84 HHV-6 PCR-positive CSF specimens, 17% were positive for HHV-6A and 86% for HHV-6B (some dual positives). Thus, HHV-6B was detected much more frequently in CSF than was HHV-6A, but the ratio of 6A to 6B was higher in CSF than in PBMCs indicating a greater relative neurotropism for HHV-6A.[92]

Germ line or iciHHV-6 enables a form of persistence in which the virus genome is present in every cell in the body. Under most circumstances, the virus appears to be quiescent, but spontaneous viral gene expression from the integrated virus does occur; U90 and U100 transcripts have been detected in tissues of several iciHHV-6-positive individuals.[197] Reactivation of iciHHV-6A with subsequent pathogenic outcomes was convincingly demonstrated in a boy with X-SCID.[56] Transplacental vertical transmission can also occur following reactivation of maternal iciHHV-6,[84] and fetal iciHHV-6 inheritance can lead to viral gene expression in the placenta and increased risk of preeclampsia.[72] It has been hypothesized that the default latency pathway for HHV-6 in individuals without germ line ciHHV-6 involves chromosomal integration in peripheral cells,[9] but this has not been demonstrated.

Human herpesvirus 7 DNA is frequently detectable in whole blood[74] and the virus establishes latent infections in CD4+ cells[70] and persistent lytic infections in salivary glands.[279] As described earlier, HHV-7 lytic antigens are present in a variety of tissues, suggesting that persistent infection occurs in many tissues *in vivo*.[124] None of three HHV-7 lytic cycle transcripts studied were detected in HHV-7 DNA-positive PBMC,[165] evidence that the virus is truly latent in these cells.

Immune Response

Immune responses to HHV-6 and HHV-7 and their immunomodulatory activities have been reviewed in detail.[45,150,270,271]

Antigens

Responses are generated to many of the virally encoded proteins. The immunodominant HHV-6 antigen in immunoblots is a virion tegument protein, pU11 (101K or p100). Responses to HHV-7 are directed predominantly to pp85 and pp89 (encoded by U14 and U11),[232] as well as to a 52 kDa species.[178] Consistent with their sequence similarities, sufficient antigenic cross-reactivity exists between HHV-6A and HHV-6B to preclude the use of conventional serologic assays for the study of variant-specific immune responses. These levels of cross-reactivity are reflected in the frequencies of cross-reactive mAb and T-cell clones.[11,21,285]

Primary Infection

Serologic studies on the association between ES and HHV-6 infection have mainly come from Japan. In patients with ES, IgM antibodies were detected on day 5 and persisted for 3 weeks but were not detectable in most sera 1 month after the onset of disease (e-Fig.14.5). The viremia during primary infection subsides coincident with the appearance of neutralizing antibodies. IgG antibodies are first detected about 7 days after onset of illness, increase for 3 weeks, and persist thereafter. HHV-6 antibody titers are boosted during infection with HHV-7 (e-Fig. 14.5). Plasma IFN-α levels are elevated during the acute febrile phase of ES compared with convalescence.[237] NK cell activity is also elevated in the exanthem phase of ES, probably induced by IL-15.[67,237] These early responses likely play pivotal roles in control of the infection.

Cellular immunity appears to be important for control of primary HHV-6 infection. Low-level *ex vivo* T-cell immune responses against HHV-6 can be detected in most healthy adults

indicating a low frequency of HHV-6-specific memory T cells. However, such effector cells can be rapidly expanded *in vitro* and be of potential therapeutic benefit.[75,177] Both $CD8^+$ class I–restricted and $CD4^+$ class II–restricted T cells recognizing HHV-6A/B peptides have been identified. With a few exceptions, such as the U90 IE1 gene product, most peptides presented to T cells are derived from virion structural proteins including the U11, U14, U31, and U54 tegument proteins; the gB and gH virion envelope glycoproteins; and the U56 and U57 capsid proteins.[16,17,75,96,159] HHV-6-specific $CD4^+$ and $CD8^+$ T cells are generally polyfunctional, secreting IFN-γ and TNF-α and are cytotoxic.[16,75,105,159] Some T-cell clones with activity against HHV-6 also responded to HHV-7 and HCMV, indicating the presence of shared T-cell epitopes.[285]

In *in vitro* studies, IFN-*α* activity was detected in PBMC from healthy seropositive adults as early as 12 hours after exposure to HHV-6; they plateaued at days 2 to 5, and gradually decreased thereafter; the response of cord blood mononuclear cells was lower.[125] HHV-6 also induces IL-1*β* and TNF-*α*, but not IL-6 in PBMC.[63] Thus, HHV-6 can exert a strong immunomodulatory effect by stimulating cytokine production in cells of myeloid lineage. IFN-*γ* regulates the production of IL-10 and IL-12 at a transcriptional level mainly through inhibiting endogenous IL-10 production in HHV-6-infected monocyte–macrophage cells.[143]

Reports on the immune response during HHV-7 primary infection are scarce because HHV-7 primary infection is seldom apparent. During a documented infection, 16 days after onset, HHV-7 antibody titer rose from less than 1:10 to 1:320 by an immunofluorescence antibody (IFA) test, whereas the HHV-6 titer remained less than 1:10.[240] In a patient with two independent ES episodes within 2 months, HHV-6 and HHV-7 were sequentially isolated; seroconversion to HHV-7 during the second episode was observed 4 days after disease onset. HHV-7 infection induces IL-15 production, which then results in an enhancement of NK cell activity that may play a major role in control of the infection.[15]

Immune Modulation

Human herpesvirus 6 infects a variety of immune cells, as described previously, and has numerous immune modulatory effects *in vivo* and *in vitro*.

Infection of PBMC or T-cell–enriched cultures by HHV-6A suppressed IL-2 synthesis after mitogen stimulation, and levels of IL-2 transcripts were diminished in experiments with enriched T-cell cultures.[64] By binding calcineurin, the HHV-6B U54 tegument protein prevents the dephosphorylation and nuclear translocation of NFAT1/2, transcription factors essential for *IL-2* gene expression.[104]

Suppression of bone marrow function may be one of the most serious effects of HHV-6 infection in bone marrow transplant recipients. *In vitro*, HHV-6 infection of normal bone marrow mononuclear cells reduced the outgrowth of granulocyte–macrophage colony-forming units (GM-CFU), granulocyte–erythrocyte–macrophage–megakaryocyte colony-forming units (GEMM-CFU), erythroid burst-forming units, and marrow stromal cells by 40% to 74%.[28] Although HHV-6A was generally a more potent inhibitor than HHV-6B, it did not exhibit as significant a suppressive effect on the formation of GM colonies. In hemopoietic progenitor cells derived from human umbilical cord blood lymphocytes, HHV-6A suppressed erythroid colonies, HHV-6B suppressed erythroid and GM colonies, and HHV-7 had no effect on either lineage.[113]

These results could be the consequence of the virus either encoding or inducing a soluble mediator or mediators that interfere with the responses of bone marrow to growth factors and block differentiation of macrophages from marrow precursors.[28]

Human herpesvirus 6A and HHV-6B, but not HHV-7, modestly (twofold) induced several T-cell adhesion markers, including CD2, CD4, CD11a, CD44, CD49d, and HLA antigen-DR. HHV-6B infection had little effect on CD4+ cytotoxic lymphocytes, but HHV-6A and HHV-7 decreased their activity; the inhibition by HHV-7 was overcome by lectin stimulation.[71] Thus, the three viruses differ in their effects on T cells.

Human lymphocyte antigen (HLA) class I expression on dendritic cells (DC) was down-regulated after infection with HHV-6A but not HHV-6B, whereas no significant change was seen in the expression of CD1a, CD83, and MHC class II; IE or E gene expression was required for this.[101] Preexposure to HHV-6 markedly impaired IFNγ- and lipopolysaccharide-induced DC maturation. HHV-6, but not HHV-7, dramatically suppressed the secretion of IL-12 p70 by DC, whereas the production of other cytokines that influence DC maturation (i.e., IL-10 and TNF-α) was not affected.[230] Children who acquired HHV-6 after 18 months of age were more likely to express IgE to common allergens, suggesting that early life exposure to HHV-6 might reduce allergic responses, possibly due to the virus down-regulating Th2 responses.[185] While HHV-6 infection led to reduced IL-5 expression in DC, systemic IL-5 levels are elevated during convalescence from primary infection.[292]

Human herpesvirus 6 infection of monocyte-derived immature DC induced CD80, CD83, CD86, and HLA antigen class I and class II molecules, but decreased their capacity to present alloantigens and exogenous virus antigens to T lymphocytes.[117] Levels of DC-specific intracellular adhesion molecule-grabbing nonintegrin (SIGN) messenger RNA (mRNA) and intracellular protein decreased following HHV-6 infection.[183]

The cytokine encoded by HHV-6A U83 is an agonist for multiple chemokine receptors, including CCR1, CCR4, CCR5, CCR6, and CCR8, which are present on immune effector and antigen presenting cells.[34,51] In contrast, HHV-6B U83 is monospecific and functionally activates the CCR2 receptor and serves as a chemoattractant for mononuclear cells.[153,301] HHV-6B U83 also competes with CCL2, the natural ligand of CCR2.

HHV-6 and HHV-7 U12 and U51 encode GPCR homologs. HHV-6 pU12 is a functional β-chemokine receptor, with selectivity that differs somewhat from its cellular homologs in its higher relative affinity for RANTES relative to macrophage inhibitory proteins 1α and 1β or monocyte chemoattractant protein 1.[111] When stably expressed in cell lines, HHV-6 pU51 specifically binds the CC chemokine RANTES and competes for binding with other β-chemokines, such as eotaxin and monocyte chemoattractant proteins 1, 3, and 4. In epithelial cells already secreting RANTES, U51 expression induces specific transcriptional down-regulation of RANTES.[168] pU51 constitutively activates phospholipase C. It also binds several chemokines and promotes chemotaxis and internalization of chemokines, suggesting roles in virus dissemination or host transmission by chemotaxis of infected cells to sites of chemokine secretion specific for pU51.[35,62] Suppression of pU51 expression by siRNA reduces the replication of HHV-6, demonstrating that pU51 is important for virus growth.[299]

HHV-7 U12 and U51 also encode functional calcium-mobilizing receptors for β-chemokines, which include thymus and activation-regulated chemokine, macrophage-derived chemokine,

EBI1-ligand chemokine, and secondary lymphoid-tissue chemokine.[180,236] Furthermore, EBI1-ligand chemokine and secondary lymphoid-tissue chemokine induce migration in Jurkat cells stably expressing U12, but thymus and activation-regulated chemokine, macrophage-derived chemokine, do not.[236]

Human herpesvirus 6A had little direct effect on cytokine production in primary adult astrocytes, but profoundly affected the response of these cells to a mixture of proinflammatory cytokines (TNF-α, IL-1β, and IFN-γ), inducing anti-inflammatory molecules (IL10 and IL-11), chemotactic and growth factors, and regulators of type 1 IFN production.[163]

Through inhibition of IRF3 dimerization, HHV-6A and HHV-6B IE1 prevent IFN-β gene expression,[116] but HHV-6B IE1 expression, and not HHV-6A IE1, impairs IFN-α/β antiviral activity. By interacting with STAT2, HHV-6B IE1 sequesters it in the nucleus, preventing ISG3 from binding to IFN-responsive promoters resulting in improper IFN-stimulated gene (ISG) expression.

HHV-6 and HHV-7 U21 proteins bind to HLA class I molecules and divert them to endolysosomal compartments, thereby removing them from the cell surface, leading to reduced or delayed cytotoxic T-lymphocyte recognition of infected cells.[77,103]

HHV-6 and HHV-7 U24 proteins cause internalization of the T-cell receptor/CD3 complex at the cell surface, resulting in improper T-cell activation by antigen-presenting cells.[234] A PxxY motif present in HHV-6A and HHV-7 U24 is responsible for this effect. Recent results also indicate that the PxxY motif of U24 binds with strong affinity to the WW3* domain of human Nedd4.[213] U24 also down-regulates the transferrin receptor, suggesting that this viral protein acts by blocking early endosome recycling.[235]

Epidemiology

Little is known about the epidemiology and natural history of HHV-6A. In contrast, HHV-6B is ubiquitous, infecting most children in the first 2 years of life. Very young infants appear to be protected against HHV-6B infection by maternal antibody as HHV-6B seroprevalence decreases from 0 to 5 months of age, as maternal antibody wanes. Beginning at about 6 months, seroprevalence increases rapidly, with almost all children acquiring infection by 2 years of age.[191,296]

Human herpesvirus 7 infection generally occurs somewhat later than does that for HHV-6B.[280] Similar to HHV-6B, seroprevalence declines over the first 5 to 6 months, as maternal antibody wanes, and then increases through about 4 years of age. It reaches its highest level from the teens until the end of the third decade, decreasing thereafter.[241,290]

Clinical Features

Primary Infection

Clinical features of primary infection due to HHV-6A have not been described, and its epidemiology and associated clinical syndromes remain undefined.

A population-based study of young infants followed prospectively over the first 2 years of

life demonstrated that HHV-6B primary infection is typically symptomatic, causing an illness characterized by fussiness (70% of affected children), fever (58%), rhinorrhea (66%), rash (31%), roseola (fever followed by a rash with defervescence, 24%), and diarrhea (26%).[296] In this study, fever, fussiness, diarrhea, rash, roseola, and visits to a physician were all more common during primary HHV-6B infections than during control periods of illness. None of the 81 children with well-defined primary infection had a seizure. In contrast, studies performed in emergency department settings have found that HHV-6B primary infection accounts for a large proportion of first-time febrile seizures (one-third in those <2 years) presenting to emergency care.[94] Among children with febrile seizures, HHV-6B primary infection has been association with more complex seizures, such as clustering seizures, prolonged seizures, partial seizures, and postictal paralysis.[233] Primary infection has also been associated with febrile status epilepticus in 22% of cases.[58]

Encephalitis/meningoencephalitis/encephalopathy can occur during primary HHV-6B infection. Of 89 cases identified in a Japanese national survey, half of the patients had neurological sequelae and 2 died.[293] In comparison to stem cell recipients, HHV-6 encephalitis during primary infection is characterized by low viral DNA levels in the CSF and differences in cytokine responses.[123]

Liver dysfunction is also associated with HHV-6 infection; although usually mild, chronic hepatitis, fatal hepatitis, and liver failure of unknown etiology that can necessitate liver transplantation have been also reported.[283] Primary HHV-6 infection has also been associated with cases of idiopathic thrombocytopenic purpura.

Primary infection with HHV-7 causes illnesses similar to those caused by HHV-6B, including roseola, high fever, and febrile seizures.[31,240,272] HHV-7 has also been associated with febrile status epilepticus in 5% of cases.[58]

Disease in Immune Compromised Patients

Because herpesviruses persist in their hosts after primary infection and can be reactivated, they are important pathogens in immune compromised hosts. Since HHV-6B and HHV-7 are acquired early in life, most instances of detection of the virus after transplantation are due to reactivation of latent virus.

Hematopoietic cell transplants

HHV-6B reactivates in approximately 40% of allogeneic hematopoietic cell transplant (HCT) recipients, most commonly within the first 4 weeks after transplantation.[188,294] HHV-6B reactivation has been associated with a number of clinical outcomes and HHV-6B is recognized as the most common cause of encephalitis in the HCT recipient.[218]

HHV-6B encephalitis occurs in approximately 1% of allogeneic HCT transplant recipients overall and 10% of cord blood transplant recipients.[99] The timeline for onset of symptoms of encephalitis is similar to the timeline for reactivation. In most studies, HHV-6B encephalitis is defined by acute encephalopathy, HHV-6B detection in the CSF, and lack of a more likely explanation. A more specific entity, posttransplant acute limbic encephalitis (PALE), accounts for a subset of HHV-6B encephalitis, and is characterized by anterograde amnesia; the syndrome of inappropriate antidiuretic hormone secretion; mild CSF pleocytosis; temporal EEG

abnormalities, often reflecting clinical or subclinical seizures; and MRI findings within the hippocampus region of the brain.[226,265]

Short of overt encephalitis, HHV-6B reactivation has also been associated with delirium and neurocognitive decline in the HCT population,[295] suggesting that the neurological impact of HHV-6B may be broader than that seen with encephalitis alone. The index of suspicion for encephalitis should be high for HCT recipients with acute encephalopathy. These patients should be tested for HHV-6B using quantitative PCR of blood or plasma and CSF.[273] Empiric therapy with foscarnet or ganciclovir is recommended for treatment of HHV-6B encephalitis,[273] and should be strongly considered while awaiting results of laboratory results.

HHV-6B has been associated with a number of other outcomes following HCT including rash, bone marrow suppression, hepatitis, lower respiratory tract disease, CMV reactivation, and acute GVHD.[3,4,26,45,202,273] Whether a causal association exists between HHV-6B and these outcomes remains to be determined; however, evidence supporting a causal association between HHV-6B and lower respiratory tract disease is accumulating. For example, studies have demonstrated detection of HHV-6B in the bronchoalveolar lavage fluid of 25% to 30% of HCT recipients with lower respiratory tract disease or idiopathic pneumonia syndrome.[100,227] In one study of 553 HCT recipients who underwent a BAL for evaluation of LRTD, HHV-6B detection in BAL fluid was associated with overall mortality and death from respiratory failure.[100] In the same study, receipt of HHV-6B-active antivirals was associated with lower levels of HHV-6B in the BAL fluid and lower mortality compared to patients without detectable HHV-6B in their BAL.

The frequency of HHV-7 reactivation following HCT is less clear as rates of viral detection in the blood have been highly variable across different studies and most studies have not found specific diseases to be associated with HHV-7 reactivation.

Solid organ transplant recipients

While HHV-6B reactivation after SOT occurs at a similar frequency and on a similar timeline as HCT, disease associations are much less frequently found. HHV-6B is not a common cause of encephalitis in SOT recipients in contrast to HCT recipients, though a wide range of clinical signs, symptoms, and entities have been associated with HHV-6B in SOT recipients including fever, cytopenias, hepatitis, gastroduodenitis, colitis, pneumonitis, and graft dysfunction and rejection.[200]

HHV-7 reactivation appears to occur at a similar rate as HHV-6B following SOT.[59] In addition, like HHV-6B, the majority of reactivation events are not associated with overt disease, though reactivation has been associated with nonspecific febrile illnesses and cytopenias.[200]

To what extent HHV-6B and HHV-7 cause poor clinical outcomes after SOT is unclear. A trial of 129 liver transplant recipients who were randomized to be monitored for HHV-6B and HHV-7 DNAemia for 12 weeks after transplantation with real-time therapeutic interventions ("monitoring/intervention" group) did not show a difference in the composite outcome of opportunistic infection, graft rejection, and severe hepatitis C virus recurrence compared to the usual care control group.[59] Therapeutic interventions for detection of DNAemia included reduction in immunosuppression and preemptive antiviral therapy, at the discretion of the patient's clinicians. In the "monitoring/intervention" group, HHV-6B and HHV-7 viremia

occurred in 23 of 64 patients (35.9%) and 21 of 64 patients (32.8%) patients, respectively. No cases of symptomatic HHV-6B and HHV-7 disease were identified. Despite the fact that some level of therapeutic intervention was performed in almost 60% of viremic episodes, there were no differences in cumulative incidence of the primary outcome between the "monitoring/intervention" group and the control group at 1 year (58.7% vs. 52.3%; odds ratio, 0.77; 95% confidence interval, 0.38 to 1.55) and 5 years after transplantation (79.0% vs. 70.3%; odds ratio, 0.63; 95% confidence interval, 0.28 to 1.42).

Acquired immunodeficiency syndrome

The possible role of HHV-6A and HHV-6B as cofactors in HIV infection has been considered because both viruses can infect CD4+ cells, and transactivate the HIV LTR.[26] In addition, they can induce CD4 gene transcription and expression in CD4-negative cells, which renders them susceptible to HIV infection. Furthermore, coinfections of macaques with HHV-6A and simian immunodeficiency virus (SIV) resulted in a plasma viremia that was associated with clinical manifestations that progressed to AIDS more rapidly than in monkeys infected only with SIV, providing *in vivo* evidence that HHV-6A may promote AIDS progression.[151]

It has been hypothesized that the most important issue with respect to HHV-6A- or HHV-6B-related disease in HIV-positive individuals may not be a direct effect on specific target organs, but by their contributing to immune deficiency.[152] Studies of HHV-6 serology or detection in the context of HIV-infected individuals versus controls have had variable outcomes making it very difficult to infer what role(s) HHV-6A of HHV-6B might play.[4,26]

Possible Disease Associations

NeoplasiaHuman herpesvirus 6 DNA has been detected in non-Hodgkin lymphoma, Hodgkin disease, S100-positive, T-cell chronic lymphoproliferative disease, oral salivary gland carcinoma tissues, pediatric and adult glial tumors, and other neoplasias.[26,38,43,55] Although there has been no conclusive demonstration that either HHV-6A or HHV-6B causes any malignancy, the frequency of detecting HHV-6 in certain tumors suggests a possible cofactorial role in multistep carcinogenesis.

Chronic fatigue syndrome Conflicting reports have appeared of a connection between chronic fatigue syndrome (CFS) and HHV-6 infection.[187] We do not consider the evidence to support an etiologic association.

Multiple sclerosis Numerous studies have found that HHV-6B and HHV-6A are commensal viruses of the human brain. Studies have variably associated serum anti-HHV-6 IgG and/or IgM, and serum DNA detection with MS.[250] However, compelling results from several studies are difficult to dismiss. For example, a longitudinal study demonstrated a higher positivity of HHV6 DNA at time of relapse when compared to remission,[18] and increasing HHV6 DNA in CSF has been associated with elevated numbers of contrast-enhancing lesions on MRI.[264] In addition, a higher prevalence of anti-HHV6 CSF IgG detection has been demonstrated in patients with MS compared to patients with other neurological diseases (34% vs. 12%, $p = 0.05$).[49] A recent study of a cohort of 8,742 persons with MS and 7,215 matched controls employed serologic assays based on the HHV-6A and HHV-6B IE1 proteins, an EBV serologic assay, and analysis of HLA haplotypes.[57] For all MS subtypes and severities of disease, a positive relationship was seen in

individuals with EBV and HHV-6A IE1 serological responses and the DRB1(*)13:01-DQA1(*)01:03-DQB1(*)06:03 haplotype.

Both indirect effects of HHV-6 via molecular mimicry between the virus and host myelin components as well as direct impact of the virus on the myelin-producing cells of the CNS have been hypothesized to explain the pathogenesis of MS.[250] Further research, including additional longitudinal cohort studies, ideally measuring both serological and viral levels in both CSF and peripheral circulation, and ultimately treatment trials, are needed to determine whether a true association exists.[129]

Other neurologic disorders HHV-6 (mostly B) DNA has been detected more frequently and at higher levels in resected brain tissues from patients with mesial temporal lobe epilepsy compared to controls, suggesting that HHV-6B may have a role in pathogenesis of the condition, though results have not been consistent across all studies.[122,129,141,276]

Progressive multifocal leukoencephalopathy (PML) is a primary demyelinating disease of the CNS, occurring almost exclusively in individuals with impaired cell-mediated immunity. The JC polyoma virus has been accepted as the etiologic agent of PML, but the question of whether herpesviruses might be associated with PML has been raised. One study found HHV-6 detection in conjunction with JC virus infection associated with the demyelinative lesions of PML.[170] However, another study did not find HHV-6 in the setting of PML but did find evidence of other herpesviruses.[179]

MyocarditisSeveral case reports of HHV-6-associated myocarditis and dilated cardiomyopathy in children and adults have been published; however, whether the association is causal remains to be determined as the virus can be detected in the heart tissue of healthy controls.[42,206]

Drug hypersensitivity Drug-induced hypersensitivity syndrome (DIHS) is characterized by a severe, potentially fatal, multiorgan reaction that usually appears after prolonged exposure to certain drugs.[4,255] Clinical signs include a maculopapular rash progressing to exfoliate erythroderma, fever, and lymphadenopathy. Reactivation of herpesviruses, including HHV-6B, HHV-7, HCMV, and EBV have been detected during severe drug-induced hypersensitivity syndrome and the related illnesses, but it is uncertain whether the virus reactivation is triggered by the disease and/or contributes to the disease.

Pityriasis rosea Pityriasis rosea has variably been associated with HHV-6 and/or HHV-7 infection or reactivation. It has also been suggested that pityriasis rosea early in pregnancy and HHV-6 viral load during pregnancy are associated with pregnancy complications.[54]

Animal Models

Animal models for HHV-6 and HHV-7 are scarce. Various groups have successfully experimentally infected various monkey species with HHV-6A/B.[142,151,281]

An *in vivo* model for immune suppression by HHV-6 was developed in severe combined immunodeficient (SCID-hu) Thy/Liv mice.[78] HHV-6A and HHV-6B efficiently infected the human thymic tissue implanted in these mice, leading to graft destruction. Virus replication was associated with severe, progressive thymocyte depletion involving all major cellular subsets. Intrathymic T progenitor cells were more severely depleted than the other subpopulations, and a

preferred tropism of HHV-6 for these cells was demonstrated. Thus, thymocyte depletion by HHV-6 may be caused by infection and destruction of their immature precursors.

Mice expressing human CD46 were developed as a model to study HHV-6A infection and pathogenesis. Although intracranial injection of HHV-6A leads to long-term viral DNA persistence, the virus does not appear to replicate efficiently.[207]

Genome analysis indicates that the mouse thymic virus is a roseolovirus. Although this virus lacks the telomeric repeats found in the DRs of HHV-6 and HHV-7, this virus could prove useful to study the pathogenesis of roseolovirus in mice.[196]

In a marmoset model, intranasal inoculation with HHV-6A or HHV-6 accelerated development of experimental autoimmune encephalomyelitis (EAE), and elevated levels of viral antigens were detected in brain lesions.[140]

Diagnosis

Diagnosis of HHV-6 and HHV-7 infections has been reviewed comprehensively elsewhere.[3,4,26,90,271,273]

Differential Diagnosis

Because the symptoms of primary HHV-6B and HHV-7 are nonspecific and the infections are generally mild and self-limiting, specific laboratory diagnosis to identify primary infection is seldom warranted. HHV-6B can be detected in the CSF of healthy children at the time of primary infection, but it is a very rare cause of encephalitis in the United States. Clinicians are often faced with the question of interpreting positive results for HHV-6B since it is now included on multiplex PCR panels for meningitis and encephalitis. Other etiologies of encephalitis, particularly those that are treatable, should be aggressively pursued.

HHV-6B is the most common cause of encephalitis in HCT recipients[218]; however, other causes of encephalitis in the immunocompromised host should be considered and testing informed by the clinical setting, season, and epidemiological exposures. For example, viral pathogens, including HSV, VZV, EBV, and CMV, should be considered in all HCT recipients, while Enterovirus and arboviruses should be considered as seasonally and regionally appropriate. Bacterial and fungal (e.g., *Aspergillus* and other molds) pathogens may disseminate from the lung or other organ systems and cause central nervous system disease. Thus, evaluation of lung and sinus imaging as well as blood cultures may be indicated, depending on the clinical setting. Finally, while they are rare causes of encephalitis, tuberculosis and parasites such as toxoplasmosis should be considered in patients from endemic regions or with pretransplant evidence of infection.

Laboratory Diagnosis

Virus detection by culture

While virus culture is seldom employed for clinical diagnosis, it remains important for research purposes. HHV-6B is easily recovered from PBMC of patients with ES during the acute phase. Lymphocyte activation with either PHA or antibody to CD3 and maintenance in IL-2 is

required.[282] A profound cytopathic effect develops within 7 to 10 days (Fig. 14.2). The refractile giant cells usually contain one or two nuclei; after CPE develops, the cells degenerate. Mononuclear cell–associated viremia caused by HHV-6 was detected in 66% of blood samples from children with ES between days 0 and 7 of the disease. The rate of virus isolation from mononuclear cells was 100% on days 0 to 2 (just before appearance of skin rash), 82% on day 3, 20% on day 4, 7% on days 5 to 7, and 0% on day 8 and thereafter. Cell-free virus was also detected in blood samples during the same period.[12] HHV-7 is sometimes isolated from peripheral blood of patients with ES, and can be readily isolated from saliva by using methods as described above for HHV-6. Isolation of HHV-6 from saliva is uncommon, although its DNA is often detectable there.

Detection of viral genome, transcripts, and proteins

HHV-6A, HHV-6B, and HHV-7 DNA are commonly detected by quantitative polymerase chain reaction assays (qPCR). Numerous primer sets have been described, including commercially available rapid quantitative and multiplex assays that enable identification and discrimination of HHV-6A, HHV-6B, and HHV-7 (fewer options).[3,4,90]

A multicenter external quality assessment among 51 laboratories that employ PCR for HHV-6 found that most labs use in-house quantitative assays, there was good qualitative agreement on specimens containing at least 200 copies/mL, but quantitative reporting was much more variable.[194] Widespread adoption of the WHO quantitative PCR standard for HHV-6B will hopefully contribute to improvement in the quality of quantitative PCR data.[81]

Latent and replicating virus can be discriminated by assays that combine reverse transcription and PCR (RT-PCR).[289] Such assays target spliced mRNAs, enabling easy discrimination between mRNA (short amplimer because of intron removal) and residual DNA contamination (long amplimer). Because HHV-6 DNA is usually cell associated,[2] it can be more useful to describe qPCR results in terms of a ratio between virus and cell genomes, rather than in terms of virus genome copies per volume of fluid (e.g., virus genomes per mL of blood) that can contain variable concentrations of cells.[73]

HHV-6 DNA is easily detectable by PCR in peripheral blood of patients with ES during the acute phase. Although detection of cell-free virus in serum or plasma by PCR offers the possibility of diagnosing active HHV-6 infections, PCR-based assays of plasma were not reliable for discriminating primary HHV-6 from iciHHV-6.[32] qPCR was less sensitive than culture for detecting primary infection, while RT-PCR was approximately as specific as culture for detection of primary infection.

A monoclonal antibody-based quantitative antigenemia assay enables enumeration of HHV-6B-infected cells and has been used to monitor HHV-6 activity in liver transplant recipients.[147]

iciHHV-6 presents several challenges to PCR-based methods for HHV-6 diagnosis.[39,89,90,198,274] Because at least one copy of the virus genome is present in every cell, high copy numbers will be detected in most clinical specimens, even if the virus is not actively replicating or otherwise contributing to the illness. Sufficient viral DNA can leak from lysed cells to cause false positives in bodily fluids that are normally relatively acellular. Cell lysis during serum clotting and during the period between blood collection and plasma separation can also lead to false positives in these acellular fluids. iciHHV-6 should be suspected when

uncommonly high levels of HHV-6 DNA are found.[89] Persistent loads greater than 5.5 $\log_{10}$ copies/mL are consistent with iciHHV-6.[198] Droplet digital PCR enables precise determination of the ratio between virus and host genomes[225,262]; integer ratios (e.g., one or two virus genomes per haploid cell genome) are reliable indicators of iciHHV-6.

Serology

Serologic assays have little clinical utility but are valuable for studies of virus prevalence and immunological reactivity in population-based studies. Numerous HHV-6 and HHV-7 serologic assays have been described,[4,26,199] including IFA, anticomplement IFA, ELISA, neutralization (NT), radioimmunoprecipitation, and immunoblot. For detection of IgM, separation of serum IgM from IgG and IgA significantly increases the specificity, but IgM testing is not useful for clinical diagnosis.[192] The products of U11 (86 kDa) and U14 (85 kDa) were identified as sensitive and specific markers for HHV-7 serology.[232] Antibody avidity assays enable identification of recent primary infections.[272] Serologic responses to HHV-6A and HHV-6B cannot be reliably discriminated by the assays described earlier.

Prevention and Control

Given that HHV-6B and HHV-7 appear to be transmitted most commonly via saliva, in the hospital setting, standard precautions will prevent spread of HHV-6B and HHV-7. For further guidance, the European Conference on Infections in Leukaemia provides evidence-based guidelines for management of roseolovirus infections in patients with hematological malignancies and after HSCT[273] and the American Society of Transplantation provides guidance in the solid organ transplantation setting.[200]

Antivirals

Ganciclovir, phosphonoformate (foscarnet), and cidofovir (including brincidofovir) are potent inhibitors of roseolovirus replication *in vitro*, and are used clinically to treat these viruses. Acyclovir (ACV) and other thymidine kinase–dependent drugs are only marginally effective.[26,45] The inhibitory effects of IFN-α and IFN-β on HHV-6 replication were also demonstrated *in vitro*, as described earlier. Ganciclovir is activated by the phosphotransferase encoded by gene U69, which can confer ganciclovir susceptibility on recombinant baculoviruses.[8] Methods have been described for rapid identification of U69 mutations in instances of clinical resistance to ganciclovir.[109] Other compounds with *in vitro* activity against HHV-6 include CMV423, a protein tyrosine kinase inhibitor,[45] and artesunate.[167] The sensitivity of HHV-7 to the guanine analogs was different from HHV-6, suggesting a difference in selectivity of specific viral enzymes.[288]

Foscarnet and/or ganciclovir are generally considered the first-line choices for treatment of HHV-6B encephalitis.[273] Strong consideration should be given to beginning empiric therapy with an HHV-6B-active antiviral (as described below) while awaiting results from laboratory testing of CSF and blood/plasma. A retrospective study using data from the Transplant Registry Unified Management Program in Japan suggested improved outcomes when full-dose ganciclovir (5 mg/kg every 12 hours) or foscarnet (90 mg/kg every 12 hours) were used to treat

HHV-6B encephalitis compared to lower doses of the same antivirals.[189] This study showed no difference in encephalitis-related outcomes in those receiving foscarnet versus ganciclovir, but there was a suggestion of improved all-cause survival in those patients receiving foscarnet. These data must be interpreted with caution given the retrospective nature of the study and the possibilities of potential confounders.

Studies of ganciclovir and foscarnet in immunocompromised hosts have demonstrated an impact on HHV-6B viral kinetics, but prospective studies of prophylactic and preemptive therapy with foscarnet have not demonstrated an impact on occurrence of encephalitis.[112,190] Thus, these strategies are generally not recommended.

Adoptively transferred HHV-6B-specific T cells can be manufactured, and results from a descriptive study of 3 patients who received infusions of such cells suggest that two of the patients may have derived some benefit.[261] Without controls, however, the true effect of this strategy remains undefined.

Further research is needed to identify effective antivirals and strategies for preventing and controlling HHV-6B infection.

PERSPECTIVE

The high prevalences of the roseoloviruses, coupled with their ability to establish lifelong infections and their relatively low associated morbidity and mortality, suggest that these highly evolved viruses have much left to teach us about host–pathogen interactions. Recent advances in diagnostics, availability of tools for genetic manipulation of the viruses, deeper understanding of virus gene expression, and advances in structural biology portend ongoing advances in our understanding of these interesting and important viruses.

Acknowledgments

Kaposi's sarcoma herpesvirus (KSHV) is the eighth human herpesvirus, originally named Kaposi's sarcoma-associated herpesvirus, and also known as human herpesvirus 8 (HHV8). KSHV is the most recently identified herpesvirus among the human herpesviruses. Chang, Moore, Cesarman, and colleagues first identified the virus from AIDS-associated Kaposi's sarcoma (KS) tissues.[106] KSHV has been classified as a member of the lymphotropic gammaherpesvirus subfamily. In this chapter, we review epidemiological evidence linking the virus to multiple human cancers, and the clinical description of these viral cancers. We also discuss the latent and lytic life cycles of KSHV and the contribution of viral genes and proteins to disease pathogenesis.

KSHV: DISCOVERY AND CLASSIFICATION

KS was first described by a Hungarian dermatologist named Moritz Kaposi in the late 19th century as "*Idiopathisches multiples Pigmentsarkom der Haut.*"[298] Classically considered an indolent disease of older men, the disease was later found to be more common in the Mediterranean region as well as parts of Africa.[17] In several regions of Africa, KS afflicts children as well as adults. Prior to the emergence of HIV infection in the human population KS was considered a rare neoplasm in the United States and Western Europe. However, with the advent of pandemic HIV in the early 1980s, KS emerged as the most common AIDS-defining cancer. The linkage between KS and HIV infection first prompted speculation that HIV was the etiological agent of KS, but this was disregarded in light of many epidemiological studies. First, classical KS occurred before the AIDS epidemic and was originally seen in HIV-negative individuals. Second, even among HIV-positive subjects, certain groups are distinctly different in their risk for KS development. KS was more widespread among patients who acquired HIV via sexual routes (e.g., men who have sex with men or MSM), compared to individuals who acquired HIV parenterally (e.g., children and hemophiliacs[41]). These data suggested that KS

might be acquired by a sexually transmitted pathogen other than HIV, which initiated a hunt for the etiological agent in question. In 1994, Yuan Chang, Patrick Moore, and their colleagues[106] identified KSHV genomic DNA in KS lesions using representational difference analysis.

It is now generally accepted that there are four main classes of KS, only one of which is strongly linked to HIV infection:

1. Classic KS
2. Endemic or African KS
3. Iatrogenic KS associated with immunosuppressive therapies in transplant patients.
4. Epidemic or AIDS-related KS

Although KSHV was first identified in an endothelial-driven tumor, it was later found to be associated with lymphoproliferative disorders, which were greatly increased in AIDS patients. The KSHV genome is consistently present in two B cell lymphoproliferative diseases.[95,567] One such disease is *primary effusion lymphoma* (PEL), which is an expansion of B cells predominantly in serosal cavities such as the pericardium, pleura, and peritoneum, although infiltration of solid organs does occur. B cells in PEL are clonal in origin, as discovered by analysis of immunoglobulin rearrangements. Every PEL cell harbors KSHV DNA in the form of a circular episome. These are in multiple copies. Some PELs also harbor Epstein-Barr virus (EBV), but KSHV is the defining pathogen for a diagnosis of PEL.

PEL cell lines can be established in culture relatively easily[96] and form tumors in immunodeficient mice.[85,572] PEL cell lines were the first system where KSHV replication could be induced *in vitro*,[512] and have yielded latent and lytic antigens for serologic test development.

Another B-cell disorder associated with KSHV infection is multicentric Castleman disease (MCD). MCD is a polyclonal[170] lymphoproliferative disorder that can develop in both HIV-negative and HIV-positive individuals. MCD is an aggressive disorder that has a higher incidence in AIDS patients, where it is always associated with KSHV infection.[567] It is a systemic disease characterized by fever, loss of weight, sweats, splenomegaly, and lymphadenopathy. The KSHV viral genome is present in the B cells of the mantle zones surrounding the germinal centers. In a given germinal center, upto 30% of the mantle zone B cells appear to be infected with virus.[173,483] All the KSHV-positive cells in MCD bear lambda light chains together with IgM heavy chains.[170] In HIV-negative individuals, less than 50% of all MCD cases are linked to KSHV infection.[567]

The KSHV genomic sequence confirmed the classification of the virus as a member of the lymphotropic (or γ-) herpesviruses (Fig. 15.1). Lymphotropic herpesviruses can be further divided into two groups: the γ1 or *lymphocryptoviruses* (which includes EBV and its simian relatives) and the γ2 or *rhadinoviruses*. KSHV falls squarely into the latter category, which also includes the prototype primate virus, Herpesvirus saimiri (HVS). With the identification of additional primate rhadinoviruses, it is now evident that rhadinoviruses are represented by two different lineages, based on their biological properties and genomic organization—one lineage is represented by KSHV and a primate virus named retroperitoneal fibromatosis herpesvirus (RFHV), and a second group is represented by HVS and rhesus monkey rhadinovirus (RRV) (reviewed in Ref.[53]).

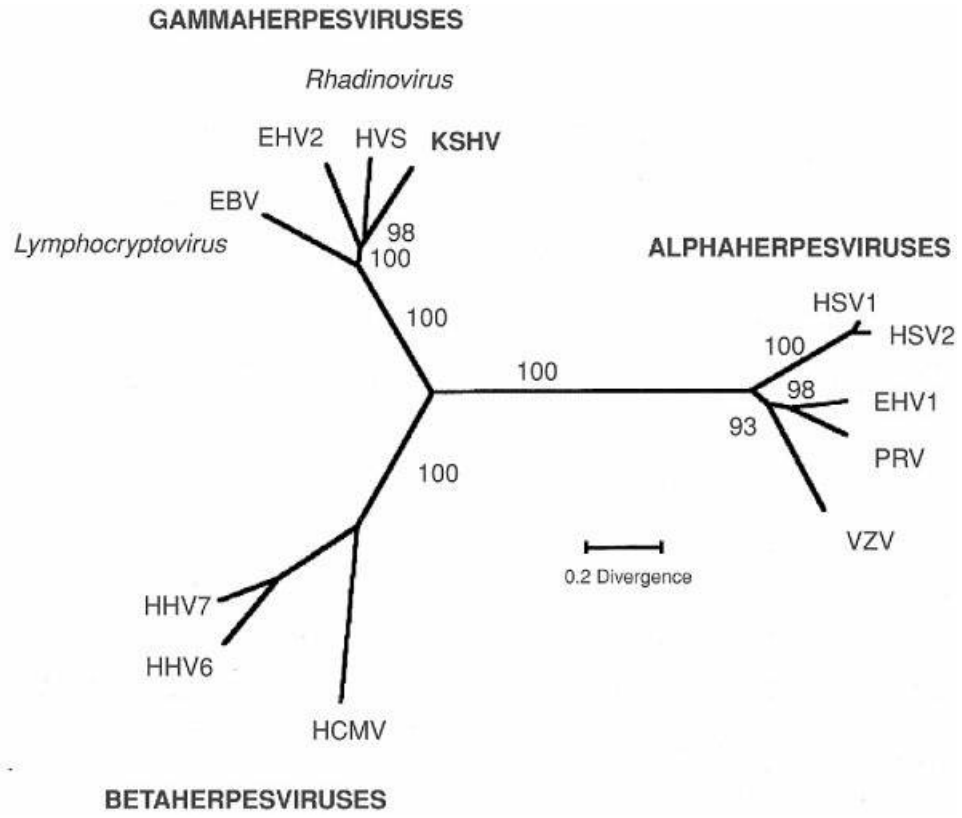

FIGURE 15.1 A radial phylogenetic tree was constructed based on comparisons of the herpesviral DNA polymerase proteins from twelve primate herpesviruses showing the relationships between members of the alpha-, beta- and gammaherpesvirus subfamilies. The human alpha herpesviruses include herpes simplex virus (HSV)1 and HSV2 and varicella–zoster virus (VZV); human beta-herpesviruses include cytomegalovirus (CMV), HHV6, and HHV7; and human gamma-herpesviruses include Kaposi's sarcoma herpesvirus (KSHV) and Epstein-Barr virus (EBV). KSHV is the first human rhadinovirus, the prototype member of which is HVS (Herpesvirus saimiri). Other viruses shown are equine herpesvirus (EHV) 1 and EHV2 and pseudorabies virus (PRV). A bar showing 0.2 divergence is depicted. (Reprinted from Moore PS, Gao SJ, Dominguez G, et al. Primary characterization of a herpesvirus agent associated with Kaposi's sarcomae. *J Virol* 1996;70(1):549–558.)

VIRION STRUCTURE

Structurally similar to virions of other herpesviruses, KSHV virions exhibit an electron-dense nucleocapsid surrounded by a lipid bilayer envelope as visualized by electron microscopy (EM). In between the capsid and envelope is a morphologically amorphous but highly organized proteinaceous layer called the tegument. The envelope is studded with viral glycoproteins—for example, glycoprotein gB is thought to engage cell surface receptors and participate directly in viral entry. The virion contains six other glycoproteins including ORF22 (gH), ORF39 (gM),

ORF47 (gL), ORF53 (gN), ORF68, and K8.1.[695] Little is known regarding the architecture of the tegument. However, multiple proteins have been identified that localize to this region.[38,695] KSHV tegument proteins share the common feature in that they are delivered to the target cell along with the genome upon primary infection, and may thus contribute to early events in the replication cycle even before the synthesis of immediate-early proteins. This is also the case for the 11 viral mRNAs that are incorporated in the tegument layer.[37] These virion mRNAs are derived from viral transcripts expressed in the prior lytic cycle and are incorporated into the tegument during the process of budding and envelopment. It is likely that one or more mRNAs are selectively incorporated into the virus particle.[37,38] How such targeted recruitment might occur is unknown.

The KSHV capsid, like its HSV and HCMV counterparts, is icosahedral. A significant amount of work has been done to characterize the KSHV capsid structure in terms of its three-dimensional architecture and polypeptide composition.[462] Cryo-EM reconstruction has revealed that the icosahedral capsid is symmetric (T= 16) with 20 triangular faces. There are three types of capsid structures as identified by electron microscopy: an empty capsid shell (A-capsid), a capsid containing scaffolding protein (B-capsid), and a capsid encapsidating the viral genome (C-capsid) (Fig. 15.2).[158,462]

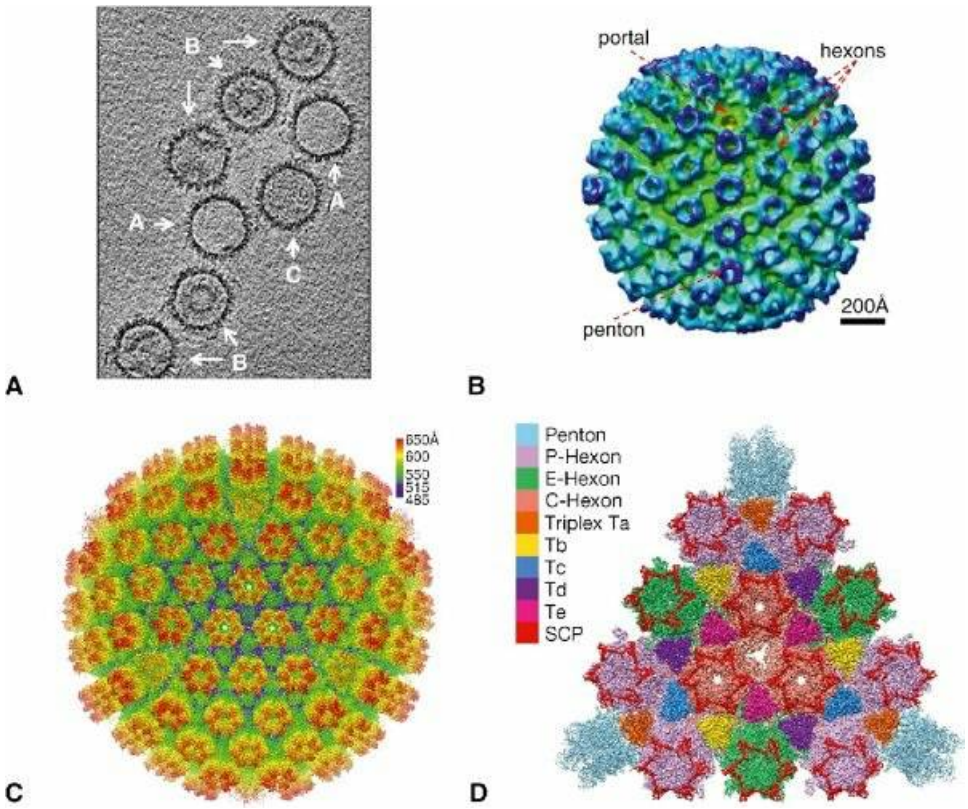

FIGURE 15.2 KSHV A-, B-, and C-capsid. A: Central slice of a tomogram showing the KSHV A-, B-, and C-capsid. **B:** Radially colored surface representation of an averaged KSHV capsid showing the characteristic herpesvirus capsomers, including an "umbilical" portal, 11 pentons and 150 hexons. **C:** Cryo-EM reconstruction and atomic modeling of KSHV capsid. Structure and mutagenesis reveal essential capsid protein interactions for KSHV replication. *Nature* 2018;553(7689):521–525. Copyright © 2018 Springer Nature.)

The capsomers are composed of hexamers and pentamers of the major capsid protein (MCP encoded by ORF25). Each capsid contains 150 hexons and 12 pentons, which are interconnected by 320 triplexes that are heterotrimer structures composed of ORF62 (1 copy) and ORF26 (2 copies). The capsomeric hexons form the capsid edges and faces, whereas the pentons are located at each capsid vertex (Fig. 15.2). The KSHV smallest capsid protein (SCP) is required for capsid assembly. It forms a crown on each hexon and cross-links adjacent MCP subunits. SCP binds MCP through hydrophobic interactions and SCP has a kinked helix that connects to neighboring MCPs[145] (Fig. 15.2). A 4.2 angstrom structure of the KSHV capsid by cryo-electron microscopy shows that the capsid contains 46 unique conformers of the MCP, the SCP and the triplex proteins Tri1 and Tri2[146] (Fig. 15.2). A hydrophobic residue containing groove present in MCP interacts with the SCP, which can cross-link with adjacent MCPs in the same hexon resulting in capsid stabilization.[146] Two Tri2 molecules and one Tri1 molecule form a triplex. The triplex binds to the capsid floor via Tri1.[146]

For the most part, the KSHV capsid resembles the features of the well-studied HSV-1 capsid, with the exception that the KSHV hexons lack the presence of a VP26 subunit, which is seen bound to the HSV-1 hexon subunits, and the KSHV triplexes appear smaller and less elongated than those of HSV-1. The viral linear genomic DNA is located inside the capsid.

THE KSHV GENOME: STRUCTURE AND ORGANIZATION

The KSHV genome is a double-stranded linear DNA that is 165 to 170 kb long.[523] The genome is composed of a central unique region of 145 kb encoding the viral open reading frames (ORFs).[523] The central region is flanked by highly GC-rich direct terminal repeats (TRs) (Fig. 15.3). Each TR unit is 85% GC rich and is 801 bp long. Commonly, viral isolates contain 20 to 25 kb of TR DNA per genome; however, the exact number of TRs present at each terminus differs.

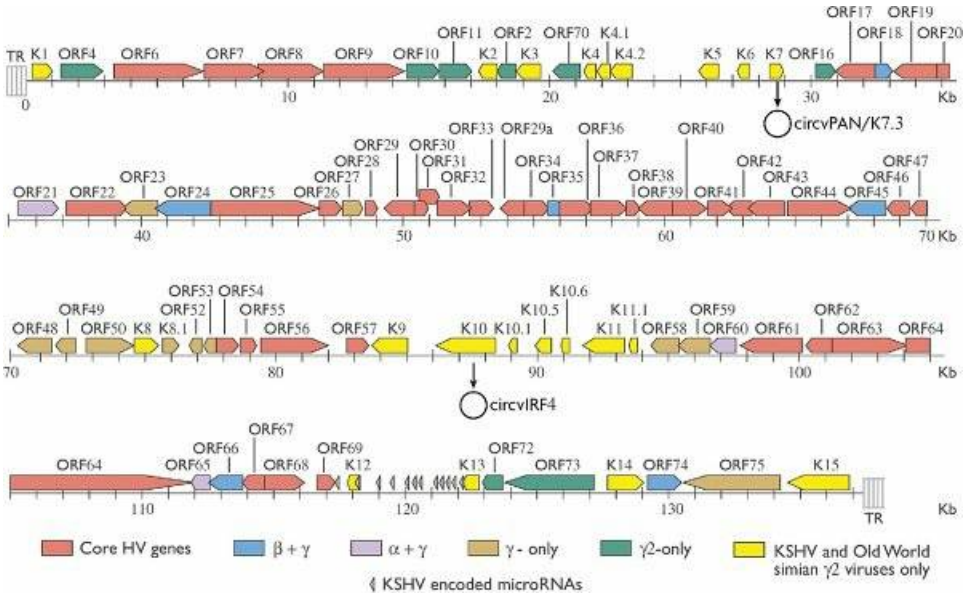

FIGURE 15.3 The KSHV (HHV8) genome map. Blocks of conserved genes between KSHV and related α, β, γ herpesviruses are indicated by the same color. *Arrows* indicate open reading frames (ORFs), with direction of *arrow* indicating direction of translation.

Comparison of the KSHV genome sequence with other herpesviruses reveals blocks of highly conserved genes that are common to all herpesviruses (Fig. 15.3). These are typically genes that encode for proteins involved in viral replication or proteins that encode for structural components of the virions. In addition, there is a group of genes that show homology to the gammaherpesvirus (γ1 and γ2) lineage, and those that are only common to the γ2 lineage. Finally, there are also a group of genes that are only encoded by KSHV and its simian relatives but not present in other herpesviruses from nonprimate species, for example, KSHV viral interleukin 6 (vIL-6), viral interferon regulatory factors (vIRFs), etc. (Fig. 15.3).

The KSHV ORFs are numbered in consecutive order from left (ORF 1) to right (ORF 75). KSHV contains numerous ORFs that are not conserved in other herpesviruses, and these are interspersed amongst the conserved herpesvirus genes. The KSHV unique ORFs are given “K” designations, ORFs K1-K15, numbered from left to right (Fig. 15.3). Some of the K open-reading frames encode for more than one protein due to alternative splicing and/or alternative translational initiation sites. Many of the K ORFs encode signaling molecules and proteins that are homologs of cellular genes, for example, vIL-6, vIRFs, etc. The KSHV genome also encodes for many small noncoding RNAs, including a set of micro RNAs[78,489,527] and a noncoding lytic 1.1 kb nuclear RNA named PAN that is polyadenylated.[134,578] Moreover, the KSHV genome also encodes for circular RNAs.[587,598,606]

Genetic Analysis of KSHV

Construction of mutant viruses using homologous recombination has revolutionized the study of replication and pathogenesis of herpesviruses. Two methods have been used to generate recombinant KSHV viruses. In earlier work, PEL cells were transfected with a targeting vector

encoding the viral gene of interest, disrupted by a GFP cassette and selectable marker. Stable GFP-positive cells were selected, followed by viral reactivation with 12-*O*-tetradecanoylphorbol-13-acetate (TPA) and supernatants were then tested for GFP transduction capacity.[618] Others have used BACmid technology to construct a KSHV BACmid.[69,692] Recombinant viruses deleted for several open reading frames and miRNAs have been described in the literature. In addition, replication-competent, KSHV viruses with markers (GFP and RFP) to track latent (GFP) and lytic (RFP) infection have been constructed[69,616] and are highly beneficial for studies of viral infectivity. Table 15.1 lists the KSHV viral genes, proteins, and their corresponding EBV homologs.

TABLE 15.1 KSHV genes and their homologs in EBV

KSHV Gene	Other KSHV Name	EBV Gene	Function
K1			Signaling protein
ORF4	KCP		Complement binding protein
ORF6		BALF2	ssDNA binding protein
ORF7		BALF3	DNA packaging terminase
ORF8	gB	BALF4	Glycoprotein B
ORF9		BALF5	DNA polymerase
ORF10	RIF		
ORF11		Raji LF2	
K2	vIL-6		IL-6 homolog
ORF02			DHFR
K3			Membrane-associated RING-CH (MARCH) ubiquitin lig
ORF70			Thymidylate synthase
K4	vMIP-II/vCCL2		Chemokine
K5			Membrane-associated RING-CH (MARCH) ubiquitin lig
K6	vMIP-I/vCCL1		Chemokine
K7			
ORF16	vBcl-2	BHRF1	Bcl-2 homolog
ORF17		BVRF2	Protease
ORF17.5	SCAF		Scaffold protein
ORF18		BVLF1	
ORF19		BVRF1	Virion protein
ORF20		BXRF1	
ORF21	vTK	BXLF1	Thymidine kinase
ORF22	gH	BXLF2	Glycoprotein H
ORF23		BTRF1	
ORF24		BcRF1	Transcription factor
ORF25	MCP	BcLF1	Major capsid protein
ORF26	Triplex 2	BDLF1	Capsid protein
ORF27		BDLF2	
ORF28		BDLF3	
ORF29b		BDRF1	Packaging protein
ORF30		BDLF3.5	
ORF31		BDLF4	
ORF32		BGLF1	Virion protein
ORF33		BGLF2	Virion protein
ORF29a		BGRF1	Packaging protein
ORF34		BGLF3	
ORF35		BGLF3.5	
ORF36	vPK	BGLF4	Viral protein kinase
ORF37	SOX	BGLF5	Exonuclease/Host shutoff
ORF38		BBLF1	
ORF39	gM	BBRF3	Glycoprotein M

KSHV Gene	Other KSHV Name	EBV Gene	Function
ORF40		BBLF2	Primase-associated factor
ORF41		BBLF3	Primase-associated factor
ORF42		BBRF2	
ORF43		BBRF1	Capsid protein
ORF44		BBLF4	Helicase
ORF45		BKRF4	Immune evasion
ORF46		BKRF3	Uracil DNA glycosylase
ORF47	gL	BKRF2	Glycoprotein L
ORF48		BRRF2	
ORF49		BRRF1	
ORF50	RTA	BRLF1	Lytic transactivator
K8	K-bZIP		
ORF52	KicGAS	BLRF2	Tegument protein/immune evasion
ORF53		BLRF1	Glycoprotein N
ORF54		BLLF3	dUTPase
ORF55		BSRF1	
ORF56		BSLF1	Primase/DNA replication protein
ORF57	MTA	BSLF2/BMLF	Posttranscriptional regulator of gene expression
K9	vIRFI		Immune evasion
K10	vIRF4		Immune evasion
K10.5/10.6	vIRF3/LANA2		Immune evasion
K11/K11.1	vIRF2		Immune evasion
ORF58		BMRF2	
ORF59		BMRF1	Polymerase-associated processivity factor
ORF60		BaRF1	Ribonucleotide reductase, small
ORF61		BORF2	Ribonucleotide reductase, large
ORF62	Triplex I	BORF1	Capsid protein
ORF63		BOLF1	Tegument protein/immune evasion
ORF64		BPLF1	Deubiquitinase
ORF65	SCP	BFRF3	Small capsid protein
ORF66		BFRF2	
ORF67		BFRF1	Tegument protein
ORF68	gN	BFLF1	Glycoprotein N
ORF69		BFLF2	
K12	Kaposin		
K13	vFLIP		viral FLICE inhibitory protein
ORF72	vCyclin		Cyclin D homolog
ORF73	LANA		Latency-associated nuclear antigen
K14	vOX-2		CD200/OX-2 homolog
ORF74	vGPCR		viral G-protein coupled receptor
ORF75		BNRF1	Tegument protein/FGARAT
K15			Signaling protein

THE VIRAL LIFE CYCLE

Viral Binding and Entry

KSHV is able to infect multiple cell types *in vitro* and *in vivo*. KSHV binds to and enters a variety of human cell lines and primary cells in culture, including transformed B cells, primary B cells, 293 human embryonic kidney cells, THP-1 monocytic cells, myeloid and plasmacytoid dendritic cells, primary monocytes, human foreskin fibroblasts, HeLa epithelial cells, mast cells, and endothelial cells. KSHV can also infect monkey cells such as Vero and CV-1, hamster cells such as BHK-21 and CHO cells, and mouse cells *in vitro*.

KSHV encodes for multiple envelope glycoproteins, including gB, gH, and gL. Attachment

of the virion to the cell is thought to be mediated by several host receptor proteins as described below and highlighted in Figure 15.4.

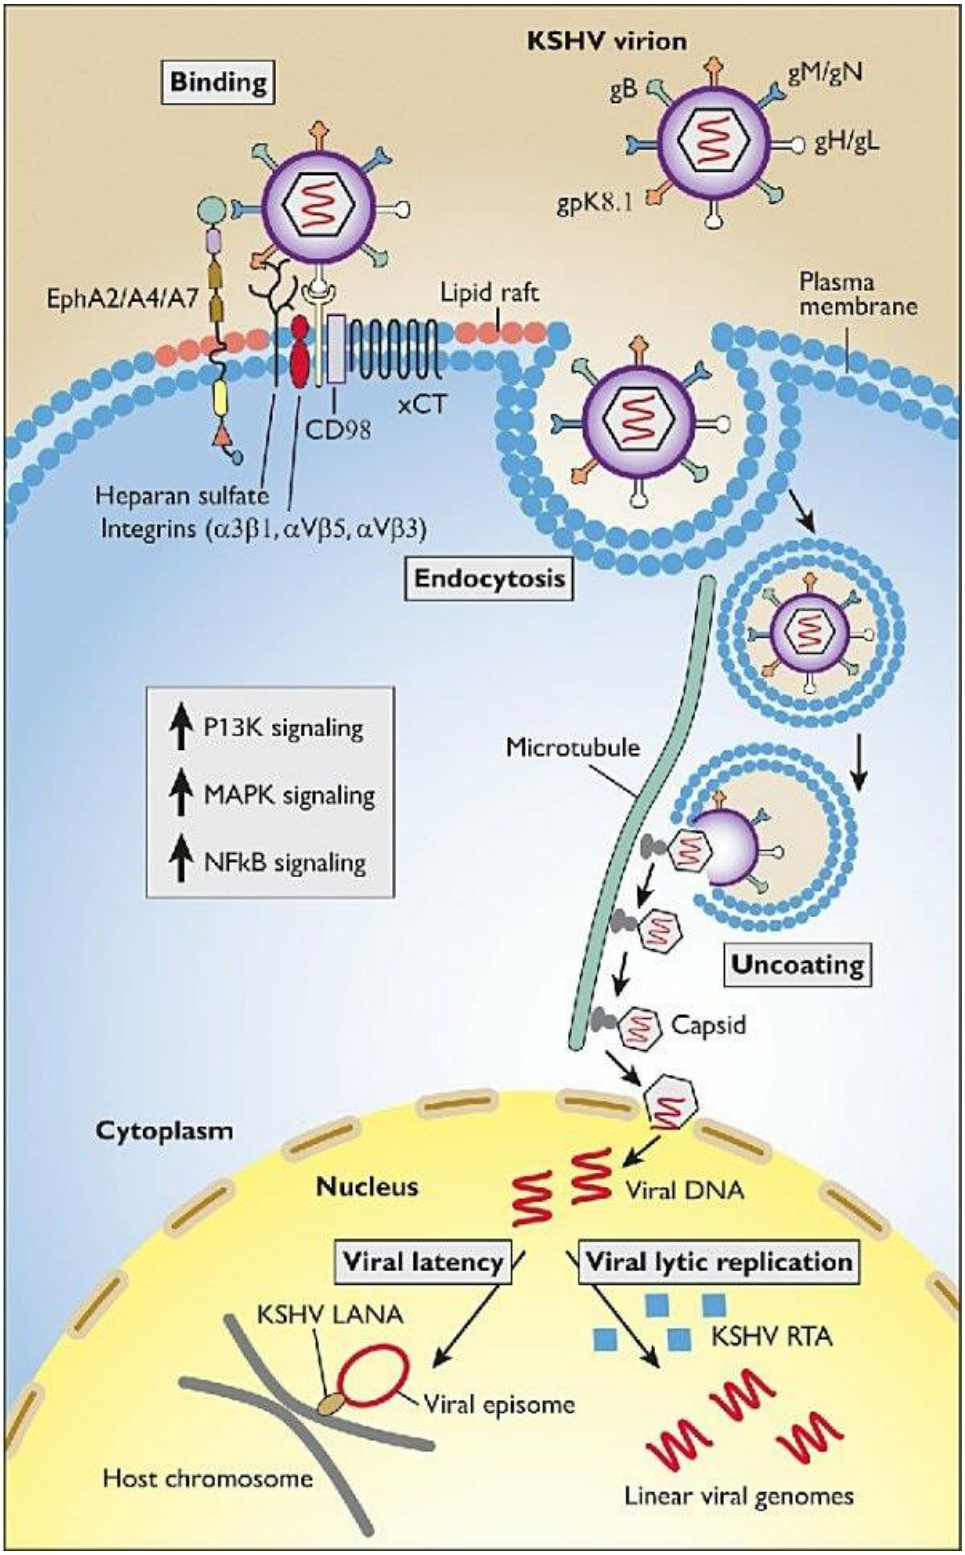

FIGURE 15.4 KSHV entry. Virion binding, attachment, and entry into the host cell. The different stages of KSHV entry are highlighted. Once the viral genome enters the nucleus, the decision to enter the latent or lytic phase of the life cycle is made.

Heparan Sulfate

Several glycoproteins encoded by KSHV have been shown to bind heparan sulfate present on the surface of the cell. These include KSHV gB, gH, ORF4, and gpK8.1A.[7,49,458] The fact that the virus encodes four proteins that bind to heparan sulfate highlights the importance of this protein for attachment. Binding to heparan sulfate may contribute to efficiency of infection, since soluble heparan competes and hinders binding and impairs (but does not eliminate) infectivity. Thus, similar to HSV, the role of heparan sulfate binding helps to concentrate virus particles on the cell surface, thereby increasing their effective local concentration for interactions with cell surface receptors.

Integrins

Chandran and colleagues were the first to identify an integrin binding motif—the RGD (Arg-Gly-Asp) motif, contained in the KSHV gB glycoprotein and showed that it contributes to KSHV binding and entry.[7,8] A twofold reduction in KSHV infection of endothelial and fibroblast cells was observed upon treatment with RGD peptides or antibodies against RGD-gB peptide.[8] Conversely, blocking of integrins using anti-integrin α3 or β1 antibodies, also prevented KSHV entry.[8] Moreover, integrin-independent entry has also been described for KSHV.[591]

DC-SIGN

Dendritic cell-specific intercellular adhesion molecule 3 (ICAM-3)-grabbing nonintegrin (DC-SIGN; CD209) is expressed on activated B cells, dendritic cells (DCs), and macrophages. KSHV is thought to bind DC-SIGN since KSHV infection can be blocked by an anti-DC-SIGN monoclonal antibody and soluble DC-SIGN.[507] However, similar to the situation with the integrins mentioned above, these agents did not completely prevent KSHV binding to the cell suggesting that additional binding partners may exist, for example, heparan sulfate (Fig. 15.4). The incomplete inhibition of viral entry by the integrin-blocking antibodies supports the notion that although integrins play an important role in viral entry, other host proteins may also be involved in KSHV entry.

xCT

xCT is a 12-transmembrane glutamate/cysteine exchange transporter protein that has also been proposed to be a KSHV entry receptor.[295] xCT is part of the cell surface CD98 (4F2 antigen) complex containing a common glycosylated heavy chain and a group of 45-kDa light chains; the xCT molecule is one of the light chains. Expression of recombinant xCT protein in cells that are not permissive for infection restores permissivity to KSHV infection. Additionally, antibodies against xCT block infection.[295] Generally, xCT exists as a heterodimer with CD98, and this complex can associate with cell surface integrins, for example, α3β1. Collectively, these studies demonstrate the interactions of KSHV with closely linked cellular receptor proteins, for example,

heparan sulfate, integrins, and xCT, in different cell types[609] (Fig. 15.4). Additionally, there are likely to be many different entry pathways *in vivo*. Of note, the KSHV-encoded microRNAs were reported to up-regulate xCT expression in macrophages and endothelial cells, through miR-K12-11 suppression of the transcriptional repressor, BACH-1.[498,557] The up-regulation of xCT by the KSHV miRNAs increased cell permissiveness for KSHV infection and protected infected cells from death induced by reactive nitrogen species.[498]

Ephrin Receptors

The ephrin receptor tyrosine kinase A2 (EphA2) has also been shown to be a cellular receptor for KSHV in endothelial and epithelial cells.[241] Furthermore, EphA2 was shown to interact with KSHV gH-gL.[240,241] EphrinA2 can modulate clathrin-mediated KSHV endocytosis involving integrin-associated signaling and c-Cbl polyubiquitination.[175] EphA2 was further reported to synergize with CIB1 to facilitate macropinocytic entry of KSHV in dermal endothelial cells.[30] Recently, Ephrin Receptor A4 (EphA4) was also shown to function as a KSHV entry receptor.[122]

Mechanisms of Viral Entry

Endocytosis is the predominant mode of KSHV entry *in vitro* for both adherent and nonadherent target cells. KSHV utilizes clathrin-mediated endocytosis and a low pH environment for its infectious entry into human foreskin fibroblasts (HFF) cells.[9] Studies also suggested endocytosis as the mode of KSHV entry in activated primary human B cells.[507]

Binding of the virus to the cell not only promotes viral entry but also triggers host cell signaling cascades, which may modulate the cellular microenvironment to enhance virus infection. For example, binding of the cell surface integrins by KSHV triggers phosphorylation and activation of focal adhesion kinase (FAK). This activates several signaling molecules including PI3K, Src, Rho GTPases (RhoA, Rac, and Cdc42), and Diaphanous 2 (Dia2). Downstream effector molecules of these signaling moieties are also consequently activated and include Akt, Ezrin, protein kinase C (PKC), MEK, ERK1/2 (extracellular signal-regulated kinase), NFκB, and p38MAPK.[329] Signal transduction does not need active viral replication, since UV-inactivated virions also elicit signaling, and signaling is inhibited by soluble α3β1 integrin peptides. FAK-PI3K activation induced by KSHV binding also activates Rho GTPase and induces cytoskeletal rearrangements.[545,546]

Following virion binding, cellular kinases are activated leading to the recruitment of signaling molecules to the plasma membrane. These signaling proteins then rapidly translocate to clathrin, caveolae, and other vesicles. Src-mediated phosphorylation of clathrin induces the translocation of clathrin to the plasma membrane where it interacts with AP2, Eps15, and dynamin.[425] Src-initiated phosphorylation also triggers the assembly of the plasma membrane–associated Ras activation complex leading to the downstream activation of Rho and Rab GTPases by Ras and PI3K. The Rho and Rab GTPases play critical roles in the formation and movement of endocytic vesicles. These various KSHV-induced signaling events are summarized below.

1. KSHV binding to integrin triggers FAK activation, which appears to be critical for viral entry.[322,545]

2. The activation of FAK and Pyk2 leads to the activation of the Src kinase family, which subsequently activates PI3K and Rho GTPases. Inhibitors of PI3K reduced viral entry suggesting that PI3K's activation of Rac, Rho, Cdc42, and Rab5 GTPases is critical for viral entry since they induce actin reorganization and provide the mechanical force required for endosome formation and trafficking. Induction of the downstream modulator, Akt kinase, early during the entry process may be beneficial for triggering a pro-survival environment in the infected cell.[322,502,545]
3. PI3K and Rho GTPase activation leads to cytoskeletal rearrangements and the formation of structures such as lamellipodia (Rac), stress fibers (RhoA), and filopodia (Cdc42). This allows for microtubule acetylation and the thickening of microtubule bundles. This process is also essential for delivery of the viral capsids to the nuclear membrane via the microtubules.[459,608]
4. KSHV also activates the ERK1/2 signaling pathway and the NFκB pathway. These pathways are thought to be important for viral gene expression.[458,481,546,666]

The viral capsids traverse down the microtubules towards the nuclear membrane. Consistent with this description, microtubule-depolymerizing agents block infection.[459] It is thought that the capsid then injects the viral genomic DNA into the nucleus through the pore complex. Once the viral DNA enters the nucleus, the virus has a choice to enter either the lytic phase of its life cycle or the latent phase (Fig. 15.4). During latency, the genome is circularized and subsequently is organized into chromatin through the assembly of cellular histones, thereby making it a suitable template for host RNA polymerase II transcription. During lytic replication, the virus is in a linear state amenable for viral DNA replication.

The Innate Immune Response Following Viral Entry

Toll-like receptors (TLRs) are the first line of defense against invading pathogens. They recognize pathogen-associated molecular patterns (PAMPs) present on invading pathogens and trigger signaling cascades, which lead to the activation of type I IFN, NF-κB and many other pro-inflammatory cytokines. Some TLRs are expressed on the cell surface, for example, TLR2 and TLR4, while others are expressed in the endosome, for example, TLR 3,7,8, and 9.[6] TLRs 3, 7, and 8 are activated by RNA. TLR3 recognizes dsRNA, while TLR7 and TLR8 recognize ssRNA. It is important to note that different cell types have distinct TLR expression profiles; hence, TLR recognition of an invading pathogen is dependent on the cell type being infected.

During infection of primary human monocytes, KSHV activates TLR3 resulting in the up-regulation of TLR3 expression (both mRNA and protein are increased) and its downstream mediators, including IFN-β1 and the chemokine CXCL10 (also called IP-10).[644] As mentioned above, KSHV is known to be endocytosed in monocytes, and during this process it is possible that the viral RNA transcripts present in the tegument of the virus trigger TLR3 activation. In human plasmacytoid dendritic cells (pDCs), which are the chief IFN producing cells in the body, KSHV infection triggers the activation of TLR9, a TLR whose agonist is CpG DNA.[645] Thus, in pDCs, TLR9 is likely recognizing KSHV viral DNA. Unlike monocytes, human pDCs do not express TLR3 and only express TLR7 and TLR9. Finally, TLR4 appears to be important for recognition of KSHV in endothelial cells, since the virus can down-regulate TLR4 expression on endothelial cells.[332] Both vIRF1 and vGPCR are involved in TLR4 down-regulation.[332]

TLRs also play a role in a very different context, for example, during reactivation from latency. Stimulation of TLR7/8 in KSHV latently infected PEL cells, either by synthesized agonist (poly-Uridine) or by infection with a biologically relevant pathogen, vesicular stomatitis virus (a known activator of TLR7 and -8), led to viral reactivation and progeny virion production.[220] This represents a new role for TLR stimulation in the context of KSHV infection (which differs from the role TLRs play during primary infection) and suggests a possible physiological stimulus that can lead to viral reactivation *in vivo*.[220]

Additional sensors that detect KSHV during infection include the nucleotide-binding domain, leucine-rich repeat protein (NLR) receptors, RIG-I-like receptors (RLRs), interferon gamma–inducible protein 16 (IFI16), and cGAS-STING sensors. During primary infection, KSHV can be detected by the NLR family members, NLRP1 and NLRP3,[221] as well as IFI16.[310] The RLR family members, RIG-I and MDA5, can activate interferon signaling in response to KSHV infection.[646,688,690] In contrast, NLRX1 and adenosine deaminase acting on RNA 1 (ADAR1) was shown to be proviral and required for KSHV reactivation from latency.[396,689] Finally, another pathway important for KSHV sensing is the cGAS-STING DNA signaling pathway.[395,466,661,686]

OVERVIEW OF THE LYTIC AND LATENT PHASES OF THE KSHV LIFE CYCLE

Following successful primary infection, KSHV can establish either a lytic or a latent state in the infected cell. Subsequent to initial viral infection, the host cell microenvironment is thought to govern the decision of which life cycle phase the virus enters. The default program appears to be latency. The kinetics of lytic versus latent gene expression during primary infection was examined in KSHV-infected endothelial cells and fibroblasts.[321] ORF50/RTA levels were detected 2 hours postinfection but declined thereafter. Conversely, low levels of the latency-associated nuclear antigen (LANA) were seen at first but expression increased substantially 48 to 72 hours postinfection. The latent genes were expressed continually while lytic viral gene expression declined.[321] Thus, concurrent expression of lytic and latent genes occurs immediately following viral infection, but only latent gene expression persists. It is thought that the minimal or marginal expression of lytic genes, many of which play key roles in immune evasion, cell proliferation, and prevention of apoptosis, could be necessary for the establishment and maintenance of latent infection *in vivo*.[226,321]

Latency is the default pathway in most, if not all, experimental situations, and no virions are produced during this stage. During latency, viral gene expression is limited to only a subset of viral genes. The latent viral genome in the nucleus is replicated as an episome by host cellular DNA polymerase, and the replicated genomes are evenly distributed to the daughter cells. Although latently infected cells do not make virus, they maintain the viral genome and thus retain the potential for virus replication and virion production. Upon different exogenous stimuli, latently infected cells can undergo reactivation, a process that switches the virus from latency back into lytic replication mode. Physiological stimuli that reactivate KSHV are not well defined,

but in tissue culture several molecules can reactivate the virus including phorbol esters, histone deacetylase inhibitors, TLR agonists, bacterial coinfection, natural products from endemic regions, calcium ionophores and IFN-γ.[51,220,441,512,649,681] Additionally, cell differentiation has also been shown to induce KSHV lytic replication.[290]

During lytic infection, the entire viral genome is expressed in a temporally regulated transcriptional cascade. Similar to other herpesviruses, the first genes that are expressed are known as the immediate-early (IE) genes. IE genes encode for transcriptional factors and regulatory proteins. The key lytic switch regulator is encoded by ORF50. ORF50 encodes for a protein called RTA (replication and *t*ranscription *a*ctivator). Expression of RTA is sufficient to initiate the lytic replication cycle. The second temporal class of mRNAs encode for the delayed-early (DE) genes. The function of DE genes is to ready the cell for viral DNA replication and viral protein production. The DE genes encode for proteins (enzymes, cofactors) that are involved in viral DNA replication, proteins that affect nucleotide precursor pools and host transcription, as well as proteins involved in immune evasion. Once DE expression is under way, lytic cycle DNA replication commences in the nucleus and the viral genomic DNA is replicated to produce many copies of the viral DNA per cell. Subsequent to the onset of replication, the late (L) genes are synthesized. Late genes are those that encode for viral structural proteins. These proteins are made after viral DNA replication since they are required in vast quantities. Late proteins are made after viral replication as they often need to be transcribed from genomic templates that have accumulated to a high enough copy number following viral genome replication.

After all three classes of IE, DE, and L genes are transcribed, virus assembly takes place in the nucleus. Newly replicated viral genomes are incorporated into newly synthesized viral capsids, which subsequently acquire their teguments by a poorly defined process. The capsids subsequently bud through host membranes in a series of steps in order to acquire a host-derived membranous envelope containing KSHV glycoproteins. Finally, viral progeny are released from the host cell. A more detailed view of KSHV latency and lytic life cycles is described below.

The transition to latency is not seamless. Following the first 12 hours postinfection, virus infected cells display both lytic and latent gene expression.[321] The lytic transcript profile is nontemporal in that different classes of IE, DE, and L genes are expressed simultaneously.[321] It is possible that at least some of these lytic transcripts are delivered to the cell via the incoming virion tegument, which contains eleven viral lytic mRNAs that are assimilated into the virion during assembly.[37] Alternatively, some of these transcripts could represent genuine transcription using the host cell machinery. Some studies[38,337] but not all[695] have detected small amounts of the lytic switch protein, ORF50/RTA, in virions, which may contribute to this process. However, why the presence of ORF50 does not trigger the full lytic cascade is unknown and may depend on the host cell environment and the lack of sufficient amounts of cellular proteins required for lytic replication. Virion-encapsidated viral genomes do not appear to harbor bound histones unlike the viral episomes found in latently infected cells.[573] Several lytic transcripts represent inhibitors of apoptosis and viral mediators of immune evasion.[321] Twenty-four hours postinfection, lytic gene expression declines, resulting in only latent gene transcription in the infected cell.

Approximately 24 to 48 hours postinfection, the classical latency program is established in nearly all the infected cells, except for a small percentage (1% to 5%) of cells that enter the lytic

cycle. The frequency with which lytic infection ensues following *de novo* infection is related to the multiplicity of infection (MOI) and the cell type. For example, a high MOI in primary endothelial cells favors early progression into the lytic cycle. However, even under such circumstances, lytic replication tends to subside a few days postinfection, and the latency program dominates.

Our knowledge of the KSHV latent program comes from the study of PEL cell lines. These cells were originally isolated from PEL patients and subsequently propagated in cell culture.[95,512] PELs stably maintain latent KSHV genomes and they express latent viral proteins in most of the cells. Although it is likely that latent gene expression in these cultured PEL cell lines is not representative of true latency *in vivo per se*, for the most part mRNA transcripts identified in PEL are detected in other contexts, for example, cell lines infected with KSHV *in vitro* as well as primary KS tumors.[162]

KSHV gene expression is complicated by the fact that a clear demarcation of latent versus lytic genes cannot always be made. For example, some genes are said to be expressed during latency, for example, LANA, while other genes are expressed only during lytic replication, for example, RTA/ORF50. However, although RTA is only expressed during the lytic cycle, LANA expression is observed during latency and lytic replication suggesting a gray area in which some latent genes continue to be expressed at low levels during lytic replication, while other latent genes are expressed during latency and then highly up-regulated during lytic replication.

It is widely accepted that LANA; vFLIP; vCyclin; kaposins A, B, and C; and v-IRF3 (aka LANA-2) are latent genes in PEL cells,[163,516] as are the 12 pre-microRNAs (pre-miRNAs).[78,527] However there has been considerable debate about whether additional genes might also be expressed in latently infected cells, and several groups have shown that additional genes are expressed under some latent conditions. There is a class of genes that is expressed at low levels during latency but is highly up-regulated during lytic infection, for example, vIL-6, K1[59,60,81,104,483,534,570,633] and K15.[2] Originally these genes were classified as purely lytic genes, but more sensitive techniques indicate that these genes are also expressed at low levels under conditions in which there is no lytic gene expression.[2,59,60,104,633] For K1, one compounding factor is that the protein is highly variable and so antibodies against K1 from one strain may not readily recognize K1 from another strain making protein expression analysis more difficult.[59,118,633] It is also worth mentioning that in EBV, genes at the same genomic positions as K1 and K15 have been shown to be expressed during EBV types II and III latency, and encode transforming abilities raising the possibility of different latency patterns occurring during the KSHV viral life cycle.

In PEL, KSHV reactivation from latency is not one hundred percent. During reactivation, low levels of latent gene expression can be detected in the background of lytic gene expression[181,285,534] due to the fact that it is usually not possible to reactivate all of the latent cells. Thus, there is always a background of latency. Finally, some viral gene products, for example, vIRF3/LANA-2 are expressed in latent PELs but are not detected in latent KS spindle cells[516] while vIRF1 has been detected in latently infected KS cells but not in latently infected PELs.[162] In EBV, three latent transcriptional programs have been described. Hence, the fact that KSHV also has a complex gene expression pattern should not be surprising.

In the following section, we first review the general patterns of latent and/or lytic transcription and then review the functions of these viral proteins.

The Latent Phase

Latent Transcripts

In PEL cells, the major latency transcript arises from a single genomic region, located between the K12 and ORF74 open-reading frames. At least two latent promoters are active, each of which initiate synthesis of a group of transcripts (Fig. 15.5). The first transcripts discovered originated from the LANA promoter, located just upstream of the LANA gene (ORF73).[163,535] This promoter appears to be constitutively active. In transgenic mice, the LANA promoter drove LacZ expression mostly in B cells, though a few epithelial cells also demonstrated LANA expression.[182,287] LANA promoter activity can be enhanced by exogenous expression of LANA, suggesting autoregulation of this transcript *in vivo*.[288] Additionally, there exists a second promoter element (just upstream of the latent LANA promoter) that up-regulates LANA transcription in the presence of increased RTA expression.[337,415,571] There also exists a third latency promoter embedded within the LANA-vFLIP transcription unit which drives the vCyclin and vFLIP transcript, as well as the kaposin transcript.[363,487] All these promoters also drive transcription of the viral miRNAs which are located in an intron obtained by read-through of the vFLIP-distal polyA-element and subsequent splicing.[77,527]

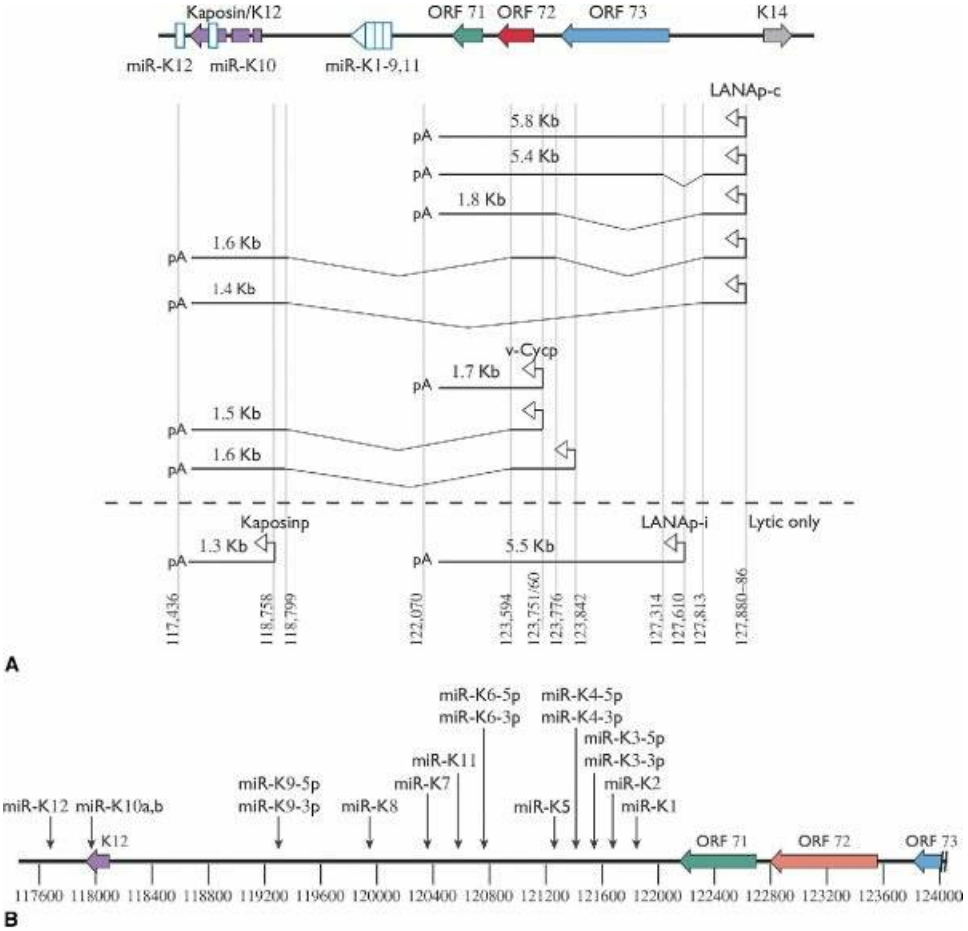

FIGURE 15.5 Map of known transcripts emanating from the main latency region of KSHV. A: *Top line* shows map of the major genomic ORFs (*arrows*), as well as the positions of most of the known microRNAs. Two major latency promoters exist: one 5′ to ORF73, the other just 5′ to ORF72; each of these can generate the indicated spliced mRNA isoforms. Additionally, a lytic cycle promoter drives transcription of a 1.3 kb kaposin (K12) transcript. All mRNAs are polyadenylated at the indicated positions. LANAp-c refers to the LANA promoter, which is expressed constitutively, and LANAp-i refers to the LANA promoter used during reactivation. (Modified by permission from Springer: Yuan Y, Renne R. Organization and Expression of the Kaposi's sarcoma-associated herpesvirus genome. In: Damania B, Pipas JM, eds. *DNA Tumor Viruses*. New York: Springer; 2009:469–493. This is a complex region of the viral genome since it has a nested arrangement of divergent promoters of latency genes (LANA, vCyclin, vFLIP, viral miRNAs) and lytic genes (vGPCR and K14). Thus, this region has a complex structure and intricate regulation so that lytic transcripts are suppressed during latent gene expression. CTCF, a cellular protein that functions at chromatin boundaries, and cohesins, proteins that mediate sister chromatin cohesion, also bind to a specific site within the KSHV major latency control region.[574] KSHV genes regulated by the CTCF–cohesin complex are under cell cycle control, and mutation of the CTCF binding sites abolished cell cycle–regulated transcription.[121,296,366] The cohesins interact with CTCF in mid-S phase and repress CTCF-regulated genes in a cell cycle–dependent manner. Deletion of the CTCF–cohesin binding site in the KSHV genome caused an inhibition of cell growth as well as viral genome instability. Thus, CTCF and cohesins play a critical role in regulating viral gene expression during latency as well as during reactivation.[296,366,574]

The LANA promoter primarily drives transcription of three genes, ORF 73 (LANA), ORF72 (vCyclin) and ORF 71 (vFLIP), which utilizes both alternative splicing and internal translational initiation.[163] Figure 15.5 depicts the spliced mRNAs generated from this locus; all of these spliced transcripts are polyadenylated at a common site downstream of ORF 71. The ORFs 73-72-71 tricistronic mRNA exists as an unspliced transcript, and another transcript with a small splice in its 5′ untranslated region (UTR). An even more highly expressed transcript is a spliced bicistronic transcript composed of ORFs 72-71. This mRNA encodes both vCyclin (ORF72) and vFLIP (ORF71). vCyclin is translated by conventional cap-dependent initiation, while vFLIP (ORF71 or K13) translation is thought to occur through the use of an internal ribosome entry site (IRES) element located within the open-reading frame of ORF72.[224]

The second set of major latent transcripts in this region encodes for proteins from the kaposin locus (Fig. 15.5). All mRNA transcripts originating from this locus are polyadenylated at a common site downstream of ORF K12. These transcripts include both ORF K12 and the upstream direct repeat sequences named DR1 and DR2. When these mRNAs are translated they generate kaposins A, B, and C proteins.[524] Several latent promoters regulate the initiation of transcripts from this region. LANAp is an RTA/ORF50-inducible LANA promoter.[571] One transcript maps upstream of ORF 72 and is spliced to a region just upstream of the direct repeats in latent PEL.[77,363,487] Extensive transcript mapping has identified multiple spliced latent transcripts (all capable of expressing kaposins). Some of these transcripts originate from the

LANA promoter through alternative splicing that removes the ORFs 71 to 73 (Fig. 15.5).[77,487] The spliced kaposin transcripts also encode for many of the viral microRNAs (miRNAs).[77,78,227,489,527] The vast majority of these miRNAs map to the region upstream of the kaposin DRs, which is essentially the intron of the latent kaposin pre-mRNAs while some miRNAs map to the mature kaposin transcript (Fig. 15.5). The miRNAs are derived by Drosha-mediated processing.

Interestingly, KSHV RNA transcripts contain N6-methyladenosine (m6A) and N6,2′-*O*-dimethyladenosine (m6Am) modifications. This is true for both the latent and lytic phases. YTH N6-Methyladenosine RNA Binding Protein 2 (YTHD2) binds to viral transcripts and stabilizes them. Depletion of YTHD2 augments lytic replication by preventing the degradation of KSHV RNA.[257,590]

KSHV Latent Proteins

Latency-Associated Nuclear Antigen

LANA, the product of ORF73,[305,306,503] is a large and multifunctional protein that is present in the nucleus of latently infected cells. LANA exhibits characteristic punctate foci in the nucleus when examined by immunofluorescence and immunohistochemistry assays. LANA is highly immunogenic and antibodies against LANA were the first utilized serologic markers of KSHV infection. LANA-specific CD8 T-cell responses have also been observed. LANA has been detected in PEL and KS tumor cells *in vivo*, in B cells in MCD, and in every latent cell type infected *in vitro*. It was recently demonstrated that EBV infection increase KSHV LANA expression and genome maintenance.[48] LANA has three major domains: an N-terminal domain involved in chromatin attachment and corepressor recruitment, a central region composed of highly acidic amino acid repeats, and a C-terminal basic region involved in DNA binding and oligomerization. LANA interacts with many viral and cellular proteins to exert its function.

The most well-characterized function of LANA is its involvement in the establishment and maintenance of the nuclear latent viral genome[27,139] (Fig. 15.6). The episomal viral genomes established in the nucleus during latency are replicated by the host DNA polymerase during cell proliferation in order to be passed on to the daughter cells. LANA plays many roles in this latent replicative process. It directly binds DNA sequences within the TRs, which contains the latent origin of replication,[26,140,203,218,254] and induces a bend. An x-ray crystal structure of the LANA C-terminal DNA binding domain (DBD) revealed that it can form a decameric ring with an exterior DNA binding surface.[168]

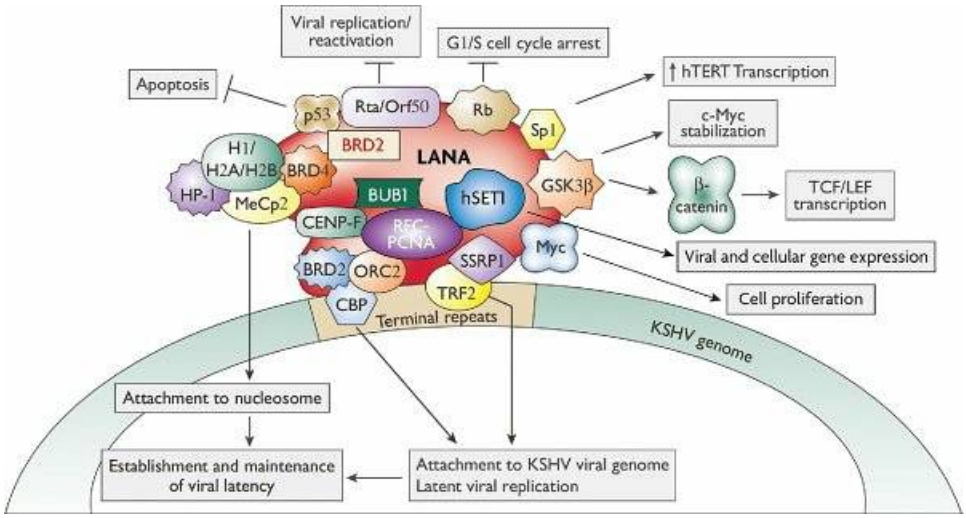

FIGURE 15.6 LANA interaction partners. Functional consequences of the interaction of LANA with other cellular and viral proteins.

The LANA-TR interaction initiates semiconservative replication by recruitment of the host DNA replication machinery to the viral episome.[225,268] This also includes the recruitment of replication factor C (RFC) and the DNA polymerase clamp (proliferating cell nuclear antigen [PCNA]) loader[581] as well as Bub1.[582] Each 801-bp-long TR contains a high- and a low-affinity LANA binding site (LBS1 and LBS2, respectively). LBS1 and 2 are separated by 22 nucleotides. There is a GC-rich replication element (RE), which is LANA binding site (LBS3), that lies upstream of the LBS 1 and 2. Deletion of this element hinders origin activity[267,613] suggesting that the RE is the site for binding of cellular proteins involved in latent replication. In sum, LANA and the TR sequences recruit the host cell origin recognition complex (ORC) and minichromosome maintenance (MCM) proteins.[573,612] LANA's C-terminal DBD binds the TRs at two sites which helps to recruit ORC and MCM.[203,268,573,612] Although the C terminal domain of LANA is sufficient for latent replication, the N-terminal chromosomal binding domain enhances latent replication, a fact that reveals that both replication and maintenance are interlinked.[31,268] LANA also binds to multiple viral and cellular promoters and associates with the H3K4methyltransferase hSET1 complex[270] and recruits the polycomb repressive complex (PRC) to the viral genome to suppress lytic gene expression following de novo infection[600] (Fig. 15.6).

The TRs undergo reorganization in late G_1/S phase when replication licensing and initiation occur.[573] The structure-specific recognition protein 1 (SSRP1) and telomeric repeat binding factor 2 (TRF2) bind to LANA and the TR region[269] to facilitate viral episomal replication during latency.[269] The LANA-TR interactions are similar to the EBV EBNA 1-oriP complex, although LANA does not show significant sequence homology to EBNA1, and the EBV oriP sequence is very different from the LANA binding elements of the TR. Yet, the LANA C-terminal DBD shows some similarity to EBNA-1 in terms of predicted secondary and tertiary structural motifs.[225] Viral genomes are replicated once per cell cycle in synchrony with replication of the cellular genome.[613]

Semiconservative replication is not sufficient to explain the establishment of stable KSHV

latency. A mechanism must exist in proliferating cells to ensure the proper segregation of replicated KSHV genomes to the daughter cells. Here too, LANA plays a critical role. Transfected plasmids with KSHV TR elements joined to a drug-resistance selectable marker produced stable colonies at a higher frequency when LANA was present than in its absence.[27,139] Such colonies display stably maintained circular genomes over subsequent generations as is seen in PEL cultures. In interphase cells, viral genomes appear to be localized to LANA-containing dots or puncta. In mitotic cells, LANA and the viral episome colocalize to mitotic chromosomes. Thus, LANA can bind to mitotic chromosomes through its N-terminal domain. These data are suggestive of a model in which the N-terminus of LANA binds to the mitotic chromosome and tethers the viral genome (bound via its C-terminus) to this structure.[32,665,679] This allows for the segregation of the tethered latent episomes to both daughter cells following mitosis. Tethering occurs through multiple protein–protein interactions, including binding to histones H2A to H2B, H1, centromeric protein F (CENP-F), budding uninhibited by benzimidazole 1 (Bub1), Brd4, and Brd2/RING3.[32,136,139,253,619,665,679] Genetic evidence for this mechanism comes from the observation that a KSHV recombinant virus with a disrupted LANA gene does not generate a stable latent episome following primary infection.[674]

Viral episome maintenance is complex. In cells harboring the KSHV genome that do not make use of drug-resistance marker inserted in the viral genome, LANA, while necessary for plasmid maintenance, is not always sufficient. When LANA expression plasmids and the TRs are introduced into cells, the resulting episomes are lost during the process of cell division.[226] This suggests that viral latency requires the *in vivo* environment and continued lytic replication.[226,446] In certain cell lines, it has been shown that small subpopulation of cells do exhibit stable genomes and enter permanent latency similar to the case in PEL tumor cell lines. In these cases the viral genome undergoes epigenetic changes that enable its being stably maintained in the cell.[226,233]

Curiously, the KSHV genome also contains a cis-acting DNA element within the long unique region that can initiate and support replication of plasmids lacking LANA-binding sequences or a eukaryotic replication origin. The replication machinery proteins, ORC2 and MCM3, associate with this sequence and are required for replication of this element. Thus, KSHV can initiate DNA replication of its genome in the absence of LANA or any other viral protein.[614]

Aside from its function in maintenance of the KSHV latent genome, LANA is also involved in the dysregulation of cell growth and survival. Transgenic mice expressing LANA from the latent promoter display splenic follicular hyperplasia and increased germinal center formation[182] as well as an increased response to antigen stimulation.[253,555] Some of the older animals developed B-cell lymphomas. The slow onset of lymphomagenesis suggests that LANA itself may not be sufficient for transformation and requires additional genetic changes once LANA drives the expansion of B cells, which is likely the result of LANA-mediated proliferation or LANA's ability to augment cell survival.

There have been many biochemical studies looking at LANA interactions with cellular proteins. It has been found that LANA binds p53, and LANA-expressing cells display less activation of p53-dependent reporter genes and also are more resistant to p53-dependent apoptosis induced by γ-irradiation.[187] At the same time, most PELs respond to p53-activating DNA-damaging agents.[488] LANA expression in endothelial cells extends their life span,

although this does not lead to immortalization.[640] LANA can also activate survivin[388] and pro-angiogenic pathways.[639]

LANA has been shown to bind the tumor suppressor Rb,[501] and this binding functionally inactivates Rb resulting in increased E2F-dependent reporter gene activation in the presence of LANA. LANA can also interact with GSK-3β, a kinase that phosphorylates and inactivates β-catenin by targeting it for ubiquitin-mediated degradation.[191] LANA binding to GSK-3β induces the kinase to move from the cytosol to the nucleus, allowing for cytoplasmic accumulation of β-catenin. Cytosolic β-catenin can then interact with the transcription factor, LEF, which relocates it to the nucleus, where this complex up-regulates proliferative genes, for example, cyclin D and c-myc. Additionally, LANA expression in other cell types induces S-phase entry.[191] LANA has also been reported to enhance the stability of the c-Myc protein through its effects on GSK-3β nuclear localization. In LANA-expressing cells, inactivation of nuclear GSK-3β inhibited c-Myc phosphorylation at threonine 58 and contributed to c-Myc stabilization by decreasing c-Myc ubiquitination.[73,381] Furthermore, LANA induces genetic alterations through chromosomal instability by regulating Bub1 and Shugoshin-1 (Sgo1).[339]

LANA also impacts host gene expression through binding of multiple components of the transcriptional machinery. Gene expression profiling of LANA-positive B cells identified many host genes whose expression is dysregulated by LANA.[513] LANA can transcriptionally modulate genes in the Rb/E2F pathway[13,513,656] (Fig. 15.6). Although LANA can activate transcription of some cellular genes,[13,513,656] LANA primarily mediates repression of transcription. LANA inhibits expression of TR-linked reporter genes and when fused to the DBD of GAL4, LANA does inhibit transcription of GAL4-dependent reporters.[203,539] LANA also binds the co-activator CBP to repress transcription by inhibiting its histone acetyl transferase (HAT) activity. LANA interacts with RBP-Jκ (also called CSL), and is targeted to RBP-Jκ sites in the ORF50 promoter,[336] where it again mediates repression. Further, LANA can inhibit the activated intracellular domain of notch (ICN)-mediated transactivation of ORF50 thereby preventing lytic reactivation.[338]

The physiological role of LANA-mediated repression might affect cell survival and/or proliferation. It may function in the repression of lytic cycle viral genes thereby allowing for establishment and maintenance of viral latency. This likely also applies to the many other nuclear proteins that can bind to LANA, for example, the methyl CpG binding protein (MeCP2), the bromodomain-containing RING3 protein 2 (Brd2), nuclear matrix proteins, and heterochromatin protein 1.[372,493] LANA also contributes to the epigenetic profile of KSHV episomes through the hSET1 complex.[270]

Specific caspase cleavage sites in KSHV LANA appear to thwart apoptosis and prevent caspase-1-mediated inflammasome activation.[151] Finally, LANA cytoplasmic isoforms are also generated through the use of noncanonical internal translation initiation sites within the N-terminal domain that do not encode a nuclear localization sequence.[597] The LANA cytoplasmic isoforms have been shown to inhibit the DNA sensor, cGAS[686] and also regulate the members of the MRN (Mre11-Rad50-NBS1) repair complex to inhibit DNA sensing.[408]

vCyclin

As described above, the KSHV latency transcripts also encode two other proteins in addition to

LANA. ORF72 encodes vCyclin, which shows homology to cellular cyclin D. The vCyclin transcript is made by splicing out the LANA gene, yielding a bicistronic ORF 72+ 71 transcript whose 5′ gene encodes vCyclin (see Fig. 15.5). Similar to its cellular homolog, vCyclin can bind and activate CDK6.[107] However, it differs from host cyclin D in that it is less active on CDK4 and although both can induce CDK6-mediated Rb phosphorylation, the viral cyclin can also activate phosphorylation of p27, histone H1, nucleophosmin (NPM), Id-2, and cdc25a.[144,361] NPM is a nuclear phosphoprotein and a histone chaperone involved in transcription and chromatin organization. Phosphorylation of NPM by the vCyclin/CDK6 complex allows NPM to interact with LANA and regulate viral latency.[533] Exogenous vCyclin expression can promote S-phase entry in 3T3 cells, and also overcome Rb-mediated cell cycle arrest triggered by CDK inhibitors[584] (Fig. 15.7). Overall, the vCyclin/CDK6 complex is less sensitive to inhibition by CDK inhibitory proteins like p27, p21, and p16. Inactivation of p27 is mediated by phosphorylation, and p27 phosphorylation by vCyclin-CDK6 targets it for degradation, further impairing p27 control of CDK6. vCyclin can also interact with CDK9 leading to increased phosphorylation of p53 at serine 33, which results in cell cycle arrest.[105] Consistent with this report, overexpression of vCyclin in multiple cell types induces apoptosis.[473] vCyclin has been demonstrated to promote KSHV-induced cellular transformation and tumorigenesis by overriding contact inhibition.[292]

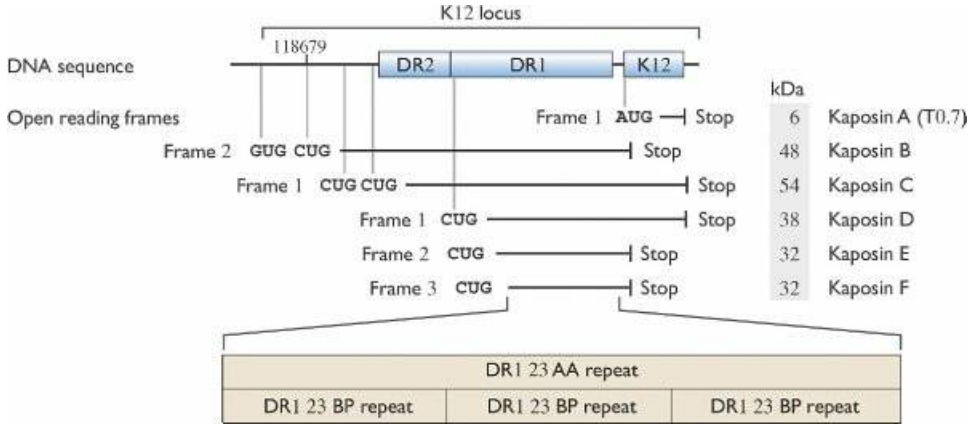

FIGURE 15.7 The coding capacity of the kaposin locus. Top line: Coding organization of kaposin mRNA. **Middle panel:** Protein products predicted from translation of each of the several CUG codons of kaposin. Kaposins A, B, and C are products of this locus. It is unclear as to whether the lower molecular weight species listed here as kaposins D,E, and F—which are regularly observed in infected cells—are in fact translated from the indicated CUG (as shown) or if they represent proteolytic end products of the larger kaposins.

However, there are some discrepancies. For example, although vCyclin overexpression destabilizes p27, PELs routinely display high levels of p27 expression and establishing stable cell lines expressing vCyclin has been difficult since such cells often undergo apoptosis, especially if they display high levels of CDK6.[473]

vCyclin-induced apoptosis is linked to the inactivation of the antiapoptotic factor Bcl2[474] due

to its phosphorylation by vCyclin/CDK6. Thus, the low levels of vCyclin protein expression during latency likely represent one way the virus avoids triggering cellular apoptosis. Alternatively, another viral protein might ablate this apoptotic effect. Along this vein, it is of interest that Verschuren et al.[615] demonstrated that loss of p53 allows for cell survival in the presence of increased levels of vCyclin. Moreover, when vCyclin was expressed in B cells in transgenic mice, lymphomas developed only in animals deleted for p53.[615] This suggests that the functional inactivation of p53 by LANA during latency (or by vIRF3; see below) might unmask the oncogenic potential of vCyclin. The antiapoptotic effects of vFLIP may also alleviate vCyclin-induced toxicity.

A different line of transgenic mice was made in which vCyclin was expressed in only the lymphatic endothelium through the use of the VEGF-R3 promoter. These mice displayed severe lymphatic dysfunction, and developed chylous ascites. The reason for this is unknown but might reflect the toxicity of vCyclin overexpression. Indeed, in human dermal microvascular endothelial cells, vCyclin induces replicative stress leading to the development of senescence and activation of the DNA damage response.[320] It has recently been shown that KSHV-infected PELs are highly dependent on cyclin D2 as well.[407]

vFLIP
