Preface

In the early 1980s, Bernie Fields originated the idea of a virology reference textbook that combined the molecular aspects of viral replication with the medical features of viral infections. This broad view of virology reflected Bernie's own research, which applied molecular and genetic analyses to the study of viral pathogenesis, providing an important part of the foundation for the field of molecular pathogenesis. Bernie led the publication of the first three editions of Virology, but he unfortunately died soon after the third edition went into production. The third edition became *Fields Virology* in his memory, and it is fitting that the book continues to carry his name. A number of changes and enhancements have now been introduced with the seventh edition of *Fields Virology*. The publication format of *Fields Virology* has been changed from a once every 5 to 6 years, two-volume book to an annual publication that comprises approximately one-fourth of the chapters organized by category. The annual publication provides both a physical book volume and importantly an e-book with an improved platform. Using an e-book format, our expectation is that individual chapters can be easily updated when major advances, outbreaks, etc., occur. The editorial board organized the four-volume series for the seventh edition to consist of volumes on Emerging Viruses, DNA Viruses, RNA Viruses, and Fundamental Virology, to be published on an annual basis, with the expectation that the topics will cycle approximately every 4 years creating an annualized, up-to-date publication. Each volume will contain approximately 20 chapters. The first volume of this seventh edition of *Fields Virology*, entitled Emerging Viruses and edited principally by Sean P. J. Whelan, was published in 2020. The second volume, DNA Viruses, has been principally edited by Jeffrey I. Cohen, Blossom Damania, Peter M. Howley, and David M. Knipe. There have been continued rapid advances in virology since the previous edition, and all of the chapters in the DNA Viruses volume are either completely new or have been significantly updated to reflect these advances. In this seventh edition, we have chosen to highlight important references published since the last edition while maintaining older classics. The main emphasis continues to be on viruses of medical importance and interest, but other viruses are described in specific cases where more is known about their mechanisms of replication or pathogenesis.

We wish to thank Patrick Waters of Harvard Medical School and all of the editorial staff members of Wolters Kluwer for their important contributions to the preparation of this book.

Introduction

DNA Viruses is the second volume of the seventh edition of *Fields Virology*. The first volume, Emerging Viruses, was published last year. The next two volumes, RNA Viruses and Fundamental Virology, will be published annually in subsequent years. There have been continued rapid advances in virology since the sixth edition that was published in 2013, and all of the chapters in the DNA Viruses volume are either completely new or have been significantly updated to reflect these advances. In this seventh edition, we have chosen to highlight important references published since the last edition while maintaining older classics.

This volume covers all of the DNA viruses of medical importance, including viruses that infect humans and animals. DNA viruses of plants, insects, and bacteria will be included in the fourth volume of the seventh edition, Fundamental Virology. In addition to DNA virus families, several thematic issues arise in the consideration of the DNA viruses in this volume. First, the smaller DNA viruses induce cell cycle progression because their genome replication is dependent on host cell DNA replication factors. When dysregulated, the viral activation of host cell DNA replication can lead to cellular proliferation and initiate oncogenic transformation pathways. In addition, some DNA viruses induce proliferation of the host cells and inhibit cellular differentiation in which they are persisting, thus expanding the number of persistently infected cells. Induction of cellular DNA replication factors and inhibition of cellular differentiation is often affected by the inhibition of tumor suppressor genes and pathways by specific DNA viral proteins encoded by these DNA tumor viruses. Indeed, just as oncogenic retroviruses led to the identification of cellular oncogenes, the DNA tumor viruses led to the identification of specific tumor suppressor genes, perhaps the best example being TP53. Second, DNA viruses manipulate the host transcriptional apparatus to allow efficient expression of their genes, and these regulatory systems have elucidated important mechanisms of eukaryotic gene expression. DNA viruses also encounter the host cell epigenetic silencing mechanisms and have evolved mechanisms to allow efficient gene expression for productive infection or silenced gene expression for latent infection, providing important model systems for the study of epigenetic regulation. Third, DNA viruses can often persist in the host cells by the establishment of persistent and sometimes latent infections. The mechanisms by which they do so vary somewhat among the different DNA viruses. The DNA genomes that persist in replicating cells are maintained in cells by the tethering of the viral genomes to cellular chromosomes by viral proteins that bind the viral genomes during mitosis. These systems have informed us about the mechanisms by which viruses can persist in the host organism. Fourth, many of the DNA viruses, including the parvoviruses, the adenoviruses, and some of the herpesviruses, have proven to be effective tools as vaccine platforms and as vectors in gene therapy and oncotherapy.

The organization of the chapters in this edition is similar to that of the previous editions. For most of the viruses, there is a single chapter that combines both the basic and clinical aspects of the virus. For several of the viruses, the basic virology related to viral replication and the viral pathogenesis are split between two chapters. In the DNA volume, this includes the papillomaviruses, the adenoviruses, the human herpesviruses, and the poxviruses. We are grateful to Jeff Cohen and Blossom Damania who joined us as the senior editors who

participated in putting this volume together. We also are thankful to the chapter authors who have updated their chapters for this volume and to the new authors who have joined us in this continued endeavor to provide a comprehensive resource in virology.

CHAPTER 1

Polyomaviridae

James A. DeCaprio • Michael J. Imperiale • Hans H. Hirsch

History
Classification
Virion structure
Genome structure and organization
- Structure of T antigens

Stages of replication
- Mechanism of attachment
- Entry, intracellular trafficking, and uncoating
- Transcription
- Translation
- Replication of viral genomic DNA
- Assembly
- Release

Pathogenesis and pathology
- Entry into host
- Immune response
- Persistence
- Transformation

Epidemiology
Clinical features
- BKPyV-associated diseases
- JCPyV-associated diseases
- Merkel cell polyomavirus and Merkel cell carcinoma
- Other HPyV-associated diseases
- SV40 and humans
- Avian polyomavirus and disease

Perspective

HISTORY

Polyomaviruses are found ubiquitously in a broad range of mammalian, avian, fish, and other species. These viruses can cause severe illness and death on an epidemic scale in birds and raccoons. By contrast, human polyomaviruses typically cause lifelong and asymptomatic

infections but can lead to severe illness in immunocompromised patients. Recognition of the ubiquitous presence of polyomaviruses in their natural hosts as well as their disease-causing ability has prompted intensive research efforts.

Polyomaviruses are composed of nonenveloped capsids with a circular double-stranded DNA (dsDNA) genome of approximately 5,000 base pairs containing a single origin of replication and a bidirectional promoter that drives expression of messenger RNA (mRNA) transcripts encoding five to nine proteins. The small size of the polyomavirus (PyV) genome, comparable to a simple plasmid, and its limited number of genetic elements with potent biological activities have fostered research that continues to be at the forefront of biology in the fields of DNA replication, gene expression, signal transduction, and oncogenesis.

The history of PyV research began in the 1950s when Ludwig Gross noted that serial passage of mouse leukemia virus in mice occasionally led to the development of parotid gland tumors instead of leukemia.[112] He isolated this specific activity and demonstrated that the parotid agent differed from murine leukemia virus in its sedimentation, filtration, and heat stability properties. Stewart and colleagues observed the formation of more than 20 different tumor types in newborn mice inoculated with this agent and coined the name *polyomavirus*, derived from the Greek word *poly*, meaning many and *oma*, denoting tumor.[317] The mouse polyomavirus is often called simply "polyomavirus" but will be referred to as MPyV in this chapter, consistent with the most recent taxonomic classification (Table 1.1; Fig. 1.1).[230] Discovered at the same time as MPyV, murine pneumotropic virus (MPtV), also known as Kilham virus or K virus, can cause severe interstitial pneumonia in newborn mice.[110,167]

TABLE 1.1 Polyomaviruses highlighted in this chapter are listed by genera. Informal and species names, abbreviation, and GenBank identification are provided

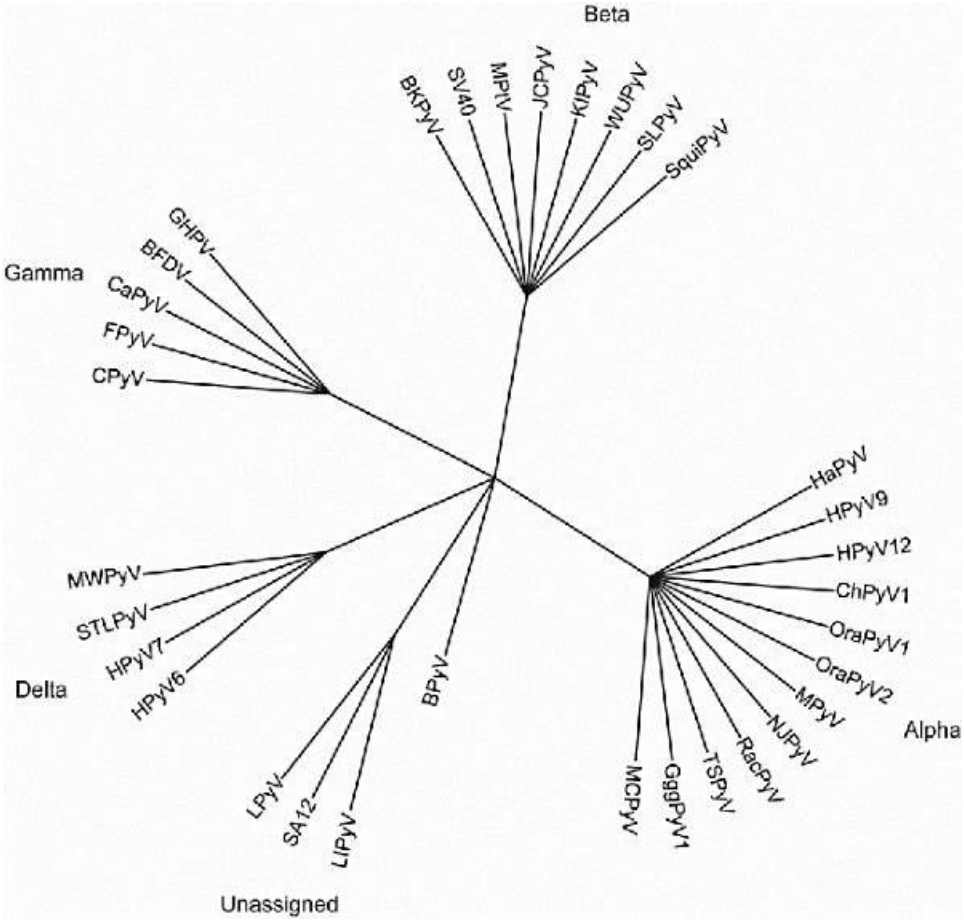

FIGURE 1.1 Taxonomy of polyomaviruses. Taxonomic tree of the family *Polyomaviridae* large T antigen proteins. Branch lengths do not correspond to phylogenetic distance. The genera Alphapolyomavirus, Betapolyomavirus, Deltapolyomavirus, Gammapolyomavirus, and unclassified polyomaviruses are labeled. See Table 1.1 for full names and GenBank Accession numbers. Figure courtesy of Jason Nomburg.

The next member of the PyV family to be isolated was simian virus 40 (SV40) by Sweet and Hilleman in 1960.[326] Poliovirus vaccine lots produced in rhesus monkey kidney cells were screened for the presence of contaminating viruses. SV40 was the 40th virus isolated from this screen and was notable for causing cytopathic or vacuolating effects in African green monkey kidney cells. It soon became evident that the early production batches of poliovirus vaccine were broadly contaminated with SV40. Although the Salk poliovirus vaccine was inactivated by formalin treatment, SV40 was relatively resistant to this treatment. The presence of potentially viable SV40 in the polio vaccine quickly became a public health concern when the ability of purified virus to cause tumors in newborn hamsters was reported.[104]

Since that time, many polyomaviruses have been isolated from a variety of mammalian, bird, and fish species. The first two human polyomaviruses, JC (JCPyV) and BK (BKPyV), were isolated in 1971 from immunocompromised patients. JCPyV was isolated by the transfer of brain tissue from a patient with progressive multifocal leukoencephalopathy (PML) into cultures of

human fetal brain tissue.[252] BKPyV was isolated from the urine of a renal transplant patient after inoculating African green monkey kidney cells.[96]

The advent of advanced molecular biology techniques including polymerase chain reaction (PCR), rolling circle amplification, and next generation sequencing has led to the identification of at least 10 additional human polyomaviruses. WUPyV and KIPyV were isolated from respiratory secretions of young children by investigators at Washington University and the Karolinska Institute, respectively. The discovery of Merkel cell polyomavirus (MCPyV) reflected recognition that the incidence of Merkel cell carcinoma (MCC), a rare form of skin cancer, was more frequent in severely immunocompromised patients and suggestive of an infectious cause. MCPyV was initially detected in MCC specimens by digital transcriptome subtraction, a method that used high-throughput sequencing of cellular transcripts to identify sequences that did not match the human genome but were distantly related to BKPyV.[84]

Two additional human polyomaviruses, HPyV6 and HPyV7, were cloned from the skin or hair follicles of healthy adults using a technique called rolling circle amplification that takes advantage of the small circular nature of the polyomavirus dsDNA genome.[288] Using the same technique, trichodysplasia spinulosa–associated polyomavirus (TSPyV) was found in a patient with a rare skin disease named trichodysplasia spinulosa.[342] Although identification of novel polyomaviruses by DNA sequencing has become easier, isolation of infectious viruses or even virion particles remains a technical challenge.

Primate polyomaviruses from Old World monkeys include the simian agent 12 (SA12), isolated from a South African vervet monkey kidney culture, and B-lymphotropic polyomavirus (LPyV), isolated from an African green monkey lymphoblast cell line. Additional primate polyomaviruses directly isolated from animals include Bornean (OraPyV1) and Sumatran orangutan polyomavirus (OraPyV2), gorilla polyomavirus (GggPyV), and chimpanzee polyomavirus (CHPyV).[185] The first New World monkey polyomavirus (SquiPyV) isolated was from squirrel monkey.[347]

In addition to MPyV and MPtV, a number of nonprimate mammalian polyomaviruses have been identified. Hamster polyomavirus (HaPyV) was discovered in a spontaneously occurring hair follicle epithelioma from a Syrian hamster. This is an interesting member of the polyomavirus family because the behavior of the virus in the tumors most closely resembles that of the papillomaviruses in that viral particles can be found in the highly differentiated layers of the tissue. However, analysis of the HaPyV DNA sequence and its genome organization revealed that it is indeed a polyomavirus and most closely related to MPyV.[67] Bovine polyomavirus (BPyV) is among the smallest of the polyomavirus genomes with fewer than 4,700 base pairs. Sea lion polyomavirus (SLPyV) was isolated from a sick animal with kidney swelling, interstitial nephritis, and an intestinal lymphoma.[55] Raccoon polyomavirus (RacPyV) is associated with neuroglial brain tumors in the wild, with the seroprevalence of this virus in raccoons over 50% in some regions of the United States.[52,66]

Polyomaviruses have been isolated from several bird species. The first of these, budgerigar fledgling disease virus (BFDV), was isolated from a parakeet in 1986.[238] Unlike the narrow host range restriction of mammalian polyomaviruses, BFDV can infect and cause disease in a wide variety of bird species and is now referred to as *Aves polyomavirus 1*. Recently identified bird polyomaviruses include canary (CPyV), crow, finch (FPyV), and goose hemorrhagic polyomavirus (GHPV).[153] In general, the avian polyomaviruses cause a severe inflammatory

illness that often results in death. Infection with GHPV causes hemorrhagic nephritis and enteritis.[152]

For many years, the polyomaviruses were studied principally as model systems for understanding basic eukaryotic cell processes including DNA replication, RNA transcription, splicing, and oncogenic transformation. The cloning and sequencing of the SV40 genome ushered in the era of recombinant DNA research. Several genetic elements from the SV40 genome, such as the origin of replication, the early promoter, the *STAG* (small t antigen) splice donor and acceptor, and the polyadenylation signal, are widely used in molecular biology laboratories throughout the world.[240,269,274]

Interest in the polyomaviruses as human pathogens lagged behind these more basic biological studies because for many years the incidence of polyomavirus-associated diseases was rare and not well recognized. The onset of the human immunodeficiency virus type 1 (HIV-1)/acquired immunodeficiency syndrome (AIDS) epidemic led to a dramatic rise in the incidence of PML, a JCPyV-induced disease. More recently, biological therapies for multiple sclerosis have also led to a significantly increased risk for developing JCPyV-associated PML. Advances in immunosuppressive regimens for hematopoietic stem cell and solid organ transplantation recipients and biological therapies for autoimmune diseases have led to increases in JCPyV, BKPyV, MCPyV, HPyV6, HPyV7, and potentially TSPyV-associated diseases. Furthermore, the transforming activity of MCPyV and its contribution to MCC and BKPyV association with urothelial carcinoma has generated further interest in the oncogenic activity of human polyomaviruses. However, while polyomaviruses share many features, there are many fundamental differences that can distinguish each member of this family.

CLASSIFICATION

Polyomaviruses were originally classified within the *Papovaviridae* family that included papillomavirus, polyomavirus, and vacuolating virus.[223] The vacuolating or cytopathic effect of SV40 virus on host cells during lytic infection led to this distinction (Fig. 1.2). Polyomaviruses and papillomaviruses are divided into separate families since 2000, after sequencing studies revealed that despite their similar physical appearance, the two groups of viruses have different genome organization. Several classifications have been proposed with the most recent report from the International Committee on Taxonomy of Viruses (ICTV) that includes four major categories (Alpha, Beta, Gamma, and Delta) plus an unclassified group containing several polyomaviruses isolated from fish (Table 1.1) (Fig. 1.1).[230] The human Alpha polyomaviruses comprise MCPyV, as well as TSPyV, HPyV9, and New Jersey (NJPyV). The Beta polyomaviruses include SV40 and the human JCPyV, BKPyV, KIPyV, and WUPyV polyomaviruses. The Gamma polyomaviruses contain species isolated from birds. Several polyomaviruses have not been officially classified within the family either because the complete viral genomic sequence is not available or they have significant differences in genome organization.

VIRION STRUCTURE

Polyomavirus virions are nonenveloped, 45- to 50-nm particles consisting of two or three virally encoded capsid proteins. All viruses have the major capsid protein Vp1 and the minor protein Vp2, and some also have Vp3 derived from an internal start site within the *VP2* gene.[286] The virions encapsidate a circular dsDNA genome wrapped with cellular histones H2A, H2B, H3, and H4.[331] The virion minichromosome exhibits the same nucleosome structure as cellular chromatin except for the absence of histone H1 that becomes associated with the viral genome in the infected cell. The particles have a T = 7 icosahedral symmetry and sediment at 240S in sucrose density gradients. The density of mature virions is 1.34 g/mL and of empty capsids is 1.29 g/mL, as determined by cesium chloride equilibrium gradient centrifugation (Fig. 1.3).[27] The polyomaviruses are relatively resistant to heat and formalin inactivation, as demonstrated by the isolation of viable SV40 from the Salk poliovirus vaccine.[319] Because polyomaviruses are nonenveloped, they are also resistant to lipid solvents. Similar to most viruses, preparations of polyomavirus virions often contain many different types of particles. For example, in addition to mature virions, one can find empty capsids or capsids that contain cellular DNA instead of viral DNA (Fig. 1.3). The ability of Vp1 and Vp2 to form pseudovirions has been exploited to generate not only infectious polyomavirus but also a variety of reporters.

The purification of simian virus 40. *Virology* 1964;24(3):381–387. Copyright © 1964 Elsevier. With permission.)

The polyomavirus capsid contains 360 molecules of Vp1 arranged as 72 pentamers, each containing five molecules of Vp1 and one molecule of Vp2 or Vp3. Only the Vp1 molecule is exposed on the surface of the capsid. The icosahedral capsid has both five- and sixfold axes of symmetry, with 12 pentamers surrounded by 5 other pentamers and 60 pentamers surrounded by 6 pentamers (Fig. 1.4).[144,145,191,316] The recent cryo-EM analysis of BKPyV revealed the position of Vp2 and Vp3 under the Vp1 shell and contacts between the viral genome and the three capsid proteins (Fig. 1.5).[145] The C-terminus of each Vp1 molecule extends out of the pentamer and contacts the neighboring capsomere. This structure is flexible and thereby provides the means to form an icosahedron. Capsomere contacts are stabilized by the presence of calcium ions and mutations in residues that bind calcium result in unstable virions. Treatment of virus with EGTA under reducing conditions results in the dissociation of the capsid into Vp1 pentamers. In addition to Vp1, Vp2, and Vp3, APyV expresses Vp4 (agnoprotein 1a) that interacts with the C-terminus of Vp1 and may be incorporated into viral capsids.[302] The capsid also contains posttranslational modifications including disulfide bonds that form between the pentameric capsomeres. In addition, Vp2 undergoes myristoylation at its N-terminus. One report found a large number of posttranslational modifications on the BKPyV Vp1 protein, although the role of these modifications during infection is not known.[81]

GENOME STRUCTURE AND ORGANIZATION

The polyomavirus dsDNA circular genome contains approximately 5,000 base pairs and can be divided into three parts: the early viral gene region (EVGR) encoding genes that are expressed prior to the onset of DNA replication; the late viral gene region (LVGR) encoding genes expressed after viral DNA replication begins; and the regulatory region, also called noncoding control region (NCCR), containing the origin of viral DNA replication and the promoters and enhancers for early and late viral genes (Fig. 1.6). The early and late promoters give rise to primary transcripts from opposite strands of the DNA. The numbering system for the polyomavirus genome differs from virus to virus with nucleotide position 1 defined in different ways.[331] There has been precedent in recent years, however, to call the nucleotide preceding the A in the *LTAG* ATG nucleotide 1, with numbering proceeding in the late direction, that is, away from the *LTAG* open reading frame.

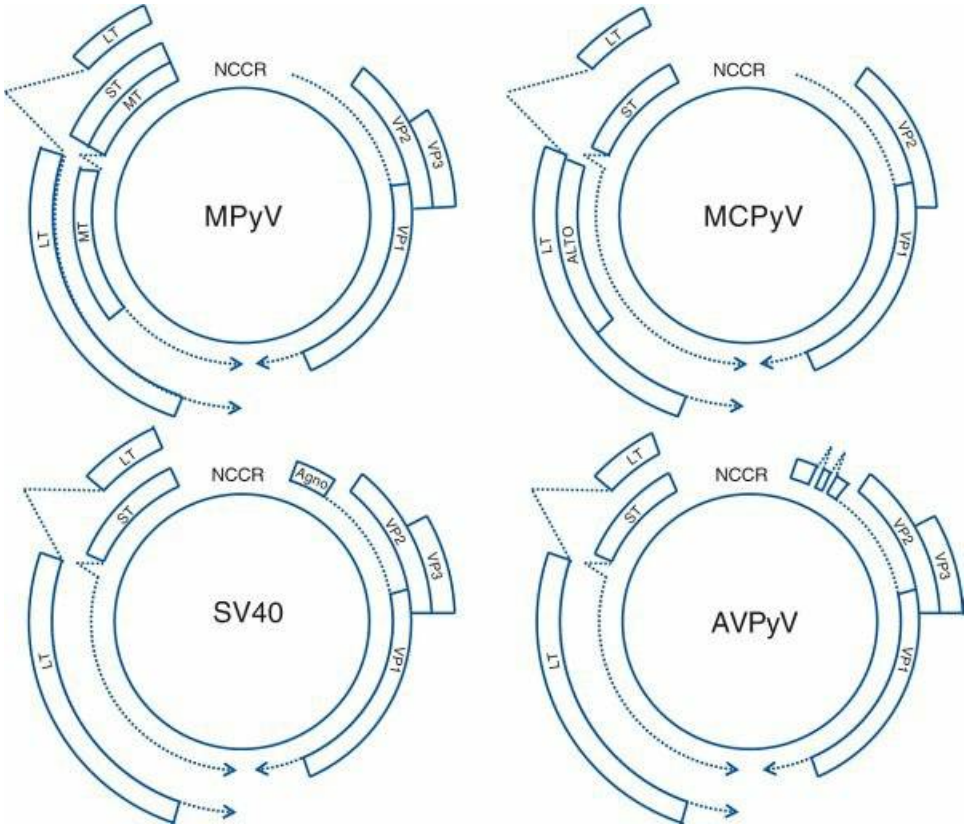

FIGURE 1.6 Polyomavirus Genome Organization depictions of major gene products of MPyV, MCPyV, SV40, and AVPyV. Noncoding control region (NCCR) controls bidirectional gene expression with early viral gene region (EVGR) shown in counterclockwise orientation and late viral gene region (LVGR) shown in clockwise orientation.

The small size of the polyomavirus genome made it amenable to classical genetic approaches.[331] Infection with temperature-sensitive mutants of SV40 led to the identification of five complementation groups, A, B, BC, C, and D. Mutations in group A mapped to the large T antigen (LTag) gene (*LTAG*); groups B, BC, and C to the *VP1* gene; and group D to the *VP2/3* gene. MPyV mutants were classified into similar complementation groups, although no standard nomenclature was developed for this virus. Other mutants of MPyV known as host range nontransforming (hr-t) mutants were selected for their ability to replicate but inability to transform cells. The hr-t mutations were later mapped to the middle T antigen (MTag) and small T antigen (STag) genes (*MTAG, STAG*) leaving an intact LTag.[309] The analysis of these early mutants set the stage for detailed and directed mutational studies enabled by recombinant DNA technology.

Another early genetic approach to the study of polyomaviruses was the selection for so-called evolutionary variants. In these experiments, viruses were passaged at high multiplicities of infection and variants were isolated. Many of these variants in SV40 and BKPyV had alterations in the NCCR involving partial sequence duplications, deletions, or combinations thereof.[184,229] The emergence of BKPyV NCCR rearrangements was partly dependent on the viral replication capacity in a given host cell. Of note, the NCCRs of BKPyV and JCPyV are frequently found to be rearranged when isolated from diseased tissues or patients' blood. These patient-derived rearranged NCCR variants also tend to replicate well in cell culture when compared to viruses containing the wild-type NCCR.[108,109]

The polyomavirus early and late promoters are contained within the NCCR and often overlap with each other as well as with the origin of replication. Transcription of the EVGR progresses from the early promoter around the genome in one direction. Transcription of the LVGR proceeds from the late promoter around the genome in the opposite direction. The EVGR mRNAs are produced by posttranscriptional processing at a polyadenylic acid or poly(A) site that is located about halfway around the circular genome from the start site and by removal of introns by the cellular splicing machinery. SV40 was one of the first experimental systems where it was demonstrated that RNA polymerase II transcribes past the 3′ end of the mature mRNA molecule, implying that the 3′ end, including the poly(A) tail, was generated posttranscriptionally.[88]

Each of the polyomaviruses encodes at least two early mRNAs by alternative splicing that are translated into the LTag and STag (Fig. 1.7). In addition, MPyV, HaPyV, and TSPyV produce a third alternatively spliced mRNA that codes for MTag.[340] The "T" in T antigen derives from the initial identification of these proteins as tumor antigens that were recognized by antisera from tumor-bearing animals inoculated with SV40. For many years, it was believed that the mRNAs encoding LTag, STag, and MTag were the only early transcripts, but it has since been demonstrated that these viruses encode additional early mRNAs that differ in their splicing patterns. In SV40 and MPyV, an additional mRNA encodes a protein called 17KT and tiny T, respectively. Similarly, JCPyV produces a series of alternatively spliced mRNAs that encode proteins referred to as T′135, T′136, and T′165, while BKPyV encodes a molecule called truncated Tag, implicated in the induction of APOBEC3 activity in infected cells. MCPyV encodes a full-length, 816-residue LTag as well as an alternatively spliced T antigen called 57kT that corresponds to the first 440 and last 100 residues of the full-length LTag.[303] MCPyV and several other polyomaviruses encode an early protein called ALTO that is produced by overprinting of the second exon of the *LTAG* mRNA (Fig. 1.6).[43] TSPyV encodes ALTO as well

as MTag in addition to LTag and STag.[344] The function of ALTO has not yet been elucidated. Of note, the Alpha polyomaviruses were previously grouped as Almi (ALTO or middle T) polyomaviruses.[43] The principle distinction in the LTag between the Alpha/Almi polyomaviruses with the Beta polyomaviruses is the number of residues between the end of the N-terminal J domain and the start of the origin binding domain. ALTO and MTag are encoded in the +1 reading frame of LTag exon 2.

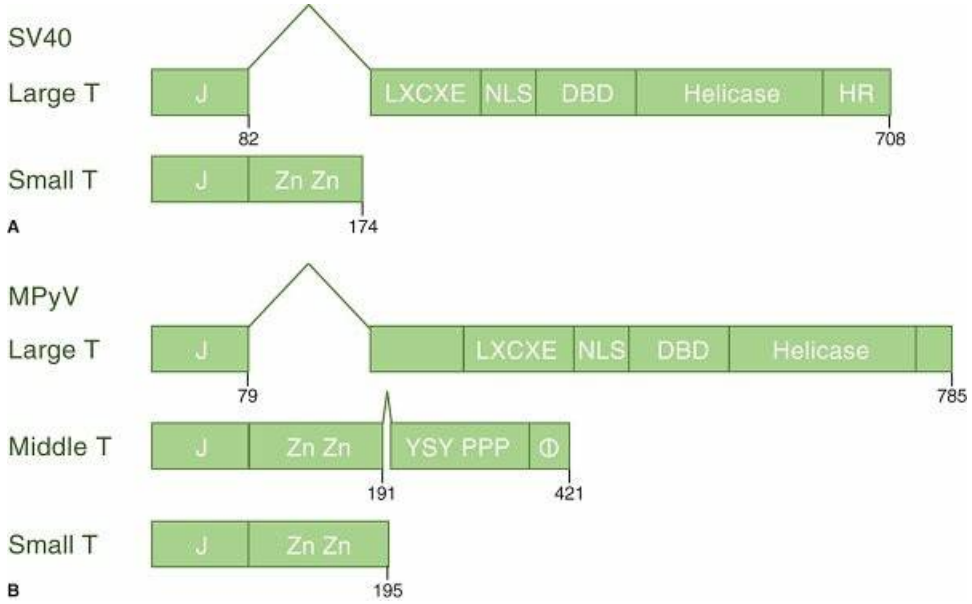

FIGURE 1.7 Simian virus 40 (SV40) (A) and mouse polyomavirus (MPyV) (B) T antigens. The N-terminal J domain is shared with all T antigens. SV40 expresses large and small T antigens, and MPyV expresses large, middle, and small T antigens. The large T antigens contain the LXCXE motif that binds directly to RB, a nuclear localization signal (NLS), a DNA-binding domain (DBD) that binds to the origin of replication, and a helicase domain. SV40 Large antigen contains a C-terminal host range (HR) domain. The small T antigens contain a unique domain not shared with large T antigen that binds to two Zn molecules. The MPyV middle T antigen shares the J domain and Zn-binding domain with small T antigen and also contains tyrosine and serine residues (YSY) that become phosphorylated, a proline-rich region, and a C-terminal hydrophobic domain. Figure courtesy of Camille Cushman.

The late mRNA is transcribed in the opposite direction from the early mRNAs. As with the early transcripts, the late transcript has a single poly(A) site approximately halfway around the genome and is alternatively spliced (Fig. 1.6). The LVGR of most polyomaviruses encodes three capsid proteins, Vp1, Vp2, and Vp3, although some, such as MCPyV, only encode Vp1 and Vp2.[286] Notably, Vp3 is translated in the same open reading frame as Vp2 but uses an alternate *AUG* start codon downstream of the *VP2* start codon and thereby shares all residues with Vp2. While it had been reported that SV40 encodes a Vp4 protein that uses an internal *AUG* start codon even further downstream from *VP3* and functions as a viroporin that promotes virus release from the infected cell, more recent studies found no effect of the start codon mutations on

SV40 or BKPyV release, and failed to detect this protein.[125] The LVGR transcript from SV40, JCPyV, and BKPyV as well as SA12, BatPyV, BPyV, SLPyV, and SqPyV encode an additional protein called agnoprotein.

Avian polyomaviruses express early transcripts encoding LTag and STag, but the late transcripts have several distinct features (Fig. 1.6). There are two late transcription start sites, PL1 and PL2, that give rise to at least eight different transcripts by alternative splicing.[189] PL1 encodes two forms of Vp4 (agnoprotein 1a) and Vp4d (*VPD4*, agnoprotein 1b), while PL2 gives rise to two forms of agnoprotein 2a and 2b that use the same splice sites as *VP4* and *VP4d* but are translated in a different reading frame. Avian agnoprotein 2a and 2b bears some similarity to the SV40 agnoprotein. All of the late avian transcripts also encode for Vp1 or Vp2 and Vp3.

The LVGR transcript can also extend past the polyadenylation signal and give rise to a microRNA (miRNA) in several polyomaviruses.[46,323] The SV40 miRNA maps just 3′ of the late poly(A) site and appears to correspond to SAS (SV40-associated small RNA), a small RNA molecule identified 25 years earlier, albeit of then-unknown function.[4] These miRNAs are complementary to the early mRNAs, target the early mRNAs for degradation, and may serve to limit the expression levels of the T antigens. MiRNAs have been identified in SV40, BKPyV, JCPyV, MCPyV, SA12, and MPyV.[46] Based on both *in vivo* and *in vitro* data, the miRNAs of SV40, BKPyV, and MCPyV have been proposed to play an important role in persistent infection. How expression of the miRNA is controlled is poorly understood; in BKPyV, it has been suggested to be driven from the NCCR, while RNA-seq data from MCPyV suggests the possibility of an independent promoter.

Structure of T Antigens

Much of what is known about the protein structure of the polyomavirus T antigens comes from studies of SV40. All polyomavirus T antigens share an N-terminal region of approximately 80 residues that shows structural and sequence homology to the DnaJ or J domain found in host cell heat shock 40 (HSP40) homologs (Fig. 1.7). The J domain corresponds approximately to the first exon of *LTAG* and is also represented in the N-termini of all PyV STag and MTag. Full-length LTag is a nuclear phosphoprotein of approximately 700 residues. The molecule's atomic coordinates have been assembled from crystallography of isolated domains, including the J domain, the retinoblastoma protein (RB)-binding or LXCXE motif, the DNA-binding or origin-binding domain (DBD or OBD), and a central domain that contains the adenosine triphosphatase (ATPase) and helicase activities required for viral replication.[168,190] The C-terminus of SV40, BKPyV, and JCPyV LTag also contain a host range domain.[87] Studies using scanning transmission electron microscopy, negative staining with atomic force microscopy, and single-particle reconstruction of cryoelectron microscopy (cryo-EM) images revealed that LTag forms a double hexamer in a head-to-head arrangement when bound to the origin of DNA replication.[60]

A number of functional domains contained within LTag are required for viral replication. Functions intrinsic to SV40 LTag include the ATPase/helicase domain and the DBD that mediates direct interactions with specific DNA sequences at the origin of replication. In addition to these intrinsic functions, the SV40 LTag domains serve to recruit host factors important for viral replication (Fig. 1.8). For example, the N-terminal J domain, containing the canonical residues HPDK, binds and activates the ATPase activity of host cell HSC70.[40] The DBD binds to replication protein A (RPA), while the helicase domain binds to the DNA polymerase α/primase

complex.[142] In addition, the helicase domains of many but not all polyomavirus LTags bind to p53. The outer surface of each SV40 LTag hexamer subunit can bind directly to the DBD of p53 (Fig. 1.9).[192] Similarly, the JCPyV, BKPyV, and MWPyV LTags can also bind to p53. However, MPyV and MCPyV LTag are notable exceptions among polyomaviruses because they do not bind to p53.[257]

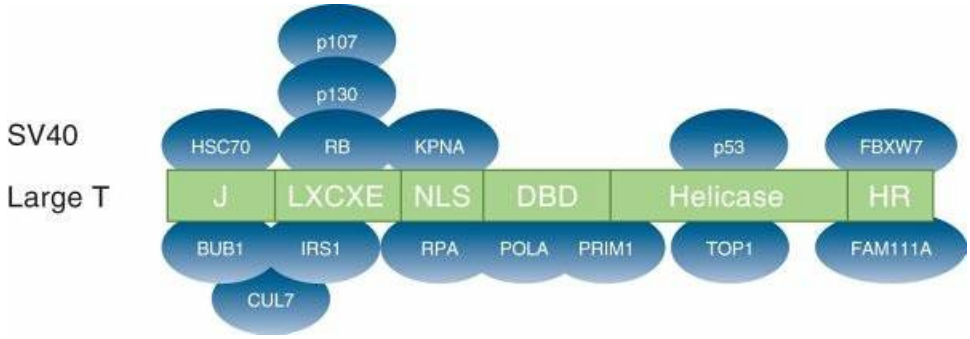

FIGURE 1.8 SV40 large T antigen interaction with host cell proteins. The J domain binds to HSC70, the LXCXE motif binds to RB and the RB-like p107 and p130, the helicase domain binds to TP53, the phosphorylated threonine residue 701 binds to FBXW7, and FAM111A binds to the host range (HR) domain. The cellular proteins BUB1, CUL7, and IRS1 bind to a region between the J domain and the LXCXE motif. Karyopherin (KPNA) binds to the nuclear localization sequence (NLS). Large T antigen recruits replication protein A (RPA), topoisomerase 1 (TOP1), DNA polymerase a (POLA), and primase (PRIM) to promote viral DNA replication. Figure courtesy of Camille Cushman.

Crystal structure of SV40 large T-antigen bound to p53: interplay between a viral oncoprotein and a cellular tumor

suppressor. *Genes Dev* 2006;20(17):2373–2382. Copyright © 2006 Cold Spring Harbor Laboratory Press.)

Smaller functional motifs within LTags include the nuclear localization signal (NLS).[155,181] Mutations that disrupt the NLS result in the cytoplasmic localization of SV40 LTag and reduced ability to support the viral lytic life cycle. All mammalian polyomavirus LTag contain the conserved residues LXCXE (leucine-X-cysteine-X-glutamate, where X is any residue) that bind directly to the retinoblastoma family of tumor suppressor proteins including RB (RB1), p107 (RBL1), and p130 (RBL2).[65] The LTag and STag from GHPyV, CPyV, and FPyV each contain the LXCXE motif, while those from APyV contain a related sequence, LXAXE. It is not known if any of the bird polyomavirus T antigens can bind to RB or p53.

SV40 LTag contains a series of posttranslational modifications, including phosphorylation, O-glycosylation, acylation, poly(ADP)-ribosylation, and acetylation. Phosphorylation regulates some of the functions of the molecule, including its subcellular localization and its ability to participate in the initiation of viral DNA synthesis. In addition, phosphorylation of C-terminally located threonine residues in SV40, BKPyV, and JCPyV LTag creates a phosphodegron motif (phospho-T-P-P-P) that binds directly to FBXW7, an F-box substrate adapter. LTag binding to FBXW7 interferes with FBXW7 binding to Cyclin E and thereby stabilizes it by reducing degradation by the SKP1–CUL1–FBXW7 ubiquitin ligase (Fig. 1.8).[355]

Polyomavirus STag is found in both the nucleus and cytoplasm. STag is a cysteine-rich protein ranging in size from 124 to 198 residues and shares its N-terminus with LTag (i.e., those residues encoded up to the 5′ LTag splice site) but contains a unique C-terminal region. STag contains the same N-terminal J domain as LTag and a unique C-terminal domain (Fig. 1.7). The unique domain of the mammalian polyomavirus STags contains a highly conserved set of cysteine and histidine residues that bind to two zinc molecules or iron–sulfur clusters.[335] These zinc-binding domains serve an important role in binding to the cellular protein phosphatase 2A (PP2A).[253] PP2A is a trimeric complex consisting of the scaffold A subunit and regulatory B subunit that bind to the catalytic C subunit. STag binds directly to the PP2A A subunit and thereby displaces or replaces the B subunit. SV40 STag binds specifically to the Aα (PPP2R1A) subunit, while MPyV and MCPyV STag binds to both the Aα and Aβ (PPP2R1B) subunits. The STag–PP2A complex contains also the Cα (PPP2CA) or Cβ (PPP2CB) catalytic subunit. There are at least 18 different B PP2A subunits identified in mammalian cells. At the very least, SV40 STag can displace the B56α (PPP2R5A), B56γ (PPP2R5C), and PR72/PR130 (PPP2R3A).[280] It is likely that the polyomavirus STag–PP2A complex not only serves to disrupt the cellular PP2A complexes but is also likely to retain specific phosphatase activity directed toward substrates. Notably, the bird polyomavirus STags do not contain the conserved cysteine/histidine residues, and it is not known if they are capable of PP2A binding.

The STags from several polyomaviruses can bind to cellular proteins in addition to PP2A. MCPyV STag can bind specifically to the MYC paralog MYCL (L-MYC) and the EP400 chromatin remodeling complex.[51] The MCPyV ST–MYCL–EP400 complex functions to transactivate a large number of genes that contribute to the oncogenic activity in MCC (Fig. 1.10). SV40 STag displaces common PP2A B subunits but also promotes A–C subunit interactions with alternative B subunits (B′, striatins) that are components of the striatin-interacting phosphatase and kinase (STRIPAK) complex. STag binding to STRN4, a component

of the STRIPAK complex, facilitates PP2A-mediated dephosphorylation of MAP4K4 and induces cell transformation through the activation of the Hippo pathway effector YAP1 (Fig. 1.10).[169]

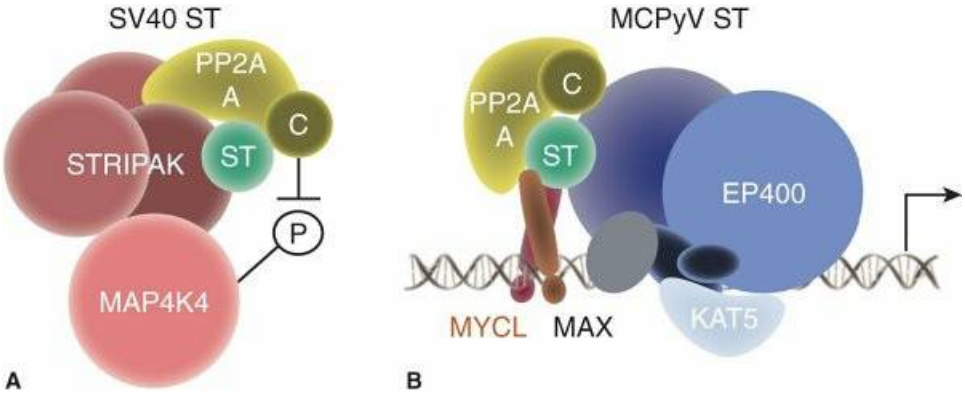

FIGURE 1.10 SV40 and MCPyV small T antigens form unique multiprotein complexes. A: SV40 small T antigen recruits the PP2A A and C subunits to the multiprotein STRIPAK complex and directs the dephosphorylation of MAP4K4 that leads to inhibition of the Hippo pathway and activation of YAP. (From Kim JW, Berrios C, Kim M, et al. STRIPAK directs PP2A activity toward MAP4K4 to promote oncogenic transformation of human cells. *Elife* 2020;9:e53003.) Ref.[169] **B:** The MCPyV small T antigen recruits the MYC paralog LMYC (MYCL) to the 15-component p400 complex containing EP400 and KAT5 to activate transcription. (From Cheng J, Park DE, Berrios C, et al. Merkel cell polyomavirus recruits MYCL to the EP400 complex to promote oncogenesis. *PLoS Pathog* 2017;13(10):e1006668. Ref.[51] Figure courtesy of Camille Cushman.)

The MTag of MPyV shares its N-terminal J domain and PP2A-binding domain with STag (Fig. 1.7). The MPyV MTag and STag are identical for the N-terminal 191 residues until a splice junction that removes four nucleotides resulting in an additional 230 residues at the C-terminus of MTag. By contrast, STag contains only four unique amino acids after this intron. The unique MTag C-terminus is encoded by an alternate reading frame to that used for coding the second exon of LTag. Notably, MTag contains an N-terminal J domain in common with both LTag and STag, and like STag, binds to the A and C subunits of PP2A. The additional MPyV MTag residues mediate binding to several proteins involved in signal transduction, including the SRC tyrosine kinase, the SHC1 phosphotyrosine docking protein, 14-3-3, phospholipase C (PLCG1), and phosphatidylinositol 3-kinase (PIK3CA and PIK3R1) (Fig. 1.11).[284] MPyV MTag can also bind to the SRC-related tyrosine kinases YES1 and FYN. The C-terminus of MTag contains a 22-residue hydrophobic domain that moves the newly translated MTag from the cytoplasm through the endoplasmic reticulum (ER) to the inner plasma membrane. The combination of membrane localization with recruitment and activation of several enzymes enables MTag, which itself has no intrinsic enzymatic activity, to essentially function as a constitutively activated receptor tyrosine kinase that activates the RAS, MAPK, and AKT downstream signaling pathways.

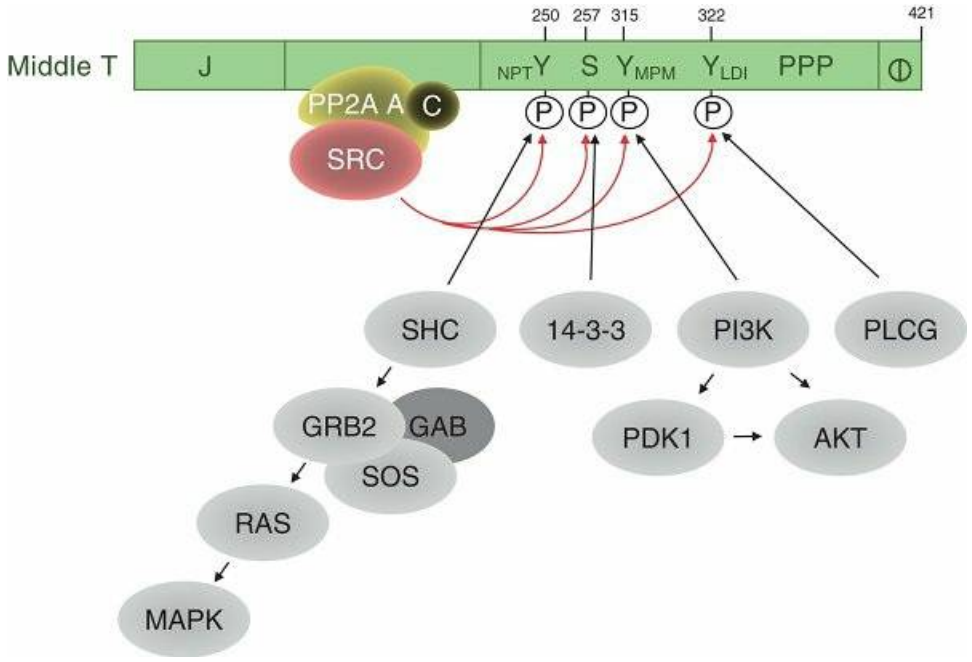

FIGURE 1.11 Mouse polyomavirus (MPyV) middle T antigen assembles an activated signaling complex. Tyrosine residues 250, 315, and 322 are phosphorylated by associated SRC kinase. Residues surrounding the phosphorylated tyrosine residues are required for specific association with SHC, 14-3-3, phosphoinositide 3-kinase (PI3K), and phospholipase C. PPP represents the proline-rich sequence. The C-terminus contains the hydrophobic membrane attachment site.[284] (Adapted from Schaffhausen BS, Roberts TM. Lessons from polyoma middle T antigen on signaling and transformation: a DNA tumor virus contribution to the war on cancer. *Virology* 2009;384(2):304–316. Copyright © 2008 Elsevier. STAGES OF REPLICATION

Mechanism of Attachment

Prior to the 21st century, the nature of the cell surface receptors for polyomaviruses was poorly understood. Early studies on SV40 indicated that it used the major histocompatibility complex (MHC) class I antigens to bind to cells. Supporting evidence for this model included observations that antibodies against MHC class I blocked virus binding to rhesus monkey kidney cells and the inability of virus to bind to human cells that do not express MHC class I, while experimentally induced expression of MHC class I in nonexpressing cells restored binding. Although the MHC class I antigens were implicated as the SV40 receptor, they were not sufficient to account for all binding. For example, virus binding occurred only on the apical surface of polarized monkey epithelial cells, while MHC class I antigens were expressed on both the apical and basolateral surfaces. In addition, expression of MHC class I on human kidney epithelial cells was not sufficient for SV40 infection.[203]

Subsequent results challenged the notion that SV40 uses a protein molecule as its receptor and demonstrated instead that it uses the branched ganglioside GM1 (Fig. 1.12).[334] This finding is more consistent with the route of entry of the virus through endosomes. In these studies, a cell line that did not express gangliosides and was unable to be infected by SV40 was rendered susceptible by preincubation with GM1. Gangliosides are glycosphingolipids that combine a sialylated oligosaccharide with ceramide consisting of sphingosine and a fatty acid. The sialic acid is critical for virion binding to the cell. In addition to providing a binding site for the virus, the gangliosides direct the virus to the correct endocytic pathway. The efficiency of SV40 infection is dependent on the relative concentration of GM1 on the cell surface as well as its ability to activate focal adhesion kinase (PTK2).[311] Interaction of the SV40 Vp1 with GM1 contributes to the vacuolization phenotype observed with SV40 infection in cell culture (Fig. 1.2).[206] The crystal structures of various PyV Vp1 molecules with gangliosides have been solved (Fig. 1.13).[37,144,242]

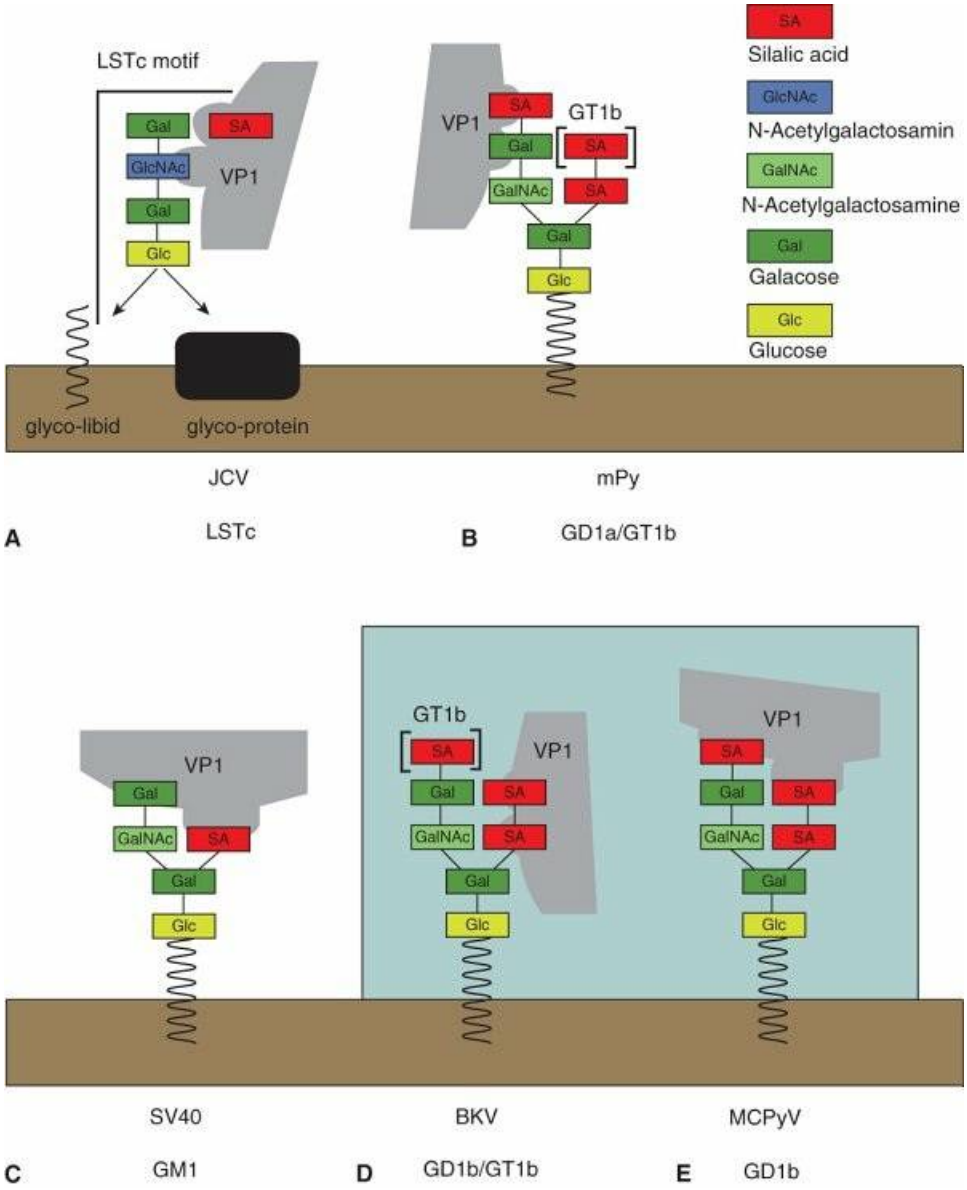

FIGURE 1.12 Polyomavirus VP1–carbohydrate interaction. A: JCV Vp1 binds to the LSTc pentasaccharide motif attached to either a protein or a lipid. **B:** MPyV Vp1 interacts with the SA-Gal motif attached to one branch of gangliosides GD1a or GT1b. **C:** SV40 VP1 engages the Gal and SA residues on both branches of ganglioside GM1 **D:** BKV Vp1 is predicted to bind to the di-SA motif of ganglioside GD1b or GT1b. **E:** MCPyV is postulated to interact with the SA on both branches of ganglioside GT1b. The shaded *light blue* area represents Vp1–sugar interactions for which there are only biochemical, but no crystal structure, data.[333] (Reprinted from Tsai B, Inoue T. A virus takes an "L" turn to find its receptor. *Cell Host Microbe* 2010;8(4):301–302. Copyright © 2010 Elsevier. With permission.)

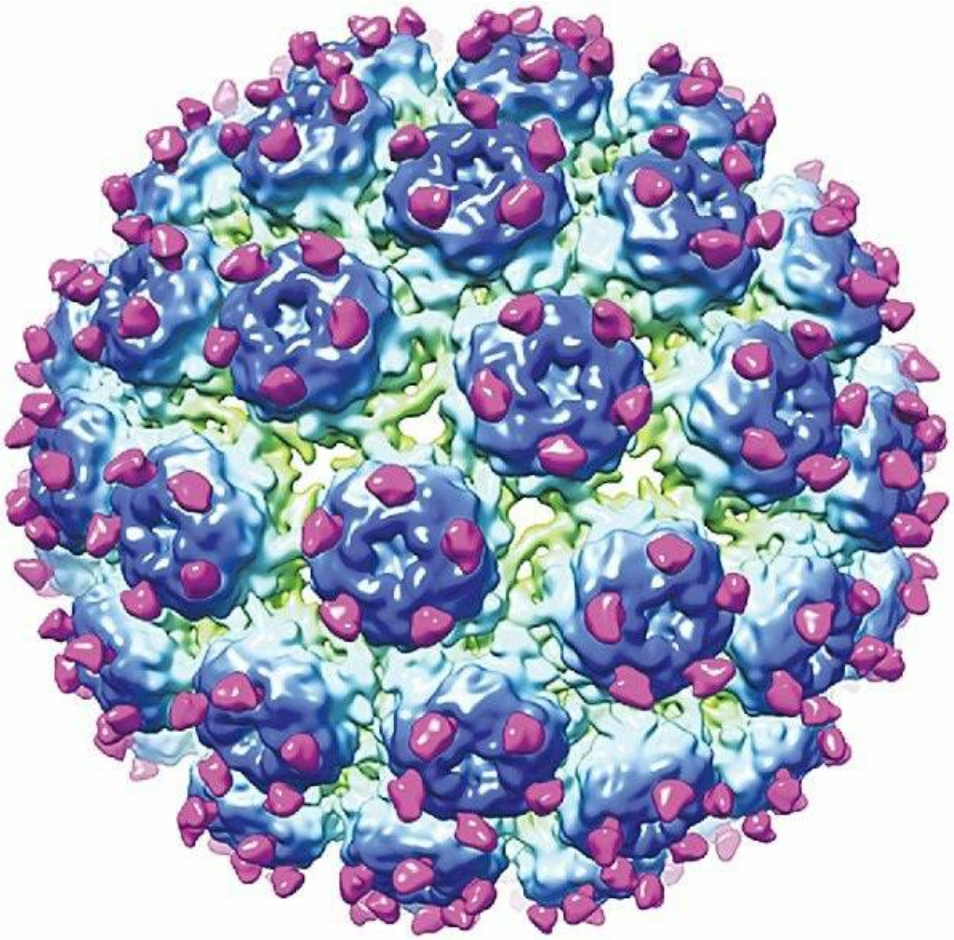

FIGURE 1.13 The structure of BKPyV and GT1b. Isosurface representation of the 3.4 Å structure of BKV, in complex with GT1b (*magenta*). (Reprinted from Hurdiss DL, Frank M, Snowden JS, et al. The Structure of an Infectious Human Polyomavirus and Its Interactions with Cellular Receptors. *Structure* 2018;26(6): 839–847.e3.https://creativecommons.org/licenses/by/4.0/.)

Other polyomaviruses use distinct gangliosides as receptors (Fig. 1.12). For example, MPyV uses GT1b or GD1b.[334] After initial binding to the ganglioside, MPyV interacts with α4β1 integrin that may serve as a secondary or cell type–specific receptor for viral entry.[249] BKPyV also uses gangliosides to enter the cell, as judged by restoration of infectivity to otherwise resistant cells upon preincubation with GT1a and GD1a. These branched gangliosides are found on the renal tubular epithelial cells that BKPyV normally infects. Another report indicated that an N-linked glycoprotein containing sialylated oligosaccharides can also mediate BKPyV binding. Both the glycolipid and glycoprotein contain sialic acid, consistent with early reports that BKPyV can hemagglutinate human red blood cells and that this activity was neuraminidase sensitive. There are various reports regarding the receptor for MCPyV, with some data indicating that MCPyV Vp1 capsomeres can bind the ganglioside GT1b, while pseudovirions can bind sulfated polysaccharides, such as heparan sulfates or chondroitin sulfates, to enter cells.[287] It has also been reported that BKPyV, SV40, and JCPyV can enter cells using nonsialylated glycosaminoglycans for infectious entry.[99]

JCPyV binds to lactoseries tetrasaccharide c (LTSc), a linear sialylated oligosaccharide that differs from the branched forms reported for other polyomaviruses (Fig. 1.12). LTSc is a pentasaccharide with the terminal sialic acid linked by an α2,6 bond to the penultimate galactose. In addition, JCPyV uses the 5-hydroxytryptamine (serotonin) receptor 2A (HTR2A), perhaps as a cell type–specific receptor, for viral entry.[78] This receptor is expressed on glial cells, the major target cell for JCPyV. Antibodies to the HTR2A receptor as well as serotonin receptor antagonists such as mirtazapine block JCPyV infection, while expressing the receptor in otherwise noninfectible cells renders them susceptible to infection.

Entry, Intracellular Trafficking, and Uncoating

The polyomaviruses use several pathways to enter into the cell and pass through the endosomes to the ER (Fig. 1.14). Although early studies indicated that SV40 and BKPyV enter the cell using a pathway involving caveolin, later studies indicated that caveolin was not essential.[374] Evidence also indicates that entry of SV40 and MPyV into the cell requires engagement of a signal transduction cascade through interactions at the cell surface.[137] Studies with various inhibitors of intracellular structures and processes have shed some light on how the virions travel within the cytosol after endocytosis. Molecules that interfere with microtubules and prevent movement of vesicles from the endosome to the ER interfere with SV40 infection. Infection can be blocked by the drug brefeldin A, which inhibits trafficking between the ER and the Golgi apparatus, and a number of other drugs that interfere with endosome maturation and trafficking to the ER.[248] A genome-wide siRNA screen revealed that BKPyV trafficking requires the Ras-related RAB18 protein and its associated factors syntaxin 18 and the NRZ complex to make its way to the ER.[372]

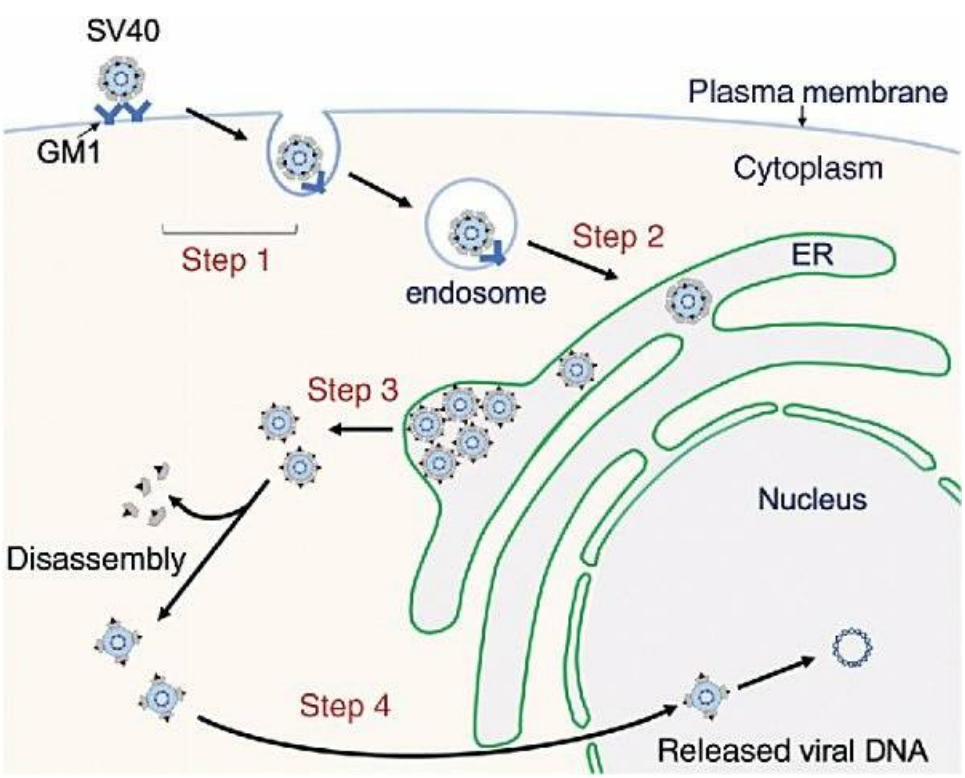

FIGURE 1.14 SV40 entry. *Step 1*: SV40 binds to the ganglioside GM1 host cell receptor at the plasma membrane. This event initiates receptor-mediated endocytosis that targets the virus to the endosomes. *Step 2*: SV40 is targeted to the ER from where it breaches the ER membrane to escape into the cytosol. *Step 3*: In the cytosol, the virus is mobilized into the nucleus. *Step 4*: The genome is released.[50] (Reprinted from Chen YJ, Liu X, Tsai B. SV40 Hijacks Cellular Transport, Membrane Penetration, and Disassembly Machineries to Promote Infection. *Viruses* 2019;11(10):917. https://creativecommons.org/licenses/by/4.0/.)

The polyomavirus capsid begins to disassemble in the ER. Evidence for this includes the appearance of epitopes on Vp2 and Vp3 that become accessible for immunostaining within the ER.[248] In addition, structural changes to the capsid, including disulfide bond reduction and isomerization mediated by ER-resident protein disulfide isomerases, can be detected biochemically at the point when the virus enters the ER. Furthermore, transmission EM experiments have detected changes in the morphology of virions that were isolated from the ER.[146] Evidence for a multistep disassembly process for SV40 includes the exposure of certain hydrophobic Vp2 and Vp3 epitopes in the ER, while further disassembly occurs later in the cytosol as evidenced by immunoassay detection of the viral genome. Similar to SV40, it has been shown that the conformation of the MPyV capsid begins to change in the ER due to the action of the endoplasmic reticulum protein 29 (ERP29) that plays a role in the processing of secretory proteins.[285,334] Capsid disassembly in the ER or the cytosol may be required because the viral particle is bigger than the functional capacity of the nuclear pore. The ER-associated degradation pathway, which functions to target misfolded cellular ER proteins for proteasome-mediated degradation, has also been implicated in polyomavirus disassembly and involves ER chaperone proteins.

The question of how the PyV genome gets transported to the nucleus remains to be answered. For SV40, it has been speculated that release from the vesicular compartment might involve Vp1, as noted earlier, or Vp2, by virtue of its myristoylated N-terminus inserting into the lipid bilayer.[248] Recent data have shown that a series of cellular factors, including BAG2, Erlin, dynein, kinesin, and SGTA can extract the particle from the ER and further facilitate disassembly.[50] An NLS in Vp2/Vp3 may mediate entry through the nuclear pore complex, since mutations in the NLS inhibit entry of the virion into the nucleus but do not affect capsid assembly or the production of new virions.

JCPyV enters the cell through clathrin-coated pits, as indicated by use of inhibitors of this pathway as well as the demonstration that JCPyV colocalizes with transferrin, known to use clathrin-mediated entry into the cell. Both microtubules and microfilaments play a role in trafficking of JCPyV to the nucleus. As with SV40, binding of JCPyV to its receptor induces a signal transduction cascade required for efficient entry that can be inhibited by genistein, a tyrosine kinase inhibitor. In addition, JCPyV appears to signal through the extracellular signal-regulated kinase (ERK) or mitogen-activated protein kinase (MAPK) pathway. Using fluorescently labeled virus-like particles (VLPs), it has been shown that JCPyV particles do not disassemble before they reach the nuclear pore and that the NLS of Vp1 is required for entry into the nucleus.

Transcription

After the polyomavirus genome enters the nucleus, it serves as a template for transcription by the cellular RNA polymerase II. Once inside the nucleus, the viral genome becomes wrapped in nucleosomes containing histone H1 in addition to the four core histones that are present in the virus particle.[345] Within the cell, the SV40 viral genome contains 24 nucleosomes with a nucleosome-free region of 400 base pairs encompassing the NCCR of early and late promoters and origin of replication. This is in contrast to the virion, where all regions of the SV40 genome are covered with nucleosomes devoid of H1. Chromatin immunoprecipitation can detect transcriptionally active chromatin, defined by the presence of RNA polymerase II, as early as 30 minutes postinfection with SV40.[10] The chromatin at this time also contains hyperacetylated histone H3 and H4, which have been associated with chromatin undergoing transcription initiation and elongation.[10]

Transcription of polyomavirus genes is governed by *cis*-acting sequences in the NCCR. The SV40 NCCR has been the most intensively studied and serves as a paradigm for the other polyomaviruses. Seminal studies involving SV40 include the demonstration that AT-rich sequences designated TATA boxes act to direct RNA polymerase II to the proper initiation site for transcription. The SV40 early promoter also contains a series of GC-rich sequences within the 21–base-pair repeat region. The host cell protein SP1, one of the first eukaryotic transcription factors to be cloned, binds to these sequences. The SV40 early promoter also contains a duplicated element called the 72–base-pair repeat, which was the first *cis*-acting DNA sequence to be deemed a transcriptional enhancer because it could activate transcription when placed several thousand base pairs distant from the transcription start site.[113,233] Interestingly, most clinical isolates of SV40 carry only a single copy of the 72–base-pair repeat, and it appears that duplication can be selected during passage in culture.[184]

In MPyV, the enhancer element consists of two neighboring enhancers called A and B, alternatively α and β, that can act independently. The activity of the MPyV enhancers is dependent on the cell environment, as viral variants that are selected for growth on differentiated or undifferentiated embryonal carcinoma cells have mutations that map to the enhancers. The MPyV early promoter is regulated by the cellular factors characterized as polyomavirus enhancer A–binding proteins (PEA) or RUNX1, CBFB, and ETV4 that are expressed when cells are growth stimulated with serum.

The JCPyV promoter shows a distinct tissue-specific activity that correlates with the sites of acute infection. While normal JCPyV virions can attach and enter many types of cells, its host range is restricted to those cells that express transcription factors that can bind to specific sequences in the JCPyV early promoter. These sequences include the TATA box as well as binding sites for the transcription factors SP1, YB1 (YBX1), Pur-alpha (PURA), AP-1, a heterodimer of JUN and FOS, nuclear factor 1 (NF1), NFAT, and NF-1 class X (NFIX). A nuclear factor-κB (NF-κB)-binding site that includes the NFAT site has been shown to be active for late transcription and contribute to positioning of other DNA-binding proteins to initiate efficient transcription.[94] NFAT consists of a family of proteins that are expressed in many cells but have multiple classes with tissue-specific expression. NFIX is highly expressed in human glial cells, stromal cells, B lymphocytes, and CD34+ stem cells that have all been reported to support JCPyV transcription and replication. Interactions between YB1 and PURA may also provide cell-specific regulation.

The BKPyV NCCR-mediated control of bidirectional EVGR and LVGR expression has been dissected in some detail by introducing discrete point mutations predicted to inactivate binding sites for a number of transcription factors and DNA-binding proteins including SP1, ETS1, NF1, YY1, and p53 (Fig. 1.15).[23] Assessing the bidirectional dual NCCR-reporter gene expression in human embryonic kidney HEK293 cells and replication activity of the corresponding BKPyV variants in primary human renal tubular epithelial cells led to identification of three phenotypic groups. Group-1 and group-2 mutations caused a strong and an intermediate level of activation of EVGR expression and viral replication, respectively, similar to NCCR rearrangements of clinical variants found in patients with BKPyV diseases,[109] whereas group-3 mutations reduced or failed reporter gene expression and viral replication.[23]

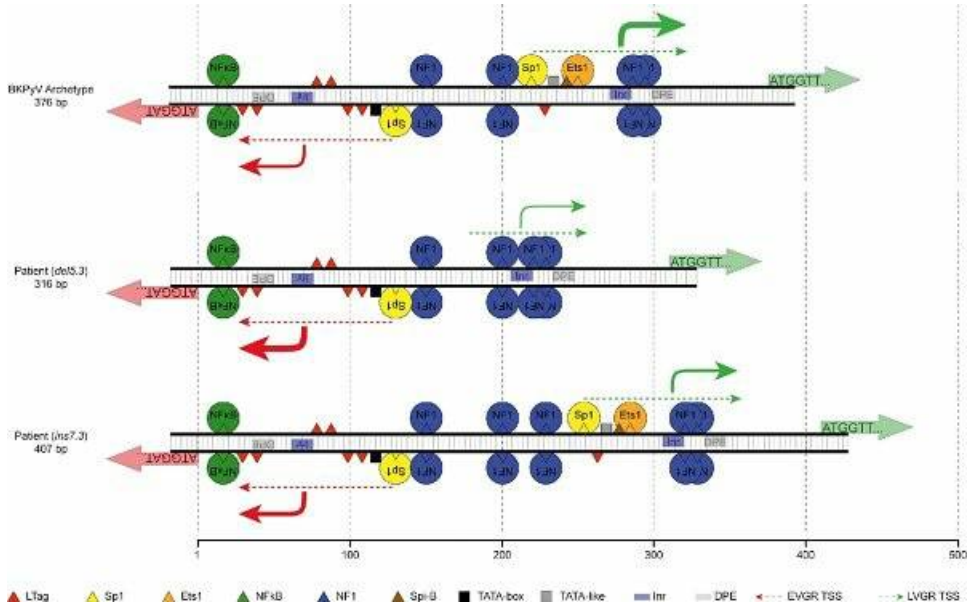

FIGURE 1.15 Bidirectional regulation from the BK polyomavirus NCCR. The transcription factors SP1, ETS1, and NF-1 determine the strength and direction of gene expression toward EVGR (early; *red arrow*) and LVGR (late; *green arrow*). **TOP:** The BKPyV archetype NCCR mediates basal activity with low EVGR expression (*dashed arrow*) and high LVGR expression (*green arrow*). SP1 and ETS1 contribute a directional effect on neighboring SP1 and ETS1, whereas NF1 has a stabilizing effect. **Middle:** Patient isolate del5.3 NCCR carries a deletion of SP1 and ETS1 transcription factor binding sites resulting in significantly increased EVGR expression and viral replication. **Bottom:** Patient isolate ins7.3 NCCR carries a partial duplication introducing additional NF1 binding sites in the center, which in an insulator-like fashion lower LVGR expression and confer significantly increased EVGR expression and viral replication.[23] (Modified after Bethge T, Hachemi HA, Manzetti J, et al. Sp1 sites in the noncoding control region of BK polyomavirus are key regulators of bidirectional viral early and late gene expression. *J Virol* 2015;89(6):3396–3411.)

SP1 emerged as a key regulatory factor conferring either a group-1 or a group-3 phenotype, if mutating the binding site *SP1-2* close to the LVGR or *SP1-4* to the EVGR promoter,

respectively.[22] Further mutational and sequence analysis indicated that the EVGR and the LVGR promoter partially overlapped in opposite outward directions in an imperfect rotational symmetry.[22] Thus, the EVGR bears the low-affinity *SP1-2* site proximal to a consensus promoter element consisting of a perfect *TATA*-box and one major initiator (Inr)/transcription start site (TSS) in a canonical distance of 31 bp, followed by a consensus downstream promoter element (DPE) at a distance of 28 bp. Thereby, the EVGR promoter of the BKPyV archetype NCCR fulfils the criteria of a developmental or regulated promoter with perfect *TATA*-box, focused TSS, and a low basal activity. By contrast, the LVGR promoter bears the high-affinity *SP1-4* partially overlapping with a potential transcription factor IIB (TFIIB) recognition element upstream (BREu), followed by two *TATA*-like elements, besides some dispersed TSSs, and potential DPEs. Thus, the archetype BKPyV LVGR promoter shows features of constitutive housekeeping or tissue-restricted genes, which changes from a focused transcription start to a dispersed type in the BKPyV Dunlop NCCR due to the deletions of the late promoter sequences.[22] Accordingly, the intertwined and imperfect symmetry of SP1 sites, *TATA*-box and -like elements, initiator, and DPEs in the BKPyV NCCR may contribute to maintenance of the archetypal focus on the LVGR side while repressing EVGR expression. At the same time, this organization permits an effective bidirectional system that is highly poised to shift the transcriptional balance to EVGR expression upon differential stimulation or group-1 type mutations.[22] Developing drugs preventing group-1 type activation or conferring group-3 type inactivation would be of interest for prevention and treatment of BKPyV replication.

The interaction of the human PyV NCCR with corresponding host cell makeup of transcription factors and DNA-binding proteins is predicted to play an important role for host cell permissiveness and likely depends on cellular differentiation and activation signals.[2] Two exploratory studies transfecting 13 HPyV NCCR reporter constructs into different cell lines derived from kidney, skin, lung, cervix, brain, and colon revealed host- and NCCR-attributable differences in EVGR and LVGR expression levels, reflecting a role for secondary host cell specificity with respect to viral gene expression and persistence.[2,231]

The MCPyV NCCR region is poorly characterized but represents an important opportunity to understand how this virus replicates normally and how it sustains LTag and STag expression in MCC. Of note, the entire NCCR region along with STag and the N-terminal region of LTag to the LXCXE, RB-binding, motif is conserved in MCC tumors containing integrated MCPyV viral DNA.[315] An early report indicated that the MCPyV early promoter could be activated by UV radiation, but no further studies have been reported.[232]

Rearrangements in the NCCR have been found in BKPyV, JCPyV, and HPyV7-associated diseases.[35] The viral NCCRs referred to as archetype are thought to be associated with naturally circulating polyomaviruses, while rearranged NCCRs arise when high levels of viral replication emerge when cultured in the lab or during disease in patients with immunodeficiency. For example, direct cloning of the JCPyV NCCR from the CSF of HIV/AIDS patients with PML identified partial duplications, deletions, and other combinations that lead to increased EVGR expression and accelerated JCPyV replication in tissue culture.[108] BKPyV NCCR rearrangements have been shown to replace archetype virus in kidney transplant patients with high levels and prolonged duration of plasma BKPyV-DNAemia and histologically proven BKPyV-associated nephropathy.[109] These rearrangements may enable higher levels of LTag and viral replication that are tolerated by the patient's immunocompromised state.[108,109] Notably, an

SV40/JCV hybrid virus containing JCPyV T antigen and Vp1, Vp2, and Vp3 coding sequences but a hybrid NCCR with elements of the SV40 enhancer grows with faster kinetics and to higher titers than wild-type JCPyV and has an expanded host range to human and monkey kidney cells as well as monkey glial cells.[337]

The SV40 early promoter undergoes negative feedback regulation by LTag.[328] When cells are infected with SV40 containing a temperature-sensitive LTag mutant at the nonpermissive or restrictive (elevated) temperature, early mRNAs are overproduced. The ability to repress early transcription is dependent on the binding of LTag to the promoter. Mutations that disrupt the DBD of LTag also typically lead to higher levels of LTag.[154] The SV40 NCCR contains three binding LTag-binding sites, referred to as sites I, II, and III, that are all involved in repression by LTag. Because site III overlaps the early promoter elements, it is possible that LTag-binding acts to prevent binding or displace other transcription factors to that region that may contribute to the ability of LTag to repress its own transcription. Furthermore, there is evidence for changes in repressive histone epigenetic marks as well as histone repositioning in SV40 chromosomes during the switch from early to late transcription.

Early gene expression in SV40 can also be down-regulated by miRNAs encoded by the LVGR.[323] Several other primate polyomaviruses have similar sequences that are predicted to form the characteristic hairpin structure of miRNA and have been detected during BKPyV and JCPyV infection in culture and patients. Somewhat surprisingly, an SV40 mutant virus lacking the miRNA does not produce more virus than wild type in cultured monkey kidney cells. However, cells infected with the miRNA-defective virus are more sensitive to killing by cytotoxic T lymphocytes *in vitro*. This observation led to the proposal that the miRNA serves to limit production of antigens recognized by the immune system and thereby protecting the infected cell.[323] Somewhat surprisingly, a mutant MPyV that cannot express its miRNA showed no difference in pathogenesis in animals.[324] More recently, it has been shown that the miRNA controls replication of BKPyV containing an archetype, but not rearranged, NCCR.[34] Moreover, the aforementioned SV40 miRNA mutant is less efficient than wild type in establishing a persistent infection in the Syrian hamster animal model, and the MCPyV miRNA also appears to control persistence.[329] Together, these findings support a model in which the relative amounts of expression of the early mRNAs and miRNAs, as governed by the structure of the NCCR, determine the outcome of infection.[34] Nonetheless, the role of the PyV miRNAs during infection remains to be fully elucidated.

Similar to the early promoter, the late promoter elements have been defined in a variety of *in vivo* and *in vitro* systems. In SV40, maximal late transcription requires sequences in the 21–base-pair GC repeats and the 72–base-pair enhancers. Late gene transcription occurs concomitantly with the onset of DNA replication, although replication is not required for activation of late transcription. LTag can promote viral replication as well as late gene expression. LTag can stimulate late transcription, although LTag binding the origin of replication is not required for this activity. Rather, transcription activation is accomplished through LTag interactions with components of the basal transcription machinery such as *TATA*-binding protein, a component of TFIID and TBP-associated factor 1 (TAF1), as well as transcription factors late SV40 factor (LSF, TFCP2), TEF-1 (TEAD1), and SP1. These interactions increase the binding of TBP and another basal transcription factor, TFIIA, to the *TATA* element.

The control of late gene expression in MPyV is more complicated. Host range or hr-t

mutants that do not express functional STag or MTag produce equivalent amounts of late proteins, as does wild-type virus.[95] However, infection with a virus containing similar mutations in cells with a different genetic background demonstrated a stimulatory role of the two T antigens during the late phase. This does not appear to be solely due to amplification of the genome but may also involve direct activation of transcription. These same studies also indicated a role for MTag and STag in the induction of early gene expression. Notably, the MPyV differs from its primate counterparts in how its late primary RNA transcript is processed. The MPyV late poly(A) site is a relatively weak site, resulting in the RNA polymerase circling the viral genome multiple times. The first exon of the late transcript can therefore be spliced to itself multiple times, although the protein-coding sequence is only present once on each mature mRNA.

Translation

Limited studies have been performed to address perturbations in translation by the polyomaviruses. An important question in the polyomavirus life cycle is how and when does translation of Vp3 occur when the same reading frame on the late transcript encodes both Vp2 and Vp3. Vp3 uses an AUG sequence downstream of the Vp2 start codon. Mutagenesis of the SV40 LVGR between the Vp2 and Vp3 start codons revealed evidence for two internal ribosome entry sites (IRESs) that could potentially promote cap-independent translation of Vp3. This observation may be particularly important because SV40 infection leads to a decrease in cap-dependent translation.[369,370] SV40 STag leads to decreased phosphorylation of 4E-BP1 that in turn binds to and represses eIF4E, reducing cap-dependent translation. This inhibitory effect on phosphorylation 4E-BP1 required the SV40 STag PP2A-binding domain and was most evident at late times after infection.[370]

The ability of SV40 STag to reduce levels of 4E-BP1 phosphorylation during infection contrasts with the effects of MCPyV STag. As described later, part of the MCPyV genome is randomly integrated into the host cell chromosomes in a manner that includes the NCCR and permits expression of an intact STag and an N-terminal fragment of LTag.[84,315] In cell lines derived from MCC that express MCPyV STag, downstream targets of AKT and mTOR including 4E-BP1 were hyperphosphorylated, leading to increased cap-dependent translation.[304] This activity appeared to contribute to the transforming activity of MCPyV STag because a phosphorylation-resistant form of 4E-BP1 reduced cell growth in the MCC cell lines. Notably, this activity was independent of the MCPyV STag PP2A-binding domain, suggesting the possibility that this represents a unique function of MCPyV STag.

Replication of Viral Genomic DNA

To a great extent, PyV LTag orchestrates the viral life cycle. Studies of SV40 LTag led to groundbreaking insights into eukaryotic DNA replication including the role of its DNA-binding and helicase activities, culminating in the establishment of the first *in vitro* system for eukaryotic DNA replication. The history of these seminal discoveries and the scientists who made them is well described in a review.[82] While many of the insights into the molecular functions of polyomavirus LTag have come from studies on SV40, investigations into other polyomaviruses have also made substantial contributions to our understanding of viral replication.

The LTag binds directly to the viral origin of replication and functions as a helicase to

unwind the viral dsDNA to enable replication. LTag also serves to recruit cellular proteins including RPA, DNA polymerase α/primase, and topoisomerases I and II to facilitate viral genome replication (Fig. 1.8). In addition, LTag induces changes in the cell to facilitate viral replication including the formation of viral replication centers within the nucleus (Fig. 1.16).

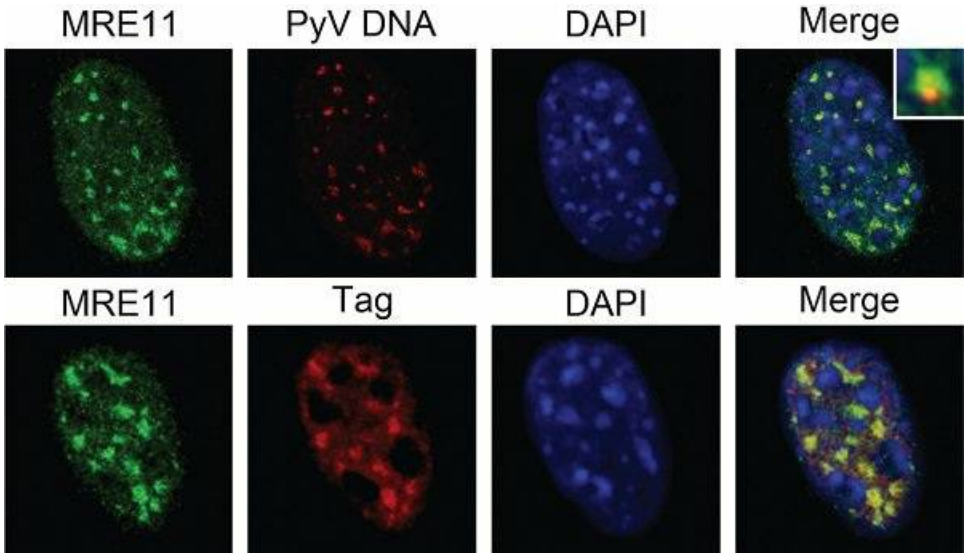

FIGURE 1.16 MPyV DNA and large T antigen form viral replication centers. C57 MEFs infected with MPyV were stained for MRE11 and PyV DNA (by FISH) or MRE11 and large T antigen.[79] (Reprinted from Erickson KD, Bouchet-Marquis C, Heiser K, et al. Virion assembly factories in the nucleus of polyomavirus-infected cells. *PLoS Pathog* 2012;8(4):e1002630. https://creativecommons.org/licenses/by/3.0/.)

Polyomaviruses normally infect quiescent or growth-arrested cells that are not actively proliferating, yet they require the host cell's DNA synthetic machinery that is fully active during the S phase of the cell cycle. LTag plays a role in inducing exit from the quiescent state and entry into S phase by binding and inactivating the retinoblastoma tumor suppressor protein. LTag also functions to counter the cell's apoptotic responses induced by viral DNA replication by binding and inactivating the p53 tumor suppressor protein. The cellular DNA damage response to replicating viral genomes is triggered in part by LTag and appears to be required for efficient viral replication.

The SV40 origin of replication contains three regions, a core origin of 64 base pairs with four pentanucleotide (GAGGC) sequences organized as a pair of inverted repeats flanked by an early palindrome (EP) on the early side and an A/T-rich region on the late side.[310] The LTag DBD binds directly to the pentanucleotide sequence.[221] After two molecules of LTag bind to opposing inverted pentanucleotide sequences, they each recruit five additional molecules of LTag to form a hexamer. The two hexamers face each other in a head-to-head orientation that surrounds the origin. After double-hexamer formation, LTag initiates melting of the DNA in the EP region and twisting of the A/T region. Viral DNA is opened to form single-stranded DNA (ssDNA) followed by LTag-recruiting RPA and topoisomerase I. The helicase domain of LTag recruits the

DNA polymerase α/primase complex (POLA1, POLA2, PRIM1, PRIM2) that contributes to RNA Okazaki primer formation on the lagging strand.

Besides its role in initiation of DNA synthesis, LTag is also required for elongation of the growing chains. Elongation is carried out by DNA polymerase δ (POLD1, POLD2, POLD3, POLD4) in conjunction with its accessory factors, proliferating cell nuclear antigen (PCNA), and replication factor C (RF-C). The LTag translocates on ssDNA on the leading strand template in the 3′ to 5′ direction. LTag has an ATPase-dependent 3′ to 5′ helicase that advances each hexamer in opposite orientations along the viral DNA.[364] Replication occurs in a bidirectional manner and ends with the decatenation of the two linked circular molecules by topoisomerase II.

The bidirectional nature of SV40 DNA synthesis was demonstrated in two ways. First, Danna and Nathans performed an elegant experiment in which they pulse-labeled infected cells with ^{3}H-thymidine for 5 to 15 minutes, isolated fully replicated DNA molecules, and determined what parts of the genome were labeled.[62] The theory behind this approach is that the labeled thymidine would appear farthest from the origin of replication in cells that were labeled for the shortest time periods, because those were the closest to completion, and extend back toward the origin as the labeling time was extended. This allowed the mapping of the origin as well as the determination that replication was bidirectional. The second approach used shadowing of DNA with electron microscopy imaging of replicating SV40 and MPyV.[346] Here, replication forks were visualized and mapped in relation to the ends of the DNA molecules, which had been digested with a restriction endonuclease at a unique site on the chromosome.

Examination of the crystal structure of the LTag helicase domain when bound to adenosine triphosphate (ATP) or adenosine diphosphate (ADP) led to the proposal that ATP hydrolysis induces conformational changes that cause twisting of the hexamers resulting in expansion and constriction of the central channel that resembles the movement of an iris within an eye.[190] Using a variety of single-molecule assays, it was shown that after assembly of the SV40 LTag double hexamer on the origin, the hexamers separate to unwind DNA as a single hexamers that translocate in opposite directions on DNA in the 3′-to-5′ direction.[364]

Phosphorylation of LTag regulates its ability to drive DNA synthesis.[310] In SV40, phosphorylation of LTag threonine residue 124 by cyclin-dependent kinases enhances binding of the protein to the origin of replication, assembly of the double hexamers, and subsequent unwinding.[220] In MPyV, the corresponding LTag threonine residue 278 is also phosphorylated and mutation of this residue abolishes replication function. Conversely, phosphorylation of SV40 LTag serine residues 120 and 123 inhibits replication. These serine residues can be phosphorylated by casein kinase I and dephosphorylated by PP2A.

The N-terminal J domain of LTag contributes to viral DNA replication, functioning through binding to HSC70. While the J domain is not required for viral DNA replication *in vitro*, it plays a significant role *in vivo*.[40] Notably, the J domain from the human HSP40 homolog HSJ-1 protein can support SV40 DNA replication when it was substituted for the homologous domain of LTag, suggesting that interaction of LTag with HSC70 and the host cell heat shock system facilitates viral replication. The mechanism by which the LTag J domain stimulates DNA replication is not known but may involve chaperone-mediated rearrangements of the initiation complex on the DNA.

An essential contribution of LTag to viral replication is to induce the cell to enter the cell cycle. Although polyomaviruses normally infect cells that are not actively dividing, they require

the host cell's DNA synthetic machinery, produced and activated during S phase, for replication of the viral genome. LTag drives the resting cell into S phase by binding to RB and the RB-related proteins p107 (RBL1) and p130 (RBL2) (Fig. 1.8).[64] The RB tumor suppressor proteins, sometimes referred to as pocket proteins, inhibit entry into S phase through binding and repression of the E2F family of transcription factors.[71] During the quiescent (G0) and G1 phase of the cell cycle, RB and p130 form complexes with E2F on the promoters of genes required for DNA synthesis. Notably, p130 binds to the repressor E2F4/DP1 heterodimer and recruits the five-protein MuvB complex to the promoters of several hundred E2F-dependent, cell cycle–regulated genes.[196,281] The DREAM (DP1, RBL2, E2F4, and MuvB) complex is disrupted when LTag binds to p130, thereby releasing the MuvB core complex and enabling activation of E2F-dependent genes. When a cell is induced to divide physiologically, cyclin-dependent kinases serve to phosphorylate the RB family proteins, enabling their release from E2F and thereby permitting gene expression. LTag subverts this pathway by binding to RB family proteins and disrupting their binding to E2F. The LXCXE motif in LTag binds directly to the RB family proteins.[168] In addition, the LTag N-terminal J domain cooperates with the LXCXE motif binding of RB family proteins to facilitate their release from E2F. The SV40 LTag J domain also perturbs the phosphorylation status and stability of RB-related proteins, thereby contributing to loss of their E2F repression functions.[321,322]

In addition to causing the cell to enter S phase, SV40 LTag carries out another important role in establishing the proper cellular environment for replication. The inappropriate entry into S phase induced by LTag causes the cell to activate a p53-dependent growth arrest and proapoptotic response. The p53 tumor suppressor protein was first discovered by virtue of its being co-immunoprecipitated with SV40 LTag from cellular protein extracts.[180,195] SV40 LTag binds directly to the DBD of p53, thereby disrupting p53's ability to transactivate its target genes such as *p21* (*CDKN1A*), *PUMA*, and *MDM2* involved in cell cycle arrest, apoptosis, and autoregulation, respectively.

The ability of LTag to activate p53 is due, at least in part, to increased levels of ARF (alternate reading frame), a product of the *CDKN2A* gene that also expresses the CDK4 inhibitor p16 (*INK4A*). ARF functions to stabilize p53 by binding to and inhibiting the E3 ubiquitin ligase activity of MDM2 directed toward p53. Although normal cell cycle entry does not induce ARF expression, SV40 and MCPyV LTag and MPyV MTag induce expression of ARF.[236,257] Although LTag from many polyomaviruses can bind to p53 and thereby inactivate its growth inhibitory and apoptotic response, MPyV and MCPyV LTag are notable for their inability to bind directly to p53. Nonetheless, MPyV is able to counter the p53-mediated growth arrest by STag inhibition of ARF.[236] By contrast, MCPyV STag indirectly inhibits p53 function by contributing to increased levels of MDM2 and MDM4 that cooperatively function to degrade p53.[257]

Recent evidence indicates that the cellular DNA damage response (DDR) is required for SV40 MCPyV, MPyV, and BKPyV replication.[124,150,373] PyV infection induces a cellular DDR response that includes activation of the ATM and ATR kinases, resulting in phosphorylation of the specialized histone γ-H2AX and the checkpoint kinases CHK1 and CHK2. LTag colocalizes with phosphorylated ATM and γ-H2AX on DNA to form nuclear foci that include the MRN complex (Mre11, Rad50, and Nbs1) and 53BP1 (Fig. 1.16).[313] LTag alone without viral DNA can also induce the DDR, and this may be dependent on LTag interaction with BUB1. In

addition to the replicative polymerases noted above, it is clear that DNA repair polymerases must also play an important role in polyomavirus genome replication, since inhibiting the cellular DDR, which is also induced by breaks on the viral genome resulting from replication fork stalling,[313] decreases the production of infectious viral genomes.[124,150] In addition, the DDR arrests cells to provide an environment that maximizes viral genome replication.

In addition to the DDR, much attention has focused on the role of nuclear structures called promyelocytic leukemia nuclear bodies (PML-NB) during replication and infection. In BKPyV infection, LTag colocalizes with PML-NB at very early times and, concomitant with the onset of viral DNA replication, induces a dramatic reorganization of PML-NB. It remains unclear if the changes in the PML-NB are a consequence or a requirement of viral replication. In MPyV-infected cells, PML-NB colocalize with structures that appear to be viral assembly factories.[79]

Assembly

Assembly of polyomaviruses begins with the translocation of Vp1, Vp2, and Vp3 into the nucleus and the formation of capsomeres. The Vp1, Vp2, and Vp3 from SV40 and MPyV each contain nuclear localization sequences. Vp2 and Vp3, in the absence of Vp1, do not accumulate in the nucleus but rather require Vp1 for nuclear transport, indicating that these proteins may be imported as a complex. The Vp2 or Vp3 NLS may be more important for trafficking of incoming virus from the ER to the nucleus than for import of the newly synthesized proteins during the late phase of the infection. This model fits with the data indicating that Vp2 and Vp3 become exposed as the virus transits through the ER.

It is unclear whether empty capsids are precursors to mature, DNA-containing virions or dead-end products, or whether the capsid assembles around the viral chromosome. While it has been reported that a *cis*-acting sequence in the origin region of SV40, *ses*, enhances DNA packaging, DNA molecules that lack this sequence element can still be encapsidated. The crystalline-like arrays of PyV virions present in nuclei may reflect the presence of viral factories. In this model, tubes comprised of Vp1, and possibly Vp2 and Vp3, can facilitate budding of virions containing viral DNA.[79] Examples of crystalline-like arrays of PyV virions have been observed in several diseases characterized by severe infection including PML, PyVAN, and trichodysplasia spinulosa (Fig. 1.17).

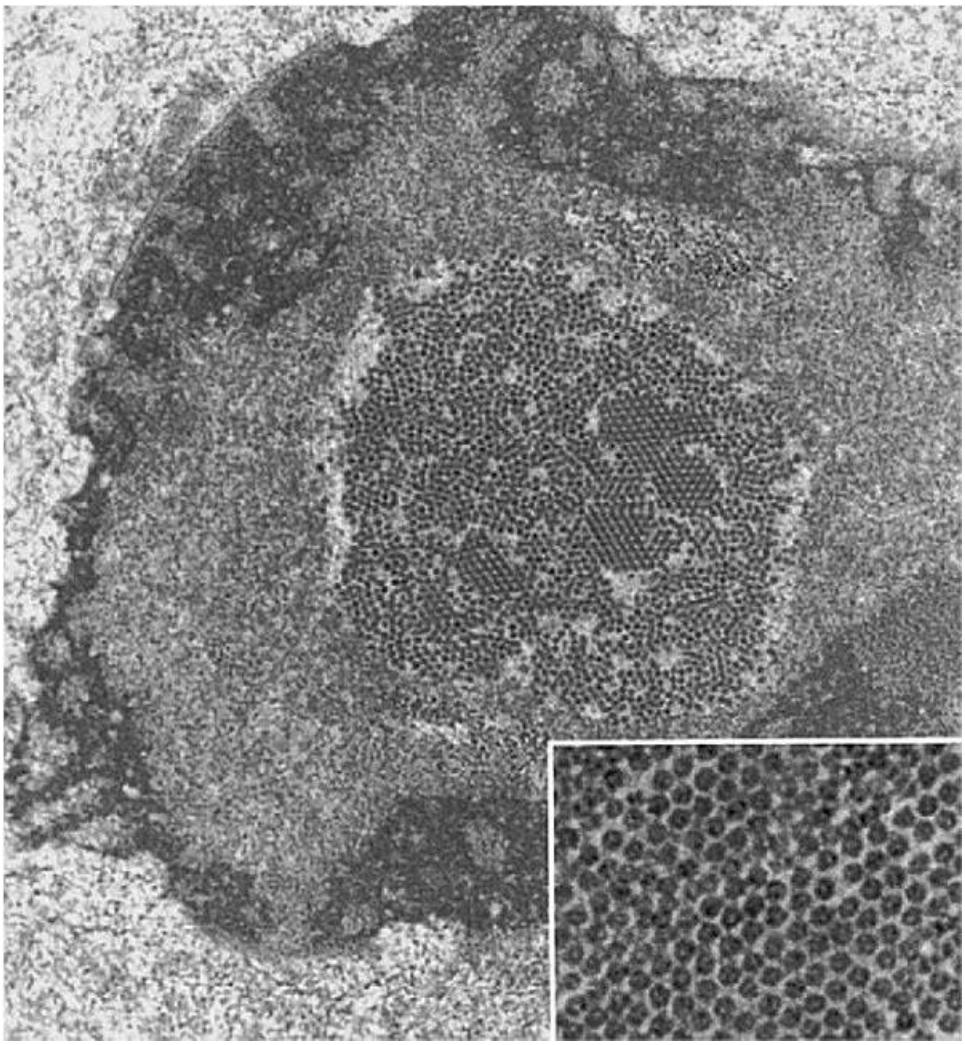

FIGURE 1.17 Crystalline-like arrays of virions in virus-associated trichodysplasia spinulosa. Purified recombinant Vp1, expressed in bacteria, yeast, or baculovirus-infected insect cells, can self-assemble into capsomeres. Under appropriate conditions, these capsomeres form capsid structures referred to as VLPs (Fig. 1.4). Therefore, viral DNA, Vp2, and Vp3 are not required for capsid formation. Changes in ionic strength and pH of the buffer can lead to formation of other structures including tubular moieties and T = 1 icosahedrons. It has been shown that chaperones such as HSP70 are required for efficient capsid assembly. VLPs are very similar to authentic virions and have been used for basic studies on receptor binding, virus entry, intracellular trafficking, and the immune response. VLPs have also been studied as vehicles for delivery of genes (i.e., as so-called pseudoviruses) and small molecules, and have been extensively used for serologic assessment of polyomavirus infection.

Release

The manner by which polyomaviruses leave the cell is poorly understood. While some studies indicate that the virus causes lysis of the cell, others indicate that virus can be shed from intact cells. For example, SV40 infection can cause a cytopathic effect (CPE) or vacuolating effect with destruction of the cell. The vacuolization effect requires interaction between SV40 Vp1 and binding to GM1 and is caused by the binding of released progeny viruses to GM1 (Fig. 1.2).[204] Alternatively, SV40 can leave polarized epithelial cells from the apical surface and can exit nonpolarized epithelial cells without killing them. A regulated virus exit process is suggested by the observation that SV40 can be detected in cytoplasmic membrane vesicles using electron microscopy, and release of virions is inhibited by monensin, which blocks vesicular transport.

JCPyV causes cell death through lytic infection of glial cells. Infection of astrocytes cultured *in vitro* supports a progressive JCPyV infection that leads to necrotic cell death and virion release. Notably, this model system did not yield any evidence for apoptosis by JCPyV infection.

The agnoprotein may also contribute to assembly and egress. SV40 isolates containing mutations in agnoprotein replicate with wild-type kinetics but produce plaques that are smaller than wild type due to inefficient release of mature virions from the cell. Other phenotypes of agnoprotein mutants that could account for inefficient viral replication include improper localization of Vp1. At the nuclear envelope, agnoprotein has been shown to dissociate heterochromatin protein 1 (HP1) from the lamin B receptor, resulting in destabilization of the envelope, perhaps explaining how agnoprotein could facilitate egress.[250] While some of the LTag host range mutations affect agnoprotein expression, the assembly defect in these mutants cannot be complemented by expression of agnoprotein *in trans*. Additional functions have been proposed for the JCPyV and BKPyV agnoprotein, including as a viroporin.[255] Recent studies demonstrate that the BKPyV agnoprotein allows the virus to evade innate immune sensing in the late viral replication phase by disrupting the mitochondrial network and membrane potential, and promoting p62/SQSTM1 mitophagy in renal tubular epithelial cells in vitro and in vivo.[214] JCPyV and SV40 infection similarly disrupt mitochondrial networks and aid in innate immune evasion by disrupting the mitochondrial network and by promoting mitophagy.

Most recently, it has been reported that, like a growing number other nonenveloped viruses, both BKPyV and JCPyV can be transmitted from cell to cell within extracellular vesicles.[234] Interestingly, JCPyV transmitted in vesicles is resistant to neutralizing antibodies, while BKPyV remains sensitive.[121,234]

PATHOGENESIS AND PATHOLOGY

Entry Into Host

The principal target cell for initial entry of polyomaviruses has been difficult to identify. However, it appears that, once exposed to a polyomavirus, an individual maintains a lifelong persistent infection as determined by specific serology to Vp1 or detection of the viral DNA on skin or in urine. For example, many polyomaviruses including SV40, BKPyV, and JCPyV are present in the urinary tract and excreted in the urine. Exposure to infected urine could be a source

of infection for these polyomaviruses, although BKPyV rapidly loses its infectivity in urine.[107] There have been reports of JCPyV infection in human colonic epithelial cells and isolation of BKPyV and JCPyV from stool specimens.[30] Notably, BKPyV, JCPyV, MCPyV, KIPyV, and WUPyV have been frequently detected in sewage samples, while BPyV has been detected in farm wastewater samples.

JCPyV is able to productively infect tonsillar stromal cells in culture with efficiency nearly comparable to human glial cells. JCPyV DNA has also been found in lymphoid tissues including bone marrow and spleen. JCPyV DNA has been identified in tonsil stromal cells and in B cells isolated from tonsils. The ability of JCPyV to infect tonsillar stromal cells in culture and the presence of JCPyV DNA in tonsil tissue suggest the possibility that the initial infection could occur in these tissues as well.

BKPyV has been detected in lung tissue from one case of interstitial pneumonia in a hematopoietic stem cell transplant (HSCT) patient and in the respiratory tract and tonsil tissue in another, as well as in salivary glands, and can replicate in salivary cells in culture. This, together with the observation that the majority of the population in both developed and developing regions of the world seroconverts in early to mid-childhood, would support a respiratory or oropharyngeal–gastrointestinal route of transmission.[127] By the same token, it is surprising that other viruses were not reported, some of which had been proposed to be associated with respiratory symptoms or febrile tonsillitis such as BK virus and other polyomaviruses.

WUPyV and KIPyV can be detected in respiratory secretions that represent either the site of acute infection or persistence. For example, WUPyV is frequently detected in tonsils and nasopharyngeal lymphoid tissue from immunocompetent children. WUPyV and KIPyV were also found in plasma, urine, and respiratory samples of renal transplant patients.

For some polyomaviruses, there is evidence for maternal–fetal transmission. MPyV can be acquired vertically through transplacental transmission or direct contact as neonates.[371] By contrast, a recent study determined that the human polyomaviruses WUPyV, KIPyV, and MCPyV were not present in more than 500 fetal tissues, although serologic assessment indicated that nearly half of the mothers had been infected with MCPyV.[282]

Polyomavirus infection in birds spreads quickly in susceptible flocks. Avian polyomaviruses can be found in the urine and fecal matter in flocks, suggesting an oral route of transmission. Bird fledglings become viremic after being bitten by blowfly larvae and shed virus from their cloaca, thereby infecting the breeding adults.[268] In parrots, viremia was followed by cloacal shedding within 1 week of experimental infection.[266] Infected birds may harbor virus persistently throughout life, but acute infection can cause neurologic damage and death in younger birds.

Immune Response

Humoral immune responses occur in all animal species infected with polyomaviruses and show some cross-reactivity within rodent, primate, or avian families but not across those barriers unless immunized with laboratory-made virions or proteins. Antibody against polyomavirus is IgG, although a number of reports identified IgM and IgA responses with viral replication.[132,159] The Multicenter AIDS Cohort Study found that approximately 80% of all participants had immunoglobulin titers specific for MCPyV Vp1. Within the remaining group of seronegative participants, approximately 26% seroconverted in the following 4 years. Notably, no clinical

signs or symptoms associated with acute MCPyV infection and subsequent seroconversion were appreciated.[330]

Measurements of cellular immune responses to JCPyV and BKPyV in infected individuals have identified CD8+ cytotoxic T lymphocytes (CTLs) that recognize epitopes on Vp1 and LTag. The epitope on BKPyV Vp1 amino acid residues 108 to 116 elicits a T-lymphocyte response that also recognizes JCPyV epitope Vp1 p100.[176] Using tetramer assays or CTL cell lysing assays, CD8+ T cells can be found in the peripheral circulation that are human leukocyte antigen (HLA) restricted to genotype A*02, B*07, and B*08, present in healthy blood donors and transplant patients.[76] Using overlapping 15mer peptide pools or immunodominant 9mers, JCPyV and BKPyV-specific CD4 and CD8 T cell responses have been detected in an HLA-independent manner in HIV, multiple sclerosis, or kidney transplant patients.[159] Viral-specific CD8+ T lymphocytes show a good correlation with time of survival in PML patients or with clearance of BKPyV in kidney transplant patients.

A CD8+ cytotoxic T-cell response was noted in an analysis of mRNA expression profiling of MCC.[261] Notably, patients with a better prognosis had a statistically significant increase in genes related to the CD8+ response. The response was most likely due to infiltrating CD8+ cells that were captured when the mRNA was prepared from the tumor.

There is also a T-cell–mediated immune response in SV40-infected monkeys and MPyV-infected mice that confers protection from infection and is thought to play a role in establishing viral persistence in SV40- and MPyV-infected animals. Stimulation of CD8+ CTLs in mice, however, affects different pathways involving CD28 and CD40 ligands during the course of either acute or persistent infection.[164]

The past few years have seen a growing interest in the innate immune response to polyomavirus infection. It was first shown that expression of LTags from SV40, JCPyV, and BKPyV induces the expression of interferon-stimulated genes (ISGs) in mouse embryonic fibroblasts.[102] Subsequently, experiments comparing BKPyV and JCPyV infection of primary human renal epithelial cells, a cell culture model first described in 2004 that has become the preferred model for these two human viruses, demonstrated that the ability of the two viruses to replicate was inversely correlated with induction of ISGs.[8] While both viruses induced interferon β, JCPyV-infected cells induced ISGs, correlating with poor replication, whereas BKPyV-infected cells had no ISG production, with robust levels of replication. On the other hand, BKPyV cannot replicate efficiently when exposed to type-1 interferons induced when infecting endothelial cells or when lacking wildtype agnoprotein.[5,214] The nature of the different responses in different cells, or even within the same cells in the presence of the two viruses, remains to be determined.

Persistence

One of the interesting biological characteristics of all the polyomaviruses is the maintenance of a chronic and lifelong infection in their hosts. Evidence for persistence of PyV infection in the urinary tract is supported by viral excretion in the urine of healthy individuals with remarkably high levels of virus, ranging from 10^3 to 10^8 copies per milliliter (c/mL). Virus can be detected in uroepithelial cells and in ductal pathways. However, there is no apparent pathology associated with such high levels of urinary excretion unless there is an underlying immune-compromised

condition. There is no information, however, on the mechanisms of viral persistence other than the possible role of the PyV miRNA or innate immune response, as described above, or what triggers viral synthesis and multiplication and the consequences of lifelong virus shedding in the urine. There is no evidence that polyomaviruses enter a true latent state in which there is little or no viral gene expression or genome replication as with the herpesviruses.

For the human polyomaviruses, the kidney or urothelium is the primary location for BKPyV, whereas the kidney and lymphoid organs are locations for JCPyV with differing consequences of infection. The sites of persistence for WUPyV and KIPyV have not been determined, although viral DNA has been recovered from respiratory secretions. MCPyV, HPyV6, and HPyV7 DNA can be readily isolated from normal skin and MCPyV virions are shed from the skin.[288] Given the rarity of normal Merkel cells in skin, this raises the possibility that MCPyV is produced by the stratified epidermal keratinocytes rather than less abundant Merkel cells. Alternatively, dermal fibroblasts, capable of supporting MCPyV replication *in vitro*, could be a source for MCPyV isolated from the skin.[198,199]

Transformation

Since their initial discovery, polyomaviruses have been used to study the transformation of normal cells. The initial observations of the tumor-causing ability by MPyV followed by the observation that injection of SV40 into newborn hamsters led to tumor development heralded the potent transforming activities of polyomaviruses.[317] Since then, many more polyomaviruses have been identified and their transforming activity has been compared to MPyV and SV40.

The transforming activity of the polyomaviruses is limited to their T antigens. The Vp capsid proteins and agnoprotein do not have transforming activity. The LTag and STag of most mammalian polyomaviruses as well as MTag of MPyV, Rat, and HaPyV have transforming activities. The LTags of the different primate viruses have been shown to have different transformation efficiencies in cells in culture.[32,122] LTag transforms cells in part by binding to and inactivating the RB and p53 tumor suppressor proteins. The contribution of STag to transformation is dependent in part on binding to the protein phosphatase PP2A.[47] As noted above, SV40 STag recruitment of the STRIPAK complex and MCPyV STag recruitment of MYCL and the EP400 complex also contribute to their transforming potential.[51,169] MTag has unique transforming activities related to its ability to assemble and activate a tyrosine kinase signaling complex.[284]

The study of cellular transformation and its relationship to tumorigenesis was led by seminal studies of the polyomaviruses. Early studies on transformation included colony or focus formation studies of primary mouse embryo fibroblasts or established 3T3 cells. Using SV40, Risser and Pollack described a hierarchy of the transformed phenotype that began with immortalization of primary cells, followed by their growth in reduced serum conditions, anchorage-independent growth, and ultimately formation of xenograft tumors in mice.[276] The degree of transformation was dependent in part on the level of LTag expression; the higher level of LTag expressed enabled the more complete transformed phenotype.

The polyomaviruses have been used to study transformation and oncogenesis in a variety of ways. In addition to using the whole viral genome, expression vectors for the T antigens have been used to study transformation. Mammalian expression vectors that drive the expression of the EVGR containing *LTAG* and *STAG* or complementary DNAs (cDNAs) specific for *LTAG* or

STAG have been used in cells as well as in transgenic mice.[117,118] The tsA58 temperature-sensitive allele of SV40 EVGR encoding an LTag mutant A438V has been used to study transformation and establish cell lines in vitro and from transgenic mice.[148,275]

A seminal breakthrough in the study of human carcinogenesis was made when it was demonstrated that the combination of just four genetic elements could fully transform normal human cells. Expression of the SV40 EVGR or separate cDNAs encoding for LTag and STag, an activated form of HRAS, plus the catalytic subunit of human telomerase reverse transcriptase (hTERT) could completely transform normal human cells, including the ability to form tumors as a xenograft in an animal.[117,118] This strategy was applied to transform a wide variety of human cell types including astrocytes, myoblasts, and epithelial cells derived from lung, breast, and prostate tissues. This approach was expanded by substitution of SV40 LTag and STag with human oncogenes and tumor suppressor genes that led to the establishment of a model system of human oncogenesis composed of completely human genetic elements.[47] This approach has been expanded to high-throughput screens of cDNAs for gain-of-function and short hairpin RNA interference (shRNAi) knockdown or CRISPR-Cas9 knockout for loss of function to identify cellular oncogenes and tumor suppressor genes.

The transforming activity of polyomaviruses is balanced by its capacity to lyse cells during infection. Polyomaviruses can transform cells and form tumors under circumstances when the T antigens are expressed but the virus does not undergo replication at sufficiently high levels to kill the cell. If the infected cell is permissive for virus replication, then it will be killed and not undergo transformation. Conversely, if a cell is restrictive for replication but enables T antigen expression, then it may undergo transformation. Typically, a restrictive cell undergoes transformation when the polyomavirus DNA becomes integrated into the host chromosomal DNA in a way that sustains expression of the T antigens. This situation occurs when MCPyV DNA becomes integrated into the host genome and contributes to the development of MCC. Integration of MCPyV DNA is typically accompanied by mutations in the EVGR that truncate LTag, eliminating the DNA binding and helicase domains, and rendering it incapable of supporting viral replication (Fig. 1.18). Alternatively, a cell can be semipermissive and sustain low levels of viral replication while expressing sufficient levels of T antigens to change the cellular growth characteristics.

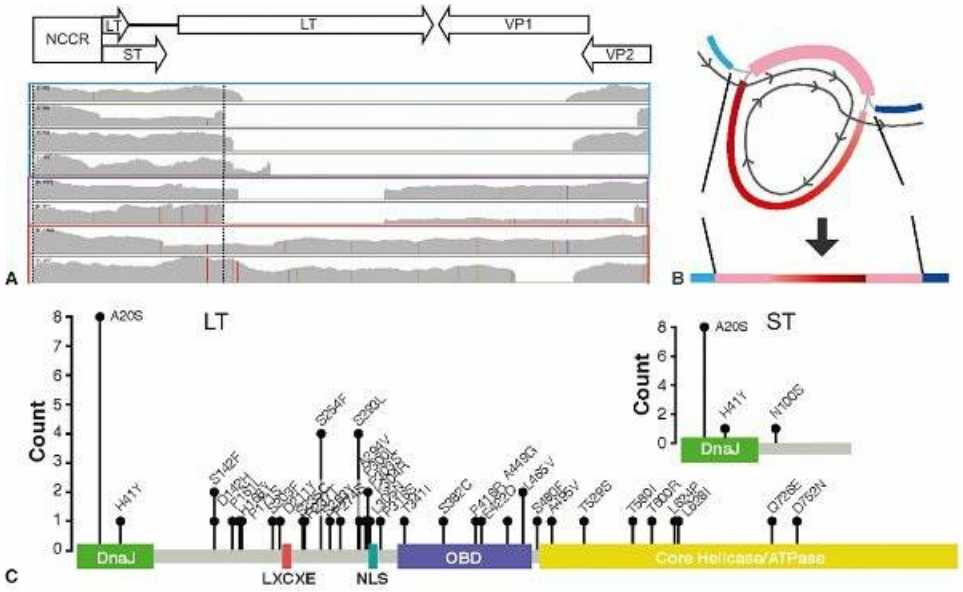

FIGURE 1.18 MCPyV Integration. A: MCPyV coverage and mutations from virus-positive cases. Read coverage for MCPyV in *gray*, and each plot represents a single patient. Scales for the coverage plots are set from 0 to the maximum read coverage per patient. The illustration above indicates relative position with MCPyV genome. Limits of minimal conserved region in MCCP tumors are indicated by dotted vertical lines. **B:** Representative assembly graph of partially duplicated MCPyV genome integrated into the tumor genome. Path for linearization of assembly graph shown by the *dark gray line*. **C:** Residue changes in MCPyV LT and ST (**inset**). Lollipop plot of LT missense mutations relative to the MCPyV reference with height reflecting the number of observations in cohort and residue change labeled above the position. LT and ST domains are highlighted by colored boxes. (Reprinted from Starrett GJ, Thakuria M, Chen T, et al. Clinical and molecular characterization of virus-positive and virus-negative Merkel cell carcinoma. *Genome Med* 2020;12(1):30. https://creativecommons.org/licenses/by/4.0/.)

The nonpermissive or restrictive environment is generally caused by species-specific differences in DNA replication factors. The best understood of these is the interaction of LTag with the DNA replication machinery including the DNA polymerase α/primase complex and recruitment to the viral origin of replication. SV40 cannot replicate its DNA in rodent cells, at least in part due to its inability to bind the DNA polymerase α/primase in these cells. BKPyV also cannot replicate in murine cells, although the cause of the restriction is multifactorial.

Another level of permissiveness involves the interaction between LTag and p53. Just as the LTag can affect p53 function, p53 has reciprocal effects on the ability of LTag to function as a replication factor.[90] A tissue-specific example of this restriction is found in the differential ability of SV40 to replicate in human fibroblasts and mesothelial cells.[29] SV40 replicates quite efficiently in fibroblasts, whereas replication is severely limited in mesothelial cells. The latter cells have higher steady-state levels of p53 than the former and decreasing p53 expression in mesothelial cells with antisense strategies increases viral replication. Changes in the viral NCCR can also change the outcome of the infection from lytic to nonlytic. Monkey kidney cells,

permissive for SV40 replication, transduced with a viral genome containing a deletion of the SV40 origin of replication that disables replication are readily transformed while the wild-type virus causes lytic infection.[106] Some rearrangements in the BKPyV NCCR that cause a decrease in DNA replication efficiency can enhance the transforming ability of the virus.

A wide variety of transgenic mice lines have been generated that express polyomavirus EVGR or individual T antigens. Many of these animals develop tumors dependent on the specific promoter used. For example, the transgenic adenocarcinoma of the mouse prostate (TRAMP) model of prostate cancer uses the rat probasin promoter and pancreatic neuroendocrine tumors uses the rat insulin promoter (RIP) to drive expression of SV40 T antigens. MPyV MTag transgenic mice have been developed using a variety of promoters. Mice with MTag expression driven by the mouse mammary tumor virus long terminal repeat (MMTV-LTR) develop multifocal mammary adenocarcinomas that can become metastatic to the lung in 3 months. Several different strains of mice expressing MPyV MTag in the prostate tissues have been developed. Mice with MTag driven by the C3 promoter develop mouse prostatic intraepithelial neoplasia (mPIN). Another strain using the (ARR)2-Probasin promoter develop mPIN as early as 8 weeks of age that develops over time to become invasive cancer.

BKPyV induces different types of tumors dependent upon the rodent species and route of inoculation. Intracerebral inoculation of BKPyV in hamsters results in ependymomas, neuroblastomas, and pineal gland tumors. Intravenous inoculation causes pancreatic islet cell tumors, fibrosarcomas, and osteosarcomas. Mouse inoculations frequently result in fibrosarcomas, liposarcomas, nephroblastomas, gliomas, and choroid plexus tumors that are also common in SV40 LTag–expressing transgenic mice. BKPyV tumor induction shows some viral strain variation, with the prototype isolate, BKPyV Gardner, possessing the greatest oncogenic potential: this is probably related to the differences in transforming potential noted earlier between viruses carrying archetype and rearranged NCCRs. It is unclear whether *trans*- or *cis*-acting factors influence tumor formation frequency, but it is assumed that NCCR variations have a dominant role.

JCPyV inoculation into hamsters also results in multiple tumor types including medulloblastomas, glioblastomas, and pineocytomas. However, unlike BKPyV or SV40, JCPyV induces a grade 4 glioblastoma multiforme or malignant astrocytoma upon intracranial inoculation into owl and squirrel New World monkeys. By contrast, JCPyV does not induce tumors when inoculated into Old World macaques or rhesus or African green monkeys. Malignant brain tumors induced by JCPyV inoculation revealed that the viral genome was integrated into the cellular DNA.[226] The astrocytoma cells can be explanted and grown in culture. In some tumor cell explants, JCPyV LTag expression gradually diminishes upon continuous culture, and it enters into senescence. One owl monkey tumor, however, demonstrated unique properties, not only surviving in culture but also becoming transplantable back into other owl monkeys. JCPyV DNA in these tumor cells, termed 586, was both integrated in the cell chromosome and episomal in high copy number. JCPyV infectious virus was produced continually in culture, resulting in a persistent viral or carrier culture.[209]

EPIDEMIOLOGY

Members of the *Polyomaviridae* family are found throughout the world in bird, rodent, nonhuman primate, and human populations. The presence of polyomaviruses in the human population has been extensively studied. In one approach, evidence for prior infection by individual polyomaviruses has been performed with serum collected from individuals. For the most part, sera testing with viral particles or more recently using VLPs prepared from recombinant Vp1 corresponding to the different polyomaviruses enables determination of prior exposure. These serologic studies have revealed that infection with polyomavirus occurs as early as several months of age and increases in frequency until, by adulthood, several species of polyomaviruses have infected nearly all individuals (Fig. 1.19). In the second approach, sequencing of polyomavirus DNA collected from the urine or the skin enabled determination of the presence of various species of polyomaviruses. This approach has revealed that for the most part, an individual maintains a lifelong infection with polyomavirus. Although protective immunity against individual polyomaviruses may prevent reinfection, it may not be sufficient to prevent infection with a different strain of the same polyomavirus. In addition, these studies have revealed that polyomaviruses have coevolved along with the human population.

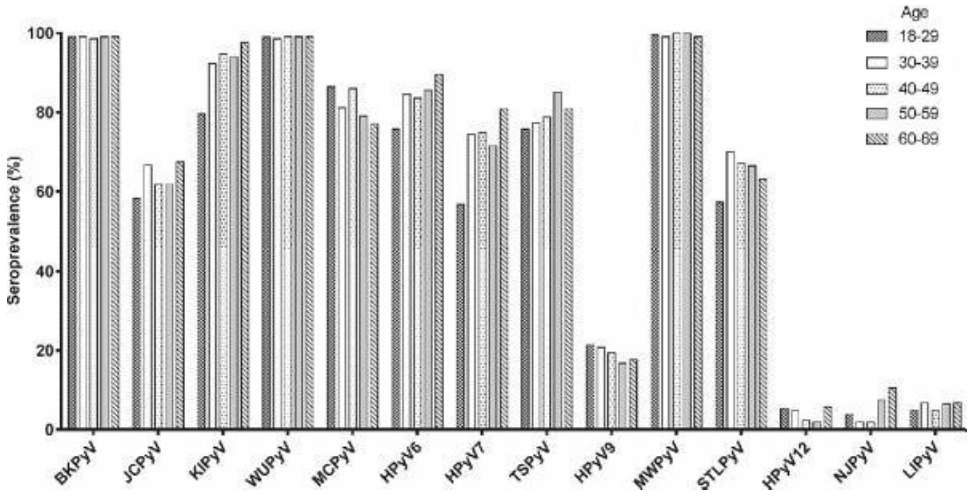

FIGURE 1.19 Seroprevalence of human polyomaviruses. "The percentage seropositivity of each polyomavirus is shown for the donor age categories 18–29".[156] (Reprinted from Kamminga S, van der Meijden E, Feltkamp MCW,et al. Seroprevalence of fourteen human polyomaviruses determined in blood donors. *PLoS One* 2018;13(10):e0206273. https://creativecommons.org/licenses/by/4.0/.)

Evidence for prior infection with specific polyomaviruses can be determined in a sensitive enzyme-linked immunosorbent assay (ELISA). Recombinant forms of Vp1 from the corresponding polyomavirus are produced in bacteria or insect cells and spontaneously form VLPs. The purified VLPs are adhered to a plate and used to capture specific immunoglobulin molecules from sera. The relative amount of antibody captured is detected using anti-IgG– or anti-IgM–labeled secondary antibodies. In a useful variation of this assay, the recombinant VLP from a polyomavirus can be used to deplete the sera of antibodies specific for a given polyomavirus prior to exposure to the VLP attached to the plate. Depletion of immune sera with a polyomavirus-specific VLP permits determination of cross-reactivity of antibodies to different

polyomaviruses. Using the VLP capture ELISA together with prior immunodepletion, evidence for infection with specific polyomaviruses can be obtained in a large collection of sera samples.

The VLP assay was initially used to detect evidence for prior infection with BKPyV and JCPyV in human sera and then expanded to search for evidence of prior infection with SV40. Some cross-reactivity in human sera has been observed between VLPs from BKPyV and SV40 and to a smaller degree between JCPyV and SV40.[163] Immune depletion of sera with BKPyV VLPs significantly reduces the titer of IgG-recognizing SV40 VLPs. Notably, reactivity of human sera against the African green monkey–derived lymphotropic polyomavirus (LPV) has been recognized for many years that was not appreciably depleted by preincubation with the VLP corresponding to SV40 or other known polyomaviruses. The discovery of human HPyV9, highly homologous to LPV, led to a direct comparison of sera reactivity for the two corresponding Vp1 proteins. Depletion with HPyV9 VLP removes most of the reactivity against monkey LPV.[332]

VLP-based assays indicate that infection with human polyomaviruses can occur in the first few years of life. Serologic surveys of populations for the detection of antibodies specific for MCPyV and BKPyV indicate that seroconversion takes place early in life. Detection of maternal antibody in newborns begins to diminish within the first 3 months and is followed by evidence for newly acquired infection soon afterward and often within the first 2 years of life. Evidence for exposure continues to increase into adulthood, with titers corresponding to prior infection observed in approximately 50% to 80% of the sera tested (Fig. 1.19).[163,332] As evidenced by antibody titers, WUPyV and KIPyV infections can occur very early in life and then progressively become more common with age, with one report indicating 100% for KIPyV in healthy blood donors older than 50 years of age.[241]

Antibodies to both BKPyV and JCPyV are quite prevalent in populated countries but less prevalent in remote populations. In a study analyzing sera from Amerindian tribes from remote regions of South America, a low percentage of samples were positive, demonstrating low titers compared to a collection of Japanese samples with the majority positive with high antibody titers, particularly to JCPyV.[208] It also seemed that introduction of the human polyomaviruses into the Amerindian population occurred at the time of human contact from other countries.

In general, detection of viral DNA by PCR or direct sequencing is less sensitive than evidence for infection by serology-based testing. A comparison of evidence for infection using VLP assays, neutralization assays, and PCR-based detection of viral DNA isolated from the skin of more than 400 patients was performed. In this study, 65% had evidence for prior infection with MCPyV based on serology, but only 18% were positive by PCR amplification of DNA isolated from skin. This may be due to the inability of certain PCR primers to amplify all possible genomes of a given virus. Notably, nearly all patients with detectable amounts of MCPyV DNA on the skin had evidence for infection by serology against the virus.[83]

Because excretion of some human polyomaviruses in the urine is relatively common, a number of studies have tested urine for the prevalence of BKPyV and JCPyV. Sequencing of the polyomaviruses has revealed variation in all regions of the viral genome, especially the NCCR and the sequences encoding the C-termini of LTag and Vp1. Sequencing of BKPyV has identified four major subgroups with evidence for coevolution with known migration patterns of human hosts.[366] This approach demonstrated that excretion of the identical JCPyV virus occurred over 5 to 7 years in 19 different individuals and indicated persistent shedding rather

than reinfection by different strains of JCPyV.[158] In addition, sequencing of JCPyV genomes revealed that the identical sequence was present in four of five families including parents and children, indicating that the virus spread horizontally within close quarters.[375]

Given that infection with JCPyV and BKPyV frequently occurs early in childhood among individuals living together, studies have been performed that reveal that polyomaviruses have coevolved with humans.[175,376] For example, a study collected urine samples from young and older individuals in Okinawa who had contact with American military and their families. The samples were analyzed using PCR to identify JCPyV DNA and nucleotide sequencing that could "type" variants of the DNA. One type was specific to Japan, while others were prominent in the United States. The results showed that none of the JCPyV DNA types found commonly in the American population were present in any age group in Japan, suggesting that virus is not easily transmitted between populations.[158] Additionally, urine samples collected from second- and third-generation Japanese Americans living in Los Angeles revealed that strains of JCPyV more commonly detected in Japan were present in the second- and third-generation Japanese American families.[325] A similar study of BKPyV found children to be infected with the local circulating strain, however, indicating transmission outside the family.[367]

Infection with MCPyV can also be traced back to childhood location by geographic areas based on sequences unique to specific polyomaviruses. Comparing the NCCR regions from different isolates revealed substitutions, small deletions, insertions, and duplications. Notably, strains detected in individuals from North America or Europe could be distinguished from those from Asia, supporting coevolution of viruses along with the host.[288]

CLINICAL FEATURES

Primary HPyV infections are assumed to occur without specific illness in the general population, either because of the subclinical course or because symptoms and signs are not specific and or usually self-limited. The natural route of transmission has not been defined for any HPyV. Person-to-person contact as well as environmental transmission of the nonenveloped virions are likely scenarios, via mucosal entry sites in the oropharyngeal, gastrointestinal, or respiratory tract.[215] Seroprevalence studies indicate that HPyV infections occur independently from one another, often during childhood and range from less than 30% to more than 90% in the general adult population, with an average of 6 to 8 different HPyV coinfections per person.[163] Detecting HPyV genomes by nucleic acid amplification testing (NAT) has been explored for identifying associations with clinical syndromes, such as KIPyV and WUPyV with respiratory tract disease. However, unequivocal evidence of proven disease by tissue pathology is currently only available for five HPyVs, plus one severe case of systemic vasculopathy associated with NJPyV (Table 1.2). In many cases, the affected patients were found to have inherited, acquired, or iatrogenic states of immunodeficiency. Thus, significant HPyV diseases must be considered opportunistic complications resulting from primary infection, secondary infection, or reactivation in immunocompromised hosts. However, inadequate HPyV-specific immune control does not appear to be sufficient for HPyV diseases but requires additional little understood local and systemic factors to account for their predilection to specific organs such as kidney, brain, or skin;

clinical settings such as transplantation, HIV infection, or old age; and co-factors such as medication or UV light exposure.

TABLE 1.2 Polyomavirus associated diseases in humans. Site of infection, disease, risk factors for advanced illness, viral state, and pathologic features are provided

PyV	Infection	Disease, At-risk Population	Viral State	Pathologic Features
BKPyV	Kidney, urinary tract	PyV-associated nephropathy (PyVAN), kidney transplantation	Replicative	Lytic denudation, inflammation
		Hemorrhagic cystitis, hematopoietic stem cell transplantation (HSCT)	Replicative	Toxic damage, lytic denudation, inflammation
		Urothelial carcinoma, kidney transplantation with PyVAN	Nonreplicative, integrated	Oncogenic transformation
JCPyV	Brain, kidney, urinary tract	Progressive multifocal encephalopathy (PML), HIV/AIDS, multiple sclerosis	Replicative	Cytopathic
		PyVAN, kidney transplantation	Replicative	Lytic denudation, inflammation
MCPyV	Skin	Merkel cell carcinoma Elderly, sun exposure, immunocompromised	Nonreplicative, integrated, transformed	Neuroendocrine carcinoma
HPyV7	Skin	Pruritic hyperproliferative keratinopathy Solid organ transplantation recipient	Replicative, transforming	Proliferative, cytopathic
TSPyV	Skin	Trichodysplasia spinulosa Solid organ transplantation, CLL	Replicative, transforming	Proliferative, cytopathic
NJPyV	unknown	Systemic vasculopathy, pancreas transplantation	Replicative	Cytopathic

Although initial infection of a host cell and placement of the viral genome into the host cell nucleus with subsequent viral gene expression underly any proven HPyV pathology, differences exist with respect to the leading contribution of virus replication–induced host cell loss, elicited inflammatory infiltrates, or host cell proliferative responses.[126] Prototypic examples for each of the three are PML in HIV/AIDS patients, PyV-associated nephropathy (PyVAN) in kidney transplant patients, and MCC in elderly immunocompromized persons, respectively. For PML in HIV/AIDS, the clinical and radiological presentation can be explained by oligodendrocyte loss from lytic JCPyV replication, causing progressive demyelination and neurological deficits in the absence of significant inflammatory infiltrates.[132,207] Conversely, significant BKPyV-induced renal tubular cell damage is nearly always marked by inflammatory infiltrates in the renal allograft, both of which contribute to declining renal function. MCC is characterized by host cell proliferation and metastasis resulting from chromosomally integrated viral genomes containing the NCCR persistently expressing MCPyV EVGR. However, the skin pathologies of *Trichodysplasia spinulosa* from TSPyV and pruritic hyperproliferative keratinopathy from HPyV7[41,138,219,342] can be placed between the extremes of replicative host cell lysis in JCPyV-PML and oncogenic transformation of MCPyV-carcinoma. In these syndromes, a prominent proliferative host cell pathology attributable to the HPyV early gene expression is followed by genome replication, Vp1 capsid protein expression, and lytic progeny release of TSPyV and HPyV7, respectively (Table 1.2).

Inflammatory responses play a mixed, often dynamic role of differing short- and long-term consequences. Following suppression of HIV replication in PML-AIDS by antiretroviral therapy (ART) effectively interrupting CD4 T cell loss, inflammatory responses become prominent as part of the immune reconstitution inflammatory syndrome (IRIS) leading to clinical and radiological aggravation, including unmasking of PML-IRIS.[132,210] Similarly, reducing immunosuppression for PyVAN in kidney transplantation can lead to functional worsening of

renal function in an IRIS-like fashion, which is difficult to distinguish from acute cellular rejection.[73,225] In MCC, tumor-infiltrating lymphocytes have been associated with improved clinical outcomes, and their exhausted Tim-3 and PD-1 phenotype can be reinvigorated by immune checkpoint inhibitors PD-1 and PD-L1 to target the viral early antigens.[243] Appreciating details of the PyV pathology features is likely to be important for developing clinically successful antiviral and immunological prevention and treatment strategies.

BKPyV-Associated Diseases

BKPyV is recognized as the main etiological agent of polyomavirus-associated nephropathy (PyVAN), polyomavirus-associated hemorrhagic cystitis (PyVHC), and the increasingly recognized polyomavirus-associated urothelial cancer (PyVUC). BKPyV has also been implicated in rare cases of ureteric stenosis, pneumonitis, encephalitis, retinitis, vasculitis, and multiorgan involvement,[130] but little is known about their prevalence, risk factors, and pathogenesis.

Polyomavirus-Associated Nephropathy

Biopsy-proven PyVAN is encountered in 1% to 15% of kidney transplantations in the current era of immunosuppression across different programs and countries (Fig. 1.20).[129,134] While most cases of PyVAN are caused by BKPyV, fewer than 5% are caused by JCPyV.[140] Rarely, PyVAN has been diagnosed in the native kidneys of recipients after nonkidney solid organ transplantation (SOT) or allogeneic HSCT, or in patients with other forms of immune dysfunction including hyper-IgM syndrome, acute lymphocytic leukemia, or HIV/AIDS.[299] The common hallmark of PyVAN in these different clinical settings is uncontrolled lytic replication of BKPyV in renal tubular epithelial cells with associated inflammatory infiltrates that together compromise organ function.

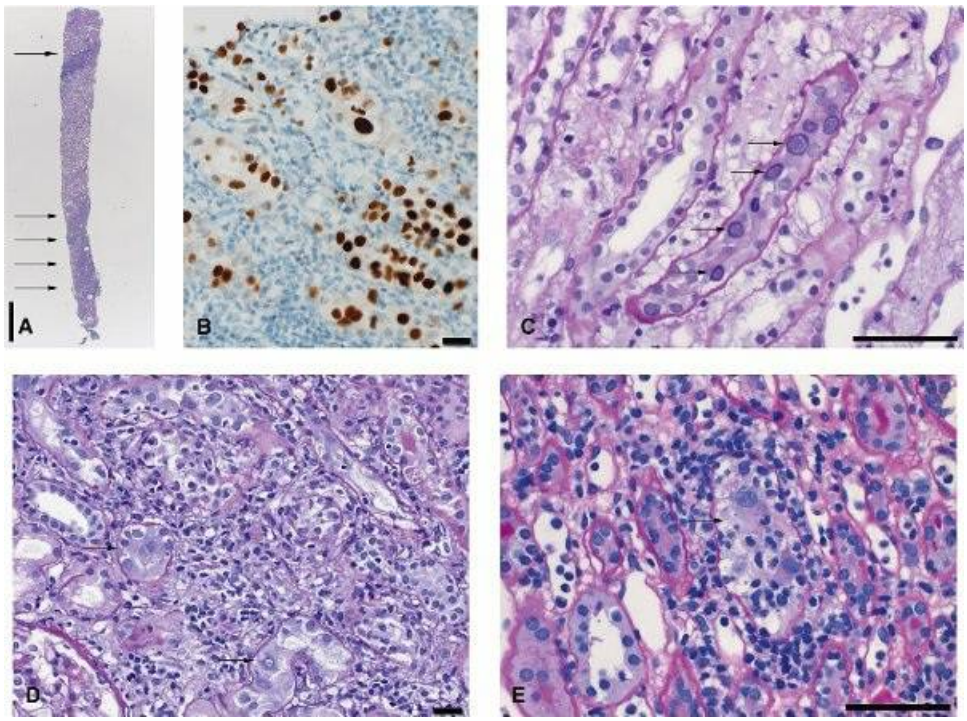

FIGURE 1.20 Histology of polyomavirus nephropathy. A: Kidney allograft biopsy showing focal involvement of cortex (*arrows*) at low magnification with striped interstitial inflammation (bar = 1 mm). **B:** PyV LTag-positive nuclei are detectable in the marked areas (bar = 20 µm). **C:** Early changes show some tubules containing virus-replicating cells (*arrows*) with little or no tubular damage or interstitial inflammation (bar = 50 µm) **D:** Florid PyVAN disease with tubular damage (*arrows*) and interstitial inflammation as prominent features, while virally infected cells are frequently more difficult to detect on routine stains (bar = 20 µm). **E:** After reducing immunosuppression, viral replication foci are cleared ("resolving PyVAN") that may be associated with dense inflammatory infiltrates and prominent intraepithelial lymphocytes in affected tubules (*arrow*, **E**, bar = 20 µm). **A, C-E:** PAS stain. **B:** PyV LTag immunohistochemistry with PAb416. Original magnifications: **A** 2.5×, **B** 20×, **C** 60×, **D** 40×, **E** 60×.

The histopathology of PyVAN shows tubular epithelial cells with enlarged nuclei carrying ground-glass inclusions, resulting from numerous, often crystal-like, arrays of PyV virions of 40 to 45 nm diameter detectable by electron microscopy. The viral cytopathic effect causes cells to round up, slough off the tubular basement membrane, and undergo lysis thereby releasing free virions and virion aggregates. Early and late stages of the BKPyV replication cycle can be identified by immunohistochemistry showing LTag early gene expression alone or together with the late gene expression of Vp1 in the nucleus and agnoprotein in the cytoplasm, respectively.[187,296] BKPyV replication can be detected in the urothelial lining of the transitional cell layer in the renal pelvis, which contribute to the shedding of so-called decoy cells into the urine, and very high urine BKPyV loads of greater than 10^7 c/mL.[91,246] In early stages of PyVAN, isolated nephrons are affected, often located in the renal medulla and without prominent inflammatory infiltrates (denoted PyVAN-A), with little impact on renal function.[74] As BKPyV

replication expands to multiple nephrons throughout the kidney, interstitial and tubular inflammatory infiltrates in response to cell lysis and tubular basement membrane denudation become dominant features (PyVAN-B). At this stage, declining renal function is progressively seen, which triggers renal biopsies for a histopathology diagnosis. This presentation is difficult to distinguish from acute cellular rejection, which requires increased, rather than lowered immunosuppression.

The interstitial infiltrates in PyVAN include mononuclear cells, granulocytes, and lymphocytes, specifically T cells and predominantly IgM-type plasma cells, which positively correlate with plasma IgM levels. Cellular regeneration failure characterized by tubular atrophy with only few BKPyV-replicating cells and extensive interstitial fibrosis are the hallmarks of end-stage disease (PyVAN-C). Thus, progressive viral tissue involvement, inflammation, tubular atrophy, and fibrosis have been associated with declining function and return to renal replacement therapy in 10% of patients with PyVAN-A, in 50% with PyVAN-B, and more than 80% with PyVAN-C.[74,135] Although most data have been obtained from kidney transplantation, histological changes similar to PyVAN-B and -C have been described in the failing native kidneys of patients suffering from other forms of immunodeficiency.[299]

Plasma DNA loads of BKPyV are a direct marker of renal involvement reflecting onset and clearance of PyVAN and have become the key diagnostic tool for screening and management of BKPyV in kidney transplant patients.[129,134] Plasma BKPyV loads are almost exclusively derived from nonencapsidated BKPyV DNA susceptible to DNase-I digestion rather than from circulating virions.[188] BKPyV-DNAemia is rarely found in nonkidney solid organ transplant (SOT) recipients except in case of proven PyVAN.

The diagnosis of proven PyVAN requires confirmation of tissue involvement. However, in kidney transplant patients with new onset of BKPyV-DNAemia and baseline renal allograft function, needle biopsies have a limited sensitivity, with false negative rates of 10% to 50%. However, in kidney transplant patients with new onset of BKPyV-DNAemia and baseline renal allograft function, needle biopsies have limited sensitivity, with false negative rates of 10% to 50%.[74] BKPyV-DNAemia serves an indicator of risk for developing biopsy-proven PyVAN, which is diagnosed in a subset of kidney transplant patients within another 2 to 6 weeks.[134] The detection rate of proven PyVAN in needle biopsies increases as plasma BKPyV loads rise above 10^4 to 10^6 c/mL, viral variants with rearranged NCCR emerge, or renal allograft function declines.[109] Conversely, in patients clearing proven PyVAN after reducing immunosuppression, the plasma BKPyV loads decline but clearance of BKPyV-DNAemia may lag several months behind the disappearance of LTag-positive cells in biopsies.[73] Upon surgical removal of the failing renal allograft with ongoing PyVAN, however, plasma BKPyV loads rapidly drop with a half-life of 1 to 2 hours to undetectable levels in less than 24 hours, even in patients on continued immunosuppression.[92] Thus, plasma BKPyV loads reflect the natural course of BKPyV complications involvement in the renal allograft and inform screening and management recommendations in renal transplant recipients.[129,134]

Importantly, BKPyV-IgG–seropositive immunocompetent healthy blood donors usually do not have detectable levels of BKPyV DNA in blood but can excrete viral DNA in urine. A small study of 20 healthy, nonpregnant, women over a 2-month period found episodic excretion of BKPyV in approximately 10% of samples tested.[77] Similar rates and levels of urinary shedding have been observed in donors and in recipients with residual urine production prior to kidney

transplantation. Following intravenous induction and oral maintenance immunosuppression therapy, urinary BKPyV shedding in kidney transplant recipients increases to a cumulative incidence of 40% to 80% by 2 years posttransplant.[134,140] In approximately half of the cases, urine BKPyV loads increase to greater than 10^7 c/mL with "decoy cells" appearing in the urine.[74,134,136] Similar to high-level viruria and urinary decoy cell shedding, the detection of three-dimensional PyV virion aggregates in urine ("haufen") may appear, which have been reported to better correlate with advanced PyVAN and tissue injury. *Vp1* mRNA transcript levels of greater than 6.5×10^5 copies/ng total RNA in urinary sediments have been explored to identify and predict outcome of kidney transplant recipients with PyVAN.[61]

Risk factors for plasma BKPyV-DNAemia and proven PyVAN include characteristics of the donor such as BKPyV viruria, high BKPyV-IgG antibodies, higher number of HLA mismatches, and blood group incompatibilities; of the recipient including older age greater than 50 years among adults, younger age among children, male gender, low or absent BKPyV-IgG and neutralizing antibody titers, and low or absent BKPyV-specific T cells; and the type and intensity of immunosuppression such as high-dose corticosteroids for acute rejection, use of tacrolimus rather than cyclosporine, or mTOR inhibitors such as sirolimus or everolimus.[134,361]

In most, but not all cases, donor-type BKPyV is detected in the urine and blood of kidney transplant recipients.[293] Recipient low-level viruria before transplantation is not associated with an increased risk of developing high-level viruria or BKPyV-DNAemia after kidney transplantation, in line with the key role of BKPyV transmitted with the donor graft, but in some cases, recipient-type or non–donor-type BKPyV has been identified. Distinct genotypes of BKPyV have been reported to induce specific neutralizing antibodies in kidney transplant recipients immunity. Low-neutralizing antibodies have been associated with an increased risk of BKPyV-DNAemia and nephropathy posttransplant.[259,312] However, the immune effector mechanism may not be restricted neutralization, since induction of high titers is not sufficient for clearance.[159,201]

Antivirals for prophylaxis or treatment of BKPyV replication have not been successful in kidney transplant recipients or in other patients suffering from PyVAN. Compounds inhibiting BKPyV replication in cell culture such as cidofovir, brincidofovir (CMX001), leflunomide, fluoroquinolones, cyclosporine A, or mTOR inhibitors have been used in uncontrolled case series as adjuncts to reducing immunosuppression, hence obscuring their actual contribution to the often slow decline in BKPyV replication. This includes the use of intravenous immunoglobulin preparations, which may contain BKPyV-neutralizing antibody activities.[159,272] A recent meta-analysis was unable to identify a significant benefit of mTOR inhibitors in reducing BKPyV events in kidney transplant recipient.[212] A recent trial demonstrating the immunologic equivalence of the mTOR inhibitor everolimus together with a low-dosed calcineurin inhibitor regarding the transplant and reported less BKPyV events compared to the standard tacrolimus mycophenolate control arm but was limited by an overall underreporting of BKPyV events.[258] Dedicated randomized clinical trials are needed to evaluate the role of intravenous immunoglobulins, neutralizing monoclonal antibody preparations for prophylaxis or treatment of BKPyV replication in kidney transplantation. One properly conducted prospective randomized clinical trial concluded that levofloxacin use during the first 3 months had no impact on levels of BKPyV viruria or DNAemia.[171]

Current guidelines recommend monthly screening of all kidney transplant recipients for

plasma BKPyV-DNAemia and reducing immunosuppression in case of BKPyV loads persisting greater than 10^3 c/mL for 3 weeks (probable PyVAN) or rising above 10^4 c/mL (presumptive PyVAN).[131,135] Since proven PyVAN is also treated by reducing immunosuppression, needle biopsy is not considered necessary unless there is a high suspicion of allograft rejection or another diagnosis. According to several larger prospective single-center cohorts, reducing immunosuppression alone has been associated with clearance rates of 50% to 100%, showing higher success rates when initiated promptly according to predefined indications. Different protocols have been applied consisting of first reducing the calcineurin inhibitor (tacrolimus, cyclosporine A) followed by the antimetabolite (mycophenolate, azathioprine), or alternatively by first reducing the antimetabolite followed by the calcineurin inhibitor. Subsequent acute rejection episodes have been observed in approximately 10% to 15% of cases, which mostly responded to antirejection treatment.[26] Based on in vitro studies and clinical observations, switching from tacrolimus/mycophenolate combinations to low-dose cyclosporine and mTOR inhibitors have been proposed.[159] However, direct comparisons of efficacy and tolerability are not available for any of the currently used approaches. Although most patients respond to reducing immunosuppression with clearance of BKPyV-DNAemia, patients with proven PyVAN appear to require more time and interventions.[26] The diagnosis of concurrent acute rejection is difficult and relies on detecting signs of endarteritis, fibrinoid vascular necrosis, glomerulitis, and C4d deposits along peritubular capillaries.[135] Molecular studies using comparative transcriptomics or proteomics failed to reveal significant differences between acute rejection and PyVAN other than the presence of BKPyV. In patients with sustained BKPyV-DNAemia and biopsy-proven acute rejection, a two-step approach of first treating acute rejection followed by reducing immunosuppression, for example, at 2 to 4 weeks after response is recommended.[135]

The outcome of BKPyV-DNAemia and PyVAN has significantly improved compared to historic reports.[271] Graft loss with ongoing BKPyV-DNAemia is seen in approximately 10% to 30% of cases.[73] However, even in patients with immunologically cleared BKPyV replication and disease, the renal graft survival is reduced due to the scarred nephrons lost shortening the time to renal replacement therapy. Further data are needed to identify the risk factors associated with an increased rate of antibody-mediated rejection after treatment.

Retransplantation after renal allograft loss secondary to BKPyV has been successfully performed with 3-year graft survival rates of 93.6%.[69,128] In most cases, immunosuppression was discontinued until retransplantation, which permitted BKPyV-specific immune recovery and clearing of BKPyV-DNAemia for at least 3 months. Surgical removal of the failing transplant or the native kidneys was not required for successful outcomes. However, in patients considered for preemptive retransplantation, a significant decline in plasma BKPyV loads of greater than 100-fold (2 log10) is recommended as indicator of emerging BKPyV-specific T cell control and preferentially combined with allograft nephrectomy.[25,128,183] Recurrence of plasma BKPyV DNAemia and PyVAN was observed after retransplantation, which responded to reducing immunosuppression in most cases.[69,128] Retransplantation has been successful in patients with other functioning allografts such as pancreas, although an increased risk of PyVAN recurrence and allograft loss has been reported.[227]

Polyomavirus-Associated Hemorrhagic Cystitis

BKPyV is the main etiological agent of PyVHC, which complicates 5% to 50% of allogeneic

HSCT, but is rarely found in other types of transplantations or immunodeficiency conditions.[44] Because of the extensive urothelial damage and associated hemorrhagic bleeding, histology studies are rarely performed except in severe cases requiring therapeutic cystectomy. The diagnosis of PyVHC is based on the triad of symptoms of cystitis (dysuria, urge, lower abdominal discomfort), signs of macrohematuria (grade 2 or higher), and high urine BKPyV loads greater than 10^7 c/mL. Each component can occur alone and is not sufficient for the diagnosis of PyVHC. Other etiologies should be ruled out such as infections from other viruses including human adenovirus, cytomegalovirus, or herpes simplex. Hematuria can be due to urotoxic conditioning alone, coagulation disorders, malignancies, or mechanical factors such as catheters, and should be graded as microhematuria (grade 1) or macrohematuria (grade 2), with clots (grade 3), or renal failure (grade 4). Imaging studies of PyVHC using sonography or MRI may show thickened bladder walls and help to identify clots and postrenal obstruction or ureteric involvement.[247]

PyVHC is typically of late onset, occurring 2 to 12 weeks after engraftment and lasting for 3 to 5 weeks.[7,17] By contrast, hemorrhagic cystitis solely attributed to urotoxic conditioning is of early onset, mostly within 1 week after HSCT and lasting for just a few days.[7,17,295] In approximately half of the patients diagnosed with PyVHC, BKPyV DNA can be detected in serum or plasma with viral loads of greater than 10,000 c/mL. Following the widespread use of the chemoprotective agent mesna, hyperhydration, and forced diuresis during myeloablative conditioning to reduce bladder exposure to urotoxic metabolites such as acrolein, the rate and duration of early-onset hemorrhagic cystitis has declined, whereas late-onset PyVHC has remained as a significant complication.[17] Although milder forms exist, PyVHC after allogeneic HSCT frequently presents with immobilizing pain requiring generous analgesic treatment, hospital admission, and intensive nursing care.

PyVHC is rarely seen after kidney transplantation despite similarly high peak urine BKPyV loads in the order 10^8 to 10^{10} c/mL. This observation suggests that immune failure to control high-level BKPyV replication in the urothelial compartment is not sufficient to explain the prominent clinical features of massive inflammation and bleeding after HSCT. Instead, it is likely that urotoxic chemotherapy conditioning causes subclinical damage to the bladder epithelium.[24] High-level BKPyV replication during the fading immune control leads to extensive denudation of the urothelial lining and urine leakage into the hyperemic submucosa. Painful hemorrhagic exacerbation ensues with abundant inflammatory infiltrates coinciding with allogeneic stem cell engraftment, hence reminiscent of IRIS.[24] A role of *bona fide* IRIS in PyVHC pathogenesis is strongly suggested by two HIV/AIDS cases, not undergoing HSCT, following a rise in CD4 T cell count upon ART. One of these cases had cyclophosphamide exposure for treatment of non-Hodgkin lymphoma.[13,105]

The risk factors of PyVHC after HSCT are multiple and include myeloablative conditioning with cyclophosphamide, high-dose busulfan, and total body irradiation; T-cell depletion with antithymocyte globulin or alemtuzumab; male gender; unrelated, mismatched, and haplo-identical donors; umbilical cord grafts; as well as graft versus host disease. Higher BKPyV-specific antibodies pretransplant were correlated with the peak urine BKPyV loads and increased risk of PyVHC, supporting the view that PyVHC is primarily caused by BKPyV reactivation in the recipient.[7,360] However, many recipient populations with low or undetectable antibodies that develop high-level viruria have been reported as well as other factors including reinfection and

nosocomial transmission. None of the risk factors have entered clinical routine protocols modifying the choice of donors or conditioning procedures. Routine screening for BKPyV replication has no impact on patient management since effective drugs for prophylaxis or treatment are not available.[44]

The treatment of PyVHC is based on unstinting pain relief and bladder irrigation combined with local urologic interventions as needed for anemic bleeding, clot removal, and renal failure. Platelet transfusion and local coagulation with fibrin glues are used as clinically indicated. Regaining BKPyV-specific immune control is thought to underly the spontaneous clearance but reducing or discontinuing immunosuppression is problematic due to the risk of precipitating or exacerbating graft versus host disease after allogeneic HSCT. Conversely, steroid treatment reducing the inflammatory component may cause transient relief but prolong the virus replicative denudation and bleeding.

A recent review of the available antiviral treatments concluded that off-label use of intravenous cidofovir is controversial due to limited efficacy and unclear benefits in the absence of randomized controlled trials.[44] This included administration of high doses of cidofovir as approved for the treatment of ganciclovir-resistant CMV retinitis. Uncontrolled case reports of successful responses following intravesical application of cidofovir, intravesical hyaluronate, intravenous immunoglobulins, leflunomide, levofloxacin, oxygen, or mesenchymal stem cells have been reported.[44] However, systemic and intravesical cidofovir were not effective in a pediatric study.[174] In the absence of randomized trials, a natural course with spontaneous resolution of PyVHC cannot be ruled out, coinciding with BKPyV-antibody increases has been reported in children.[174] This caveat also applies also to brincidofovir/CMX001, a lipid conjugate of cidofovir, which is approximately 400-fold more effective in inhibiting BKPyV replication in cell culture, but also showed cytostatic effects on the host cells. Recently, a randomized phase III trial investigating the role of oral brincidofovir for CMV prophylaxis in allogeneic HSCT but found no reduction in BKPyV events predefined as secondary end points.[217] In line with the role of virus-specific T cells in controlling BKPyV replication, adoptive transfer of BKPyV-specific T cells from stem donors or third-party donors may have promise as potential prophylactic or therapeutic modality for PyVHC.[336] Thus, significant efforts are needed to better understand the pathogenesis of PyVHC in order to develop effective prevention or therapies by targeting one or several components of the PyVHC triad.

BKPyV-associated cystitis with or without macrohematuria has been occasionally encountered in other immunocompromised hosts including in HIV/AIDS patients or in SOT recipients including kidney transplantation. In case of declining renal function in the absence of macrohematuria, ureteric stenosis or PyVAN should be considered in the differential diagnosis, in which case imaging studies and biopsies should be sought. Indeed, in some cases, BKPyV cystitis occurred together with proven PyVAN including patients after allogeneic HSCT.

Polyomavirus-Associated Urothelial Carcinoma

The host cell–transforming properties of the polyomavirus EVGR may contribute to the onset of PyVUC.[256] Morphological variations of PyVUC include transitional cell carcinoma, Bellini collecting duct carcinoma, and other intrarenal manifestations. PyVUC has been primarily encountered in patients with a history of prolonged BKPyV replication and PyVAN, most commonly after kidney transplantation or rarely in nonkidney SOT recipients. In a recent

retrospective multicenter survey from the United States, approximately eight-fold more cases of urothelial carcinoma were reported among patients with prior PyVAN, although this association did not reach statistical significance.[277] Linking 55,697 kidney transplant recipients in the scientific registry of transplant recipients (SRTR) to 17 U.S. cancer registries, 584 incident renourinary malignancies were identified including 80 bladder cancers, a three-fold higher incidence for invasive bladder carcinoma among recipients previously treated for presumed or proven PyVAN compared to the control patients.[115] In a large single-center study, prolonged BKPyV replication and smoking were identified as independent risk factors for urothelial carcinoma.[197] Moreover, the donor origin of PyVUC pointed to a role of HLA mismatching in addition to immunosuppression, T cell depletion, and nonuse of mTOR inhibitors.[115]

The pathogenesis of PyVUC has been attributed to the immunologically uncensored high level of BKPyV replication leading to the occurrence of genetic accidents such as chromosomal genome integration of the BKPyV DNA, which disrupt or interfere with host cell–(onco-)lytic viral replication. NCCR rearrangements without genome integration might also play a role by favoring BKPyV EVGR expression without matching LVGR expression.[239] The role of BKPyV EVGR–encoded tumor antigen expression is supported by the absence of driver mutations in the top 50 genes found in non-BKPyV–associated cancers.[239] Replication of BKPyV is associated with induction of APOBEC3B, a single-stranded DNA cytosine deaminase that can induce C-to-T and C-to-G mutations in the viral and host genome. Prolonged high levels of BKPyV viruria can lead to significant changes in the host genome with a characteristic APOBEC mutational signature.[314] In some cases, chromosomal integration of BKPyV genomic sequences with rearranged NCCRs as single copies or concatemers or as nonintegrated viral episomes has been detected.[314]

PyVUC diagnosis relies on the surgical removal and histological analysis of the tumor, which is also considered therapeutic for in situ bladder cancers. Recurrence in immunocompromised patients and progression with metastatic lymph nodes or invasive disease are associated with a poor prognosis. Lasting remission of otherwise metastatic PyVUC has been observed after discontinuation of immunosuppression,[239] a maneuver not similarly feasible in nonkidney SOT patients.

Other BKPyV-Associated Diseases

Ureteric stenosis has been linked to BKPyV replication in kidney transplantation before the widespread emergence of PyVAN[56] but is rarely diagnosed in the current era despite the overall increased incidence of high-level BKPyV viruria. Less traumatic anastomosis surgery and routine ureteric stenting may account for this decline in events. Conversely, ureteric stents have been associated with an increased risk of BKPyV-DNAemia and PyVAN in some studies.[211] Local injury upon stent placement or removal has been suggested to cause local BKPyV reactivation, but ureteric stents clearly facilitate vesicoureteric reflux during bladder contraction and may cause accelerated retrograde spread to the renal allograft.[91,160] Stenosis resulting from inflamed ureters (ureteritis) after allogeneic HSCT has been described in the context of PyVHC. The clinical diagnosis is based on altered flux through the ureteric ostium or outright hydronephrosis in sonography or MRI studies together with high-level BKPyV viruria. Treatment involves urologic interventions including ureteric stenting, nephrostomas, and surgical reanastomosis to assure urinary drainage.

BKPyV encephalopathy is a rare, but well-documented entity in severely immunocompromised patients with disseminated replicative disease in the context of HIV/AIDS[33,339] or inherited immunodeficiency syndromes,[63] or hematopoietic disorders including chronic lymphatic leukemia, Hodgkin lymphoma, or allogeneic HSCT. Though not specifically documented, these conditions appear to combine T cell defects, absent or deficient antibody responses with chemotherapy and CD20 lymphocyte depletion using rituximab.[86,186] Focal neurological symptoms and signs reflect the areas of involvement and include visual disturbance, palsy, seizures, headache, nausea, ataxia, or cognitive deficits. Imaging studies using MRI may show edema with or without contrast-enhancing areas in the affected locations of the cortex, subcortical white matter, cerebellum, or brain stem. Thus, BKPyV encephalopathy is reminiscent of the more frequently encountered PML caused by JCPyV. Laboratory-confirmed cases of BKPyV encephalopathy combine clinical and imaging abnormalities with detectable BKPyV DNA in the cerebrospinal fluid (CSF), while JCPyV or other viral genomes by NAT are absent. CSF pleocytosis is rare and low, protein levels are normal or elevated, and glucose and lactate levels inconspicuous. In proven cases, stereotactic brain biopsy or autopsy tissue reveals very high tissue BKPV-DNA loads by NAT, LTag expression, and Vp1 capsid expression in the enlarged nuclei of infected cells by immunohistochemistry and intranuclear PyV virions of 40 nm diameter by electron microscopy.[63,339] Nonspecific monocytic and lymphocytic infiltrations have been described in the perivascular space, leptomeninges, cortex, and white matter, in addition to astrogliosis, reactive astrocytes with nuclear hyperchromatic changes, and oligodendroglia-like cells and occasional neurons with enlarged nuclei.[63] Where analyzed, the BKPyV NCCR was rearranged with deletions and duplications, which have been proposed to increase BKPyV replication in the CNS compartment.[63,318] In approximately half of the case reports of BKPyV encephalopathy, there was a significant preceding or coexisting pathology such as PyVAN[33,318,339] or PyVHC grade 4 suggesting dissemination of BKPyV from the renourinary tract with encephalopathy, meningoencephalitis, and retinitis.[33] However, BKPyV encephalopathy without involvement of another organ has been described in one apparently immunocompetent patient with serologically primary BKPyV replication who eventually recovered.[349]

The role of BKPyV in the CNS manifestations has been explored in a study of 124 children without known underlying disease presenting with suspected viral encephalitis. BKPyV, but not JCPyV DNA was been detected in the CSF of 3 (2.4%), all of whom were BKPyV seropositive, but JCPyV seronegative.[18] Among 42 immunocompetent adults presenting with meningoencephalitis, BKPyV DNA was found in the CSF of two (4.7%).[18] Thus, BKPyV should be considered in patients presenting with symptoms and signs of CNS involvement having undetectable JCPyV or other neurotropic viruses. Treatment of CNS disease caused by BKPyV has not been established. Given the dire prognosis of BKPyV encephalopathy in immunocompromised patients, some experts have administered intravenous cidofovir or high-dose intravenous immunoglobulins without changing outcome. Moreover, BKPyV CNS manifestations have been reported in patients receiving intravenous immunoglobulin prophylaxis, which raise questions about the efficacy and dosing.[63] Removing the underlying cause of immunodeficiency would be key and hence to consider adoptive T cell transfer alone or together with high-dose neutralizing antibodies.[336] Immune recovery in HIV/AIDS patients may be associated with paradoxical worsening of BKPyV CNS diseases, marked inflammation reminiscent of IRIS as well described for JCPyV-PML.

BKPyV pneumonia has been identified in a limited number but well-documented cases with mostly disseminated replication, all of which were fatal due to rapidly progressive respiratory failure. Postmortem studies showed diffuse alveolar damage, interstitial inflammatory infiltrates, cytopathically altered pneumocytes with enlarged nuclei, intranuclear inclusions staining positive for LTag, and PyV virions by electron microscopy.[93,339] The patients suffered from severe immunocompromising conditions such as HIV/AIDS,[339] allogeneic HSCT, or chronic lymphatic leukemia undergoing chemotherapy.[93,318] Steroids were used for treating graft versus host disease or for the complicating interstitial lung disease. In two-thirds of the cases, significant replicative BKPyV manifestations such as PyVAN or PyVHC preceded the pulmonary complications suggesting hematogenous viral spread and secondary multiorgan involvement including the CNS. In only one case of PyVHC grade 4, the diagnosis of BKPyV pneumonia was made antemortem, whereby the CT scan of the lungs showed diffuse ground glass infiltrates and typical cytopathic cells with enlarged nuclei harboring ground-glass inclusions in bronchoalveolar lavage samples.[363] Treatment attempts using cidofovir, vidarabine, or intravenous immunoglobulin were unsuccessful in all of these cases.

Other clinical entities with histologically proven involvement of BKPyV are rare and linked to exceptional presentations. This includes a profoundly immunosuppressed kidney transplant patient seropositive for BKPyV, who developed muscle weakness and a severe capillary leak syndrome with anasarca and died from myocardial infarction and circulatory arrest.[265] Postmortem, BKPyV replication was demonstrated in endothelial cells of the skeletal and heart muscle, but sparing the vasculature of the liver, lungs, and kidney.[265] The NCCR of the BKPyV was of archetype architecture but contained nucleotide substitutions[49] inactivating a conserved ETS1 transcription factor binding, which increased BKPyV EVGR expression and replication in cell culture similar to NCCR rearrangements.[23] Finally, BKPyV has been implicated in other clinical conditions including autoimmune disorders including systemic Lupus erythematosus[235] and sclerosing lymphocytic inflammatory salivary gland disease found in a subgroup of HIV-infected individuals. However, a role for BKPyV as a driver or bystander in these diseases and the role of immune dysfunction from immunogenetics, HIV coinfection, or immunosuppressive treatment have not been resolved.[245]

JCPyV-Associated Diseases

JCPyV is the main etiological agent of PML.[85,132,210,252,377] Other neurological manifestations are granule cell neuronopathy in the cerebellum, encephalopathy targeting cortical pyramidal neurons, as well as meningitis and encephalitis.[85,120,132] Despite its major tropism for the renourinary tract and persistent shedding in immunocompetent persons,[77] JCPyV is a rare cause of PyVAN in kidney transplant patients.[132] In addition, an association of JCPyV infection with malignancies in the brain, in lymph nodes, and in gastrointestinal tract has been reported.

JCPyV—Progressive Multifocal Leukoencephalopathy

The clinical entity of PML was first described in 1958 as a rare fatal demyelinating complication in immunocompromised patients exposed to chemotherapy and corticosteroids for treating hematological malignancies such as chronic lymphatic leukemia and Hodgkin lymphoma.[9] The histopathology is characterized by the loss of myelin-producing oligodendrocytes through lytic

JCPyV replication, localizing predominantly to the subcortical white matter, but can extend into neurons in the cortical gray matter.[20,101] The expanding demyelinated areas show increased gliosis, surrounded by JCPyV-replicating oligodendrocytes with characteristic enlarged inclusion-bearing nuclei, reactive, partly multinucleated "bizarre" astrocytes, fat-loaded "foamy" macrophages, and variable numbers of infiltrating lymphocytes preferentially cuffing the perivascular space (Fig. 1.21).[350,353] JCPyV particles can be detected in the intranuclear inclusions of the oligodendrocytes by electron microscopy, but the specific diagnosis is commonly based on detecting intranuclear JCPyV genome by in situ hybridization or Vp1 capsid protein by immunohistochemistry.[151] NAT for JCPyV DNA is very sensitive and typically shows very high tissue viral loads with rearranged NCCRs that can be distinguished from latently persisting JCPyV in brain tissue.[132,210]

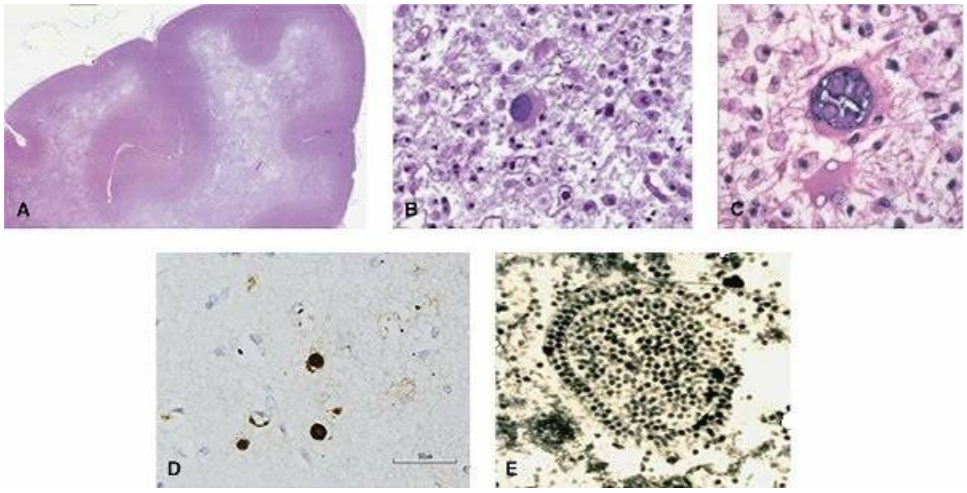

FIGURE 1.21 Histology of progressive multifocal leukoencephalopathy. A: Luxol fast blue staining with hematoxylin counterstain of the frontal lobe in a patient with progressive multifocal leukoencephalopathy (PML) shows extensive multifocal and confluent areas of demyelination. Small islands of demyelination coalesce to produce large confluent areas resulting in a "ground glass" bright appearance on T2-weighted MRI scan. **B:** Enlarged oligodendrocyte with a large inclusion-bearing nucleus is characteristic of PML. No discrete intranuclear inclusion is seen. **C:** A large bizarre astrocyte is depicted. **D:** Immunostaining with polyclonal antibody to JC virus from Abcam Inc. shows dark brown staining of nuclei of several oligodendrocytes. **E:** Electron micrograph of crystalline array of assembled JC virions in nuclei of infected oligodendrocyte in PML brain lesion. Virions measure 40 nm in diameter.[20] (Reprinted with permission from Berger JR, Aksamit AJ, Clifford DB, et al. PML diagnostic criteria: consensus statement from the AAN Neuroinfectious Disease Section. *Neurology* 2013;80(15):1430–1438. Copyright © 2013 American Academy of Neurology.)

The incidence of PML in the general population is low and has been estimated to be less than 0.1 per 100,000 person years in North America and Europe, but at least 10- to 1,000-fold higher in patients with immunodeficiency states such as HIV/AIDS, allogeneic HSCT, SOT, or

autoimmune diseases under therapy.[6] In addition, PML has been described in case reports of patients with less well-defined immunodeficiency including CD4 lymphocytopenia.[116] During the HIV/AIDS epidemic in the 1980s, a more than 10-fold overall increase in PML diagnoses was observed affecting 1% to 5% of HIV patients in the era before effective ART. Thereby, PML in HIV/AIDS patients became the classic reference with respect to risk, clinical presentation, imaging, pathology, and outcome.[132,210] HIV/AIDS patients with PML were JCPyV seropositive and had CD4 T cell counts falling below 100/μL blood,[165,222] implicating failing immune control and JCPyV reactivation in the CNS. Moreover, paradoxical clinical worsening as well as unmasking of PML by IRIS emerged as a novel manifestation of the disease following effective ART suppressing HIV-1 replication and reconstituting CD4 T-cell counts.[133,283] In the current era of early ART intervention, PML has practically disappeared among HIV-1–infected patients except for those presenting late but then still remains associated with significant morbidity and mortality.[6,165]

During the past decade, the decline of cases in HIV/AIDS has been replaced by a resurgence of PML among patients treated with novel drugs and antibody therapies targeting specific cells and pathways of the immune system for various underlying conditions.[42,103] The emerging therapeutics have been tentatively classified into four risk groups according to whether the underlying condition predisposes for PML in the absence of drug, the time from initiation of the drug to PML, and the frequency of PML.[19] Natalizumab represents the only class I agent conferring a high risk. Dimethyl fumarate and fingolimod are associated with low risk (class II). Class III agents confer very low or no risk and include alemtuzumab, mitoxantrone, rituximab, and teriflunomide and depend on the clinical context of previous or concurrent exposure to other drugs. Class IV drugs such as type-1 interferons have no risk.[19] Thus, PML in patients with refractory-remittent multiple sclerosis treated with natalizumab has provided novel insights with respect to the pathogenesis, risk assessment, presentation, and clinical management.[28,170]

The pathogenesis of PML appears to involve several steps associated with end-organ pathology caused by insufficient immune control over JCPyV replication in the CNS.[132,210] Since virtually all patients with PML are seropositive for JCPyV including those with HIV/AIDS or with multiple sclerosis treated with natalizumab, JCPyV replication in the CNS is viewed as the result of JCPyV reactivation. To reach the brain, JCPyV is delivered either by infected blood precursor cells from the bone marrow, by hematogenous spread during secondary viremia, or primary infection associated with viremia.[45,48,132,210] CD4 T cells appear to have a central role in JCPyV control, which involves the loss of helper functions needed for cytotoxic CD8 T cells to kill JCPyV-replicating cells, and for B cells to mount sufficient levels of neutralizing antibodies. Although the relative contributions are likely to differ depending on the underlying conditions, this notion is also consistent with PML cases associated with idiopathic CD4 T-cell lymphopenia and with lymphocyte depletion using antibody therapies such as OKT3, antithymocyte globulins, and rituximab, with therapies interfering with lymphocyte proliferation and function including homing to the sites of JCPyV replication in the CNS, and with high-dosed or prolonged corticosteroids exposure.[19,21,103] PML may arise following cancer immunotherapies by checkpoint inhibitor blockade targeting lymphocyte PD-1 exhaustion markers.[59,216] In HIV/AIDS, the systemic CD4 cell recovery after antiretroviral suppression of HIV replication has been associated with JCPyV-specific T-cell responses and PML survival.[75,165,194] Tissue studies reveal increasing inflammatory infiltrates including CD4 and CD8 T cells around active

lesions suggesting that HLA class I and class II presentation via oligodendrocytes, astrocytes, and monocyte/macrophages is also locally operative.[149] Natalizumab treatment blocks α4β7-integrin–dependent lymphocyte homing to active multiple sclerosis lesions in the CNS, without notably increasing the overall risk of opportunistic diseases. Hence, local failure of CNS immune surveillance must be viewed as a pivotal factor in PML pathogenesis.

The clinical presentation of PML depends on the location and the spread of the initially focal replication sites. Progressive neurological deficits in motor, visual, cognitive, and behavioral functions are noted as well as ataxia affecting everyday life activities including posture, movement, and speech. Epileptic episodes are rare in HIV/AIDS but have been more frequently noted in patients with leukocortical inflammation, particularly with PML-IRIS.[132,166]

Magnetic resonance imaging (MRI) of the CNS has become the key diagnostic procedure, while computed tomography of the CNS is neither sensitive nor specific to rule in or rule out PML. The most characteristic MRI pattern shows subcortical PML lesions of T2-hyperintense or fluid-attenuated inversion recovery (FLAIR) sequences, T1-hypointense, or demyelinated areas as hyperintense lesions in diffusion-weighted imaging (Fig. 1.22).[368] Gadolinium enhancement in T1-weighted imaging is seen in approximately half of the cases indicating inflammation and blood–brain barrier disruption and is less frequent in HIV/AIDS than in natalizumab-treated patients, but characteristic of IRIS-PML.[368] Although unilateral or bilateral involvement of the subcortical areas is frequent, infratentorial lesions can occur in the cerebellum or the brain stem with corresponding clinical deficits. A mass effect is usually not seen but may arise suddenly upon significant inflammation associated with PML-IRIS. Conversely, burned-out lesions can regress to atrophic areas, which correlate with persisting functional deficits. The differential diagnosis includes varicella zoster encephalopathy, CNS vasculitis, and various malignancies, which may sometimes coexist.[20] A challenging issue is distinguishing active multiple sclerosis and early PML, which may arise during the close MRI follow-up recommended in JCPyV-seropositive patients started on natalizumab.[354]

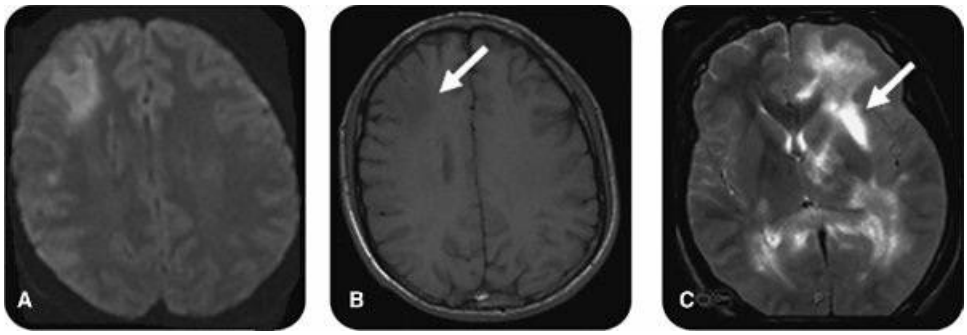

FIGURE 1.22 MRI in progressive multifocal leukoencephalopathy. A: Fluid-attenuated inversion recovery image with large subcortical lesion of right frontal lobe. A smaller lesion is observed posterior to this lesion. **B:** T1-weighted image shows hypointense lesion (*arrow*) in the right frontal lobe. **C:** T2-weighted image from another patient with extensive high signal intensity lesions in the white matter sparing the cortex. An area of hyperintensity similar to that of CSF suggests an area of cavitation. (Reprinted with permission from Berger JR, Aksamit AJ, Clifford DB, et al. PML diagnostic criteria: consensus statement from the AAN Neuroinfectious Disease

Section. *Neurology* 2013;80(15):1430–1438. Copyright © 2013 American Academy of Neurology.[20])

The clinical diagnosis of PML is graded according to the strength of criteria, whereby possible PML defines a case with typical clinical presentation and corresponding MRI results, but without the risk factor of known immunodeficiency. Probable PML is diagnosed in a typical case with the known risk of underlying immunodeficiency and corresponding MRI results. In such patients, detecting JCPyV-DNA in the CSF by highly sensitive NAT is recommended for a laboratory-confirmed (presumptive) diagnosis of PML.[20] However, even highly sensitive JCPyV-DNA assays detecting DNA as low as 10 to 50 c/mL CSF have been negative in approximately 25% of patients with histologically proven PML.[53] Thus, undetectable JCPyV-DNA in CSF does not exclude PML. A recent study suggested that the probability of detecting JCPyV-DNA in CSF increases with the volume of the PML lesions.[210,358] Thus, laboratory confirmation could be sought by repeating CSF testing for JCPyV-DNA[20,205] or by demonstrating intrathecal JCPyV-specific antibody titers.[20,352] In case of probable PML that cannot be resolved because of noninformative CSF results or because of suspicions of another etiology, the diagnosis should be sought by stereotactic brain tissue demonstrating the histopathologic triad of demyelination, oligodendrocytes with enlarged nuclei, reactive multinucleated astrocytes, and detection of JCPyV antigens or genome.[20]

Prevention of PML is difficult to achieve other than by avoiding the loss of functional virus-specific immune effectors in JCPyV-infected patients. For HIV-1 infected patients, this is achieved by the current strategy of early ART to prevent opportunistic infections that occur at lower CD4 cell counts.[279] Attempts to establish JCPyV-DNA detection in blood samples of HIV/AIDS patients taken 2 years to 6 months before PML diagnosis have been unsuccessful.[348] However, significant increases in JCPyV-specific antibody levels have been observed in HIV/AIDS patients at 6 months before the PML diagnosis.[165,348] For transplant patients, no specific predictors have been identified that could translate into prevention measures despite overall PML rates of 1.24 per 1,000 patient years among heart and lung transplant recipient and case fatality rates of more than 80%.[218] For multiple sclerosis patients, however, prolonged duration of natalizumab therapy of more than 18 months, prior exposure of immunosuppressive drugs, and a positive JCPyV serology status have led to risk stratification, monitoring, and counseling of the patients as the risk of PML increases more than 100-fold from 0.1 to 10–30 per 1,000 patient years.[28,210,267,292] As reported for HIV/AIDS patients,[132,165,348] the higher antibody levels are interpreted as an early marker of recent systemic exposure to JCPyV Vp1 capsid proteins, which are not consistently captured by viral DNA detection in blood. Notably, the level of JCPyV antibodies has been associated with a 10-fold higher risk when increased to high titers defined by a normalization index greater than 1.5 times higher than a reference serum as compared to low antibody levels with a normalization index less than 0.9.[210,267,292] To mitigate the devastating consequences of PML in the current absence of specific antiviral prophylaxis, the otherwise annual MRI of the CNS used to follow the multiple sclerosis lesions is recommended to be performed every 4 to 6 months to search for early radiological signs of presymptomatic PML in patients having or developing JCPyV antibody indices greater than 1.5, prior immunosuppression, and receiving natalizumab therapy for more than 18 months.[210,292,352] Small PML foci are often presymptomatic and have previously been overlooked unless

becoming very large or impairing well-defined functions, for example, of the motor or visual cortex, cranial nerves or the cerebellum. Early diagnosis of presymptomatic or limited PML has been associated with better outcomes following discontinuation of natalizumab. The radiological diagnosis of probable PML in an asymptomatic multiple sclerosis patient at increased risk should be laboratory confirmed by testing for JCPyV DNA or intrathecal antibody in CSF. Thus, the risk stratification of multiple sclerosis patients has enabled the previously unknown diagnosis of asymptomatic or presymptomatic PML.

Treatment of PML is based on regaining specific immune control over JCPyV replication in the brain. In HIV/AIDS, this is achieved by rapidly suppressing HIV replication with potent ART typically including integrase inhibitors and nucleoside/nucleotide reverse transcriptase inhibitors. In patients on immunosuppressive therapies, the discontinuation of the respective drugs is attempted but is not always possible because of the underlying condition such as transplantation, acute rejection, graft versus host, or exacerbation of the autoimmune disorder. Similarly, adjuvant treatments with compounds improving immune recovery may have a role in patients with idiopathic CD4 lymphocytopenia and possibly HIV/AIDS including interleukin-7 and toll-like receptor-7 agonists. Given the potential role of PD-1 lymphocyte exhaustion, monoclonal blocking antibody therapy with the checkpoint inhibitor pembrolizumab has been reported to result in improvement or stabilization of at least two-thirds of PML patients.[59,139] As a more direct approach, adoptive cell therapy using JCPyV-specific or cross-reactive BKPyV-specific T cells has been explored for treatment of PML.[11,237] However, efficacy data from controlled clinical trials are lacking for any of these immunostimulatory therapies, and safety may be a limiting concern in transplant recipients and patients with autoimmune disorders. Finally, the emergence of PML in patients treated concomitantly with checkpoint inhibitors and corticosteroids suggests that immunosuppressive ablation of immune effectors overrides potential functional reconstitution. Conversely, corticosteroids may be lifesaving in severe cases of IRIS with increasing intracranial pressure,[327] but prolonged high-dose application should be avoided.[283]

Antivirals with documented or presumed inhibitory activity on JCPyV replication in cell culture have been used alone or in combinations with the hope to modify or ameliorate PML outcomes, but there is little evidence of clinical benefit. The list includes cytosine arabinoside, cidofovir, brincidofovir (CMX001), artesunate, and more recently mefloquine and mirtazapine. Intravenous immunoglobulins may deliver neutralizing activity and have been explored as an alternative to steroid treatment of PML-IRIS.[143,177,224] However, immunoglobulins penetrate poorly across the blood–brain barrier except in areas of inflammation.[39,54,177] The emergence of viral capsid escape mutants in PML necessitate dedicated clinical protocols and may include novel strategies for passive and active vaccination. Thus, either alone or together with immunological interventions, effective antivirals suppressing intracerebral JCPyV replication remain an unmet clinical need in prevention and treatment of PML.

Other JCPyV-Associated Diseases

JCPyV-associated granule cell neuronopathy has been proposed as a separate clinical entity from PML and is caused by lytic JCPyV replication in granule cell neurons of the cerebellum.[172,362] Clinically, the patients present with cerebellar ataxia as the leading sign, with corresponding active lesions in the gray matter without affecting the white matter identified by

MRI. Accordingly, treatment faces the same challenges of regaining immune control, IRIS, and persisting atrophy. JCPyV replication of neuron in cortical and hippocampal areas has been described.[101,362]

JCPyV meningitis is a rare diagnosis presenting with the clinical signs of meningeal inflammation of neck stiffness, headache, and fever, with detectable JCPyV DNA in CSF in the absence of other pathogens. Pathology correlates are usually lacking,[132] though JCPyV replication with inflammation in the leptomeninges and the choroid plexus but sparing the brain parenchyma has been demonstrated in a fatal case of hydrocephalus.[1] A postmortem study identified leptomeningeal involvement in approximately 15% of fatal PML cases.[58]

JCPyV-associated nephropathy has been identified as a rare cause of renal allograft failure and graft loss affecting less than 1% of kidney transplant patients.[72,141] The patients have high urine JCPyV loads of more than 10^7 c/mL and decoy cell shedding, but unlike BKPyV DNAemia, JCPyV DNA is usually low or undetectable.[72] The clinical and histopathology features are indistinguishable from the more frequent BKPyVAN showing declining renal function and LTag staining in the enlarged nuclei of tubular epithelial cells. Since JCPyV may be detectable in native kidneys, specific diagnosis requires abundant detection of the JCPyV Vp1 capsid antigen or high genome tissue viral loads by in situ hybridization or NAT, while BKPyV genomes are typically absent or low.[72,182] Posttransplant screening is currently not recommended, but a high index of suspicion is warranted in patients with LTag-positive biopsy and undetectable BKPyV DNAemia or unexplained decline in renal function.[129,131] Successful treatment by reduced immunosuppression has been reported in cases of limited renal involvement, whereas direct or indirect graft failure was reported in other cases.[72,182] Serological studies in pediatric recipients indicate significant primary or secondary JCPyV exposure after kidney transplantation in 25% and 12.5%, respectively,[365] which result from reactivation or exogenous sources including the donor graft.[290] In a postmortem study of 111 HIV/AIDS patients, JCPyV has been identified in the native kidneys 7 (6.3%) cases, with limited tubuloepithelial signs of replication and damage in 4 (3.6%), but mostly little or no inflammation.

JCPyV-associated malignancies have been searched for ever since the initial demonstration of the transforming properties of JCPyV following nonlytic infection of nonpermissive cells and hosts.[132,359] In humans, malignancies with detectable JCPyV genomes, some with documented early viral gene expression have been described in the CNS such as oligodendroglioma, astrocytoma, medulloblastoma, ependymoma, and glioblastoma, primary CNS lymphoma as well as gastrointestinal carcinoma. However, other epidemiologic data are scarce. A recent study associated JCPyV with hematological malignancies and better survival,[202] while a meta-analysis covering 24 studies reported a four-fold increased risk of JCPyV detection in colorectal cancers but requires validation.[301] Mechanistically, JCPyV as driver or passenger needs to be addressed as well as a role of immunologically less surveyed anatomic locations, uncoupling of early versus late gene expression, and failure to immunologically clear EVGR-expressing tumor cells, as discussed.[132] Similar to PyVUC by BKPyV, a case of JCPyV-associated urothelial cancer has been reported occurring in a kidney transplant patient 5 years after JCPyV-associated nephropathy.[270]

Merkel Cell Polyomavirus and Merkel Cell Carcinoma

MCC is a highly aggressive, rapidly growing, neuroendocrine carcinoma of the skin that can quickly spread to lymph nodes and many other organs. The neuroendocrine features include a high nuclear–cytoplasmic ratio, giving it the appearance of a small blue cell tumor (Fig. 1.23). The chromatin pattern is typically open with few nucleoli, yielding a salt-and-pepper appearance. MCC typically presents on sun-exposed areas of elderly patients. Intense and lifelong UV exposure from the sun seems to be a particular risk for Caucasian patients, although MCC can occur in non–sun-exposed areas in young adults and children as well. Risk for developing MCC is increased in patients with severe immunocompromised conditions including HIV/AIDS, SOT, other cancers, and chemotherapy.[15]

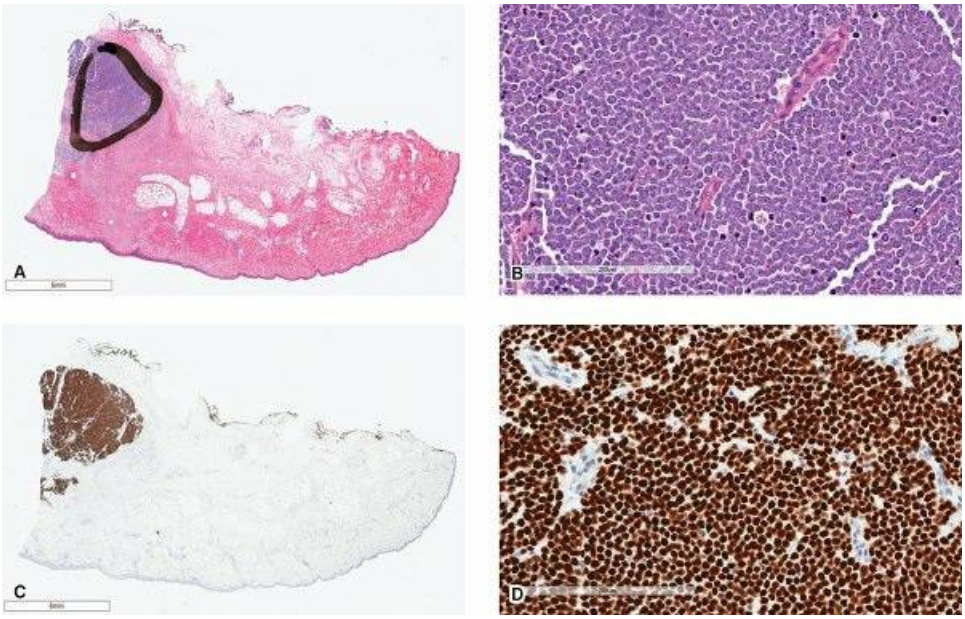

FIGURE 1.23 Merkel cell carcinoma. Hematoxylin and eosin **(A, B)** and immunohistochemistry with antibody specific for MCPyV LTag **(C, D)**. The low power H&E image **(A)** with pathologist's mark highlights the tumor in the dermal layer of the skin. The tumor appears *blue* due to the cellular high nuclear to cytoplasmic ratio. The high powered image shows the salt-and-pepper appearing chromatin pattern and high mitotic index. **C:** The low power IHC shows LTag-positive cells corresponding to the tumor only **D:** The high power image highlights the appearance of LTag in the nuclei of each tumor cell with blood vessels unstained.

Recognition of the increased risk for MCC in immunocompromised patients led to a focused search in the transcriptome of primary MCC tumors. The original report of the discovery MCPyV in MCC revealed many important insights reflective of polyomavirus biology.[84] In particular, the MCPyV viral DNA was found to be clonally integrated into the tumor genome. In one informative case, the integration pattern was identical in the primary tumor and a metastatic lymph node from the same patient. This indicates that the viral integration was an early event in the tumor formation. In addition, it has been repeatedly demonstrated that while the MCPyV is

clonally integrated, the viral genome is highly mutated with preservation of the MCPyV NCCR and part of the EVGR leaving STag intact but deleting the C-terminal half of LTag (Fig. 1.18). Typically, the MCC-associated LTag contains the shared N-terminal J domain with STag and the LXCXE, RB-binding, motif. However, the LTag DBD and helicase domain are lost in most MCC tumors leaving it incapable of binding to the integrated origin of replication in the NCCR. The LVGR is often not present in the integrated viral genome and, if present, the *VP1* and *VP2* genes are not expressed. Notably, not all MCC tumors contain integrated copies of MCPyV. Some MCC tumors instead contain a high number of mutations with a characteristic UV mutational pattern reflective of chronic sun exposure. These UV-associated MCC tumors are histologically indistinguishable from virus-positive MCC tumors. By contrast, the MCPyV-positive tumors have a very low number of host genome mutations. The virus-positive MCC tumors show expression of MCPyV T antigens in every tumor cell (Fig. 1.23).

While antibodies to MCPyV Vp1 are widespread in the general population and may be significantly higher in MCC patients,[260] antibodies to LTag and STag are usually only detected in patients with MCPyV-positive MCC and can be used as a biomarker to follow the disease course.[262] Antibodies to STag are present initially in approximately 50% of all patients with MCC. Titers to STag drop within several months after the tumor has been successfully treated but can rise again if the tumor returns.

Other HPyV-Associated Diseases

Trichodysplasia Spinulosa

The clinical entity of *trichodysplasia spinulosa* has been described in 1995 in an adult kidney transplant recipient who developed widespread hair-like follicular spiny hyperkeratosis together with sebaceous gland hyperplasia.[147] Inner root sheath keratinocytes in the proliferative lesions were found to contain intranuclear arrays of polyomavirus-like particles, which sequencing revealed to be the eighth human polyomavirus.[123,251,342] Clinically, *trichodysplasia spinulosa* often affects the face with hair-like spiculae most visible around the nose, together with alopecia of the eyebrows and eyelashes, and thickening skin with increasing duration of disease (Fig. 1.24). Extensive involvement of the skin of trunk and extremities has also been described with hypopigmented folliculocentric papules of 1 to 2 mm in diameter.[12,251] Histopathology studies reveal signs of activated inner root sheath cell proliferation and expression of the viral LTag, MTag, and capsid proteins, with enlarged trichohyalin cytoplasmic granules and minimal inflammation (Fig. 1.25).[351] Hair-shaft formation is missing or rudimentary with parakeratotic debris extending outward forming the hair-like spiculae. Although probably underreported, fewer than 50 cases have been described to date, all of which occurred in immunocompromised patients due to transplantation, hematological malignancy, or cancer chemotherapy.[161]

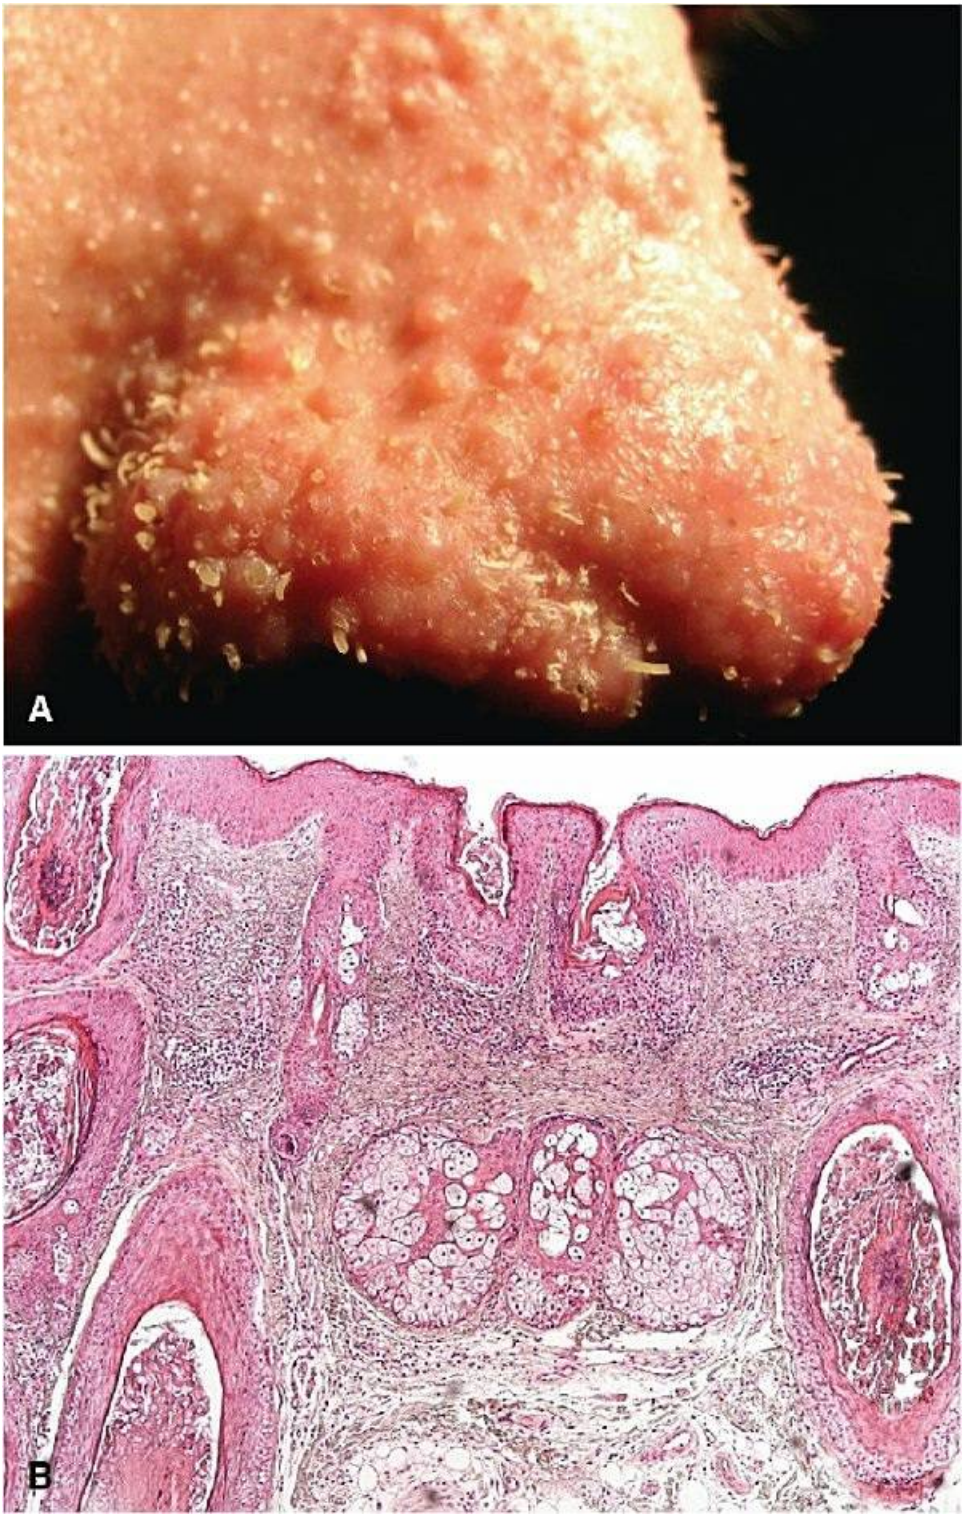

FIGURE 1.24 Trichodysplasia spinulosa. Affected nose with papules and spicules **(A)**. Biopsy of a hyperkeratotic follicular papule from the forehead. The epidermis reveals enlarged, hyperplastic hair bulbs and hypercornification within a distended follicular infundibulum (hematoxylin and eosin [H&E] stain, 10×) **(B)**.[342] (Reprinted from van der Meijden E, Janssens RW, Lauber C, et al. Discovery of a new human

polyomavirus associated with trichodysplasia spinulosa in an immunocompromized patient. *PLoS Pathog* 2010;6(7):e1001024.https://creativecommons.org/licenses/by/3.0/.)

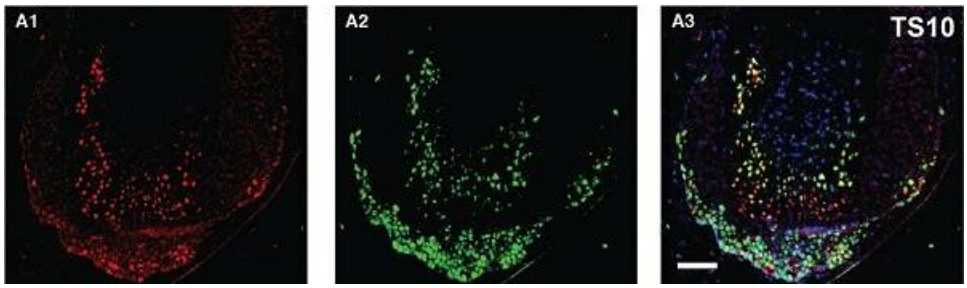

FIGURE 1.25 Immunohistopathology of TSPyV-associated trichodysplasia spinulosa. Colocalization of TSPyV large T antigen, Ki-67, and phosphorylated pRB. TSPyV LT-antigen (*red*) (A1) with Ki-67 (*green*) (A2) and merge (*yellow*) (A3) in a vertical section of hair follicle of TS10 is shown in the upper row.[162] (Reprinted from Kazem S, van der Meijden E, Wang RC, et al. The pathogenesis of *trichodysplasia spinulosa* is not well understood. Person-to-person transmission of TSPyV mostly within families has been linked to the early rise in seroprevalence from 10% among children to more than 80% among adults, making TSPyV part of the normal adult skin microbiome.[89,343,357] Uncontrolled TSPyV reactivation has been proposed to occur in severely immunocompromised patients.[356] Alternatively, primary TSPyV infection in immunocompromised individuals has been proposed to explain the low rate of this complication despite the increasing number of profoundly immunocompromised people.[341] Detection of TSPyV DNA in noncutaneous specimens including blood and urine has been interpreted as marker of systemic dissemination.

The diagnosis of *trichodysplasia spinulosa* is based on the typical clinical presentation in an immunocompromised patient, which is supported by histopathology, and a high tissue TSPyV load of more than 10^6 c/μg DNA not found in other hyperkeratoses.[12,38] There is currently no specific prevention, screening, or prophylaxis for patients at risk. The treatment of *trichodysplasia spinulosa* is based on attempting to restore TSPyV-specific immunity, for example, by reducing immunosuppression, which is often limited or unsuccessful due to the underlying condition such as transplantation or hematological disorders. Cidofovir gel has been applied topically to target the TSPyV-replicating hyperproliferative cells, and responses to leflunomide, topical or systemic retinoic acid derivatives, and the physical removal of spiculae have been reported, likely by stimulating local inflammation and immune responses.[14,57,157,342]

HPyV7-Associated Pruritic Hyperproliferative Keratinopathy

New-onset, pruritic, brown hyperproliferative skin changes have been linked to HPyV7

replication in immunocompromised patients.[41,138] In the initial report, two lung transplant recipients developed highly pruritic velvety hyperproliferative plaques on the trunk, buttocks, and extremities several years after transplantation (Fig. 1.26).[138] On skin biopsy, the epidermal stratum corneum was thickened with cytopathic keratinocytes forming a peacock plumage pattern, with very little perivascular lymphocytic infiltrates in the dermis. By electron microscopy, intranuclear PyV inclusions were identified together with a high HPyV7 DNA load averaging 10^3 c/cell. Immunohistochemistry demonstrated early and late viral gene expression (Fig. 1.26). In both patients, HPyV7 DNA was detected in peripheral blood mononuclear cells. In one patient, pseudomembrane-like changes and glandular epithelium with viral inclusions of the gastric antrum mucosa was detected together with encapsidated DNase-resistant HPyV7 genomes in plasma suggesting hematogenous HPyV7 dissemination.[138] In both cases, the HPyV7 NCCRs were rearranged carrying a 16 bp-insertion and 12 bp-deletion, respectively, which conferred increased EVGR expression compared to the archetype NCCR.[2,138] Given the widespread exposure among adults[89] and the limited number of cases, risk factors and pathogenesis of HPyV7 skin disease are undefined other than profound immunodeficiency. Notably, mTOR inhibitors provided no protection while worsening following steroid exposure has been reported.

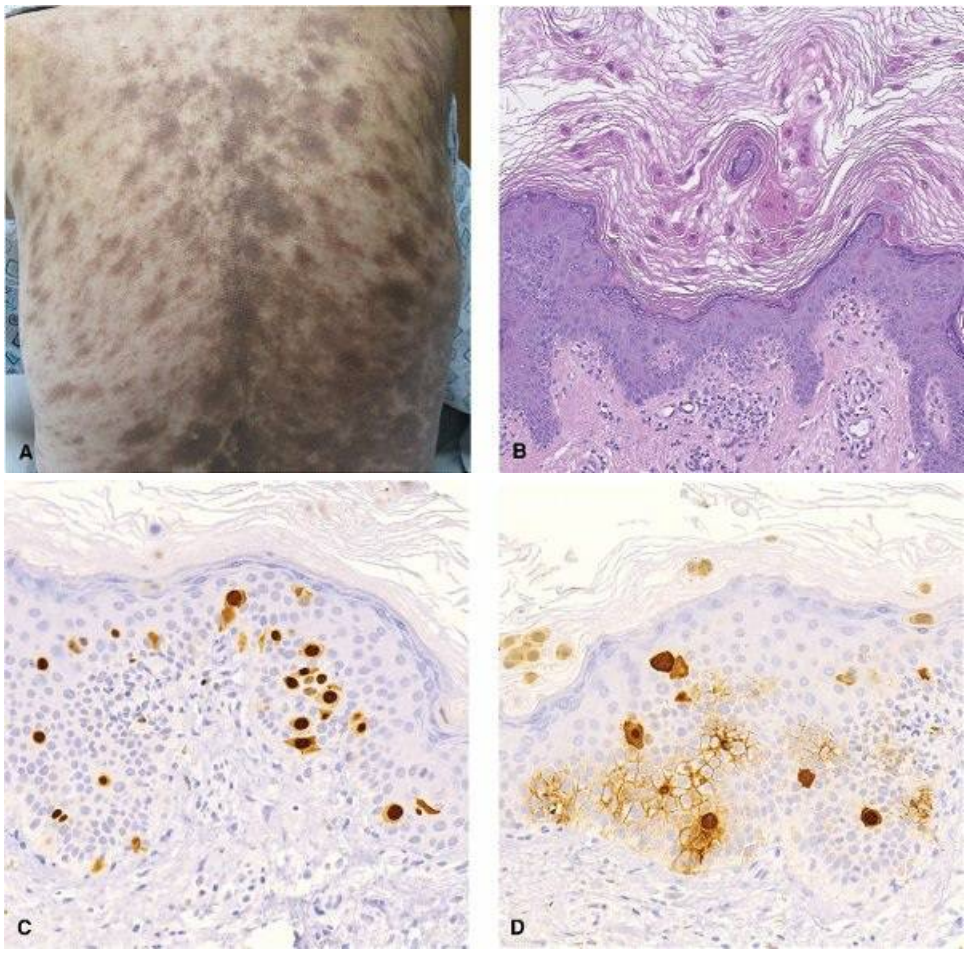

FIGURE 1.26 Clinical and pathologic features of HPyV7-related skin

manifestations. A: Pruritic velvety plaques on the trunk. **B:** Viropathic keratinocytes in a peacock plumage pattern (original magnification, 20×; hematoxylin–eosin staining). **C:** Strong HPyV7 T antigen nuclear and cytoplasmic immunostaining in the keratinocytes (original magnification, 40×) **D:** HPyV7 viral capsid staining in the skin shows nuclear and cytoplasmic staining in keratinocytes, as well as a lacy pattern representing lysed virions in the intercellular space (original magnification, 40×).[138] (From Ho J, Jedrych JJ, Feng H, et al. Human polyomavirus 7-associated pruritic rash and viremia in transplant recipients. *J Infect Dis* 2015;211(10):1560–1565. Reproduced by permission of Oxford University Press.)

The clinical diagnosis is suggested by the expanding highly pruritic plaques in an immunocompromised patient and confirmed by histopathology on skin biopsy and high HPyV7 DNA loads by NAT. A similar clinical picture has been ascribed to HPyV6,[244] which should be tested in parallel. The differential diagnosis includes other infectious and noninfectious causes of pruritic hyperkeratoses, and specifically mTOR inhibitor toxicity.[264] Treatment attempts of HPyV7-associated pruritic hyperproliferative keratinopathy has been targeting the pruritus with little success using antihistamines, while limited improvement of the skin changes have been reported using topical or systemic cidofovir, except for one case of complete resolution following oral aciretin.[41]

Other HPyV-Associated Manifestations

Explorative studies associating HPyVs with other clinical manifestations have largely been inconclusive with the possible exception of HPyV6 detection in approximately 50% of keratoacanthomas.[16] However, in a few cases, comprehensive histopathology and molecular studies supported an etiological or contributory role of HPyVs, which await independent confirmations. Thus, HPyV6 was detected in one case of BRAF inhibitor-induced epithelial proliferation, whereas no association with other dermatotropic HPyVs was detected.[289] HPyV6 has been described in a patient with angiolymphoid hyperplasia and eosinophilia (Kimura Disease).[273] HPyV13, also called NJPyV, was discovered in a kidney pancreas transplant patient presenting with localized necrotic skin and muscle disease due to viral replication in endothelial cells causing microthrombosis.[228] Cases of respiratory WUPyV replication[307] including subsequent disseminated multiorgan involvement were reported in allogeneic HSCT recipients.[306] KIPyV replication has also been documented in cases of pneumonia.[305] Both reports are consistent with the initial identification of KIPyV and WUPyV in respiratory fluids of patients with otherwise unidentified causes of pneumonia.[3,97] However, larger epidemiologic studies have not supported a consistent role for KIPyV and WUPyV in respiratory tract infectious diseases. KIPyV and WUPyV have been detected in fewer than 5% of patients with acute respiratory infectious disease including those requiring hospital admission, but frequently coexist with other respiratory pathogens. In a comprehensive study of 222 allogeneic HSCT recipients, the cumulative incidence of KIPyV and WUPyV detection during the first year posttransplant was 26% and 8%, respectively, and mostly involved co-detection of another respiratory virus.[178] The clinical presentations were mostly mild wheezing and sputum production. No association of either virus was found with acute graft versus host disease, lymphopenia, or death.[178] Thus, despite serological and molecular evidence of frequent exposure

among immunocompetent and immunocompromised individuals, the contribution of KIPyV and WUPyV to human disease requires further study.

A recent report of a new human polyomavirus, Lyon IARC PyV (LIPyV), may have been isolated due to environmental exposure to domestic cats.[80,100] Similarly, HPyV12 may represent exposure to shrews.[98,173]

SV40 and Humans

From the mid-1950s to 1963, the simian polyomavirus SV40 was unknowingly introduced into more than 100 million people who had received contaminated poliovirus vaccines.[297] Because SV40 is tumorigenic in rodents and can transform human cells in culture, there has been concern about whether SV40 can contribute to cancer development in humans vaccinated with the contaminated polio vaccine or from other sources. There has also been controversy regarding whether SV40 can replicate and establish a productive infection in humans.

Follow-up studies from the initial polio vaccination efforts have concluded that there was not an increase in neoplasia over three decades in the population that was directly exposed to SV40 when compared with matched control populations not exposed to SV40.[298] A retrospective cohort study of data collected by programs designed to track tumor incidence in specific populations also did not find any association between SV40 exposure and increased risk.[320]

The FDA Office of Vaccine Research and Review convened a meeting of international authorities to discuss the topic of SV40 in the human population and the technical approaches needed to evaluate its presence as an infectious agent and role, if any, in human tumors.[36] The Institute of Medicine published a study concluding that the epidemiologic evidence regarding SV40 infections in humans was insufficient and recommended additional research.[319] There have been sporadic reports that SV40 DNA and LTag could be detected in human tumors such as ependymomas, osteosarcomas, mesotheliomas, and choroid plexus papillomas. However, unlike the presence of integrated MCPyV viral genome in MCC, there have been no reports of integrated SV40 viral genomes or expression of transcripts in human tumors. Instead, the frequent detection of SV40 viral DNA in human tumors may represent contamination in the laboratory with plasmids containing SV40 NCCR, splicing, polyadenylation, and other elements present in molecular biologic reagents.[200,213,269]

It is not certain if SV40 can establish a persistent infection in humans. While SV40 can replicate at very low levels in human fibroblasts and mesothelial cells in culture, it does not appear to be capable of replicating in lymphocytes.[29,300] Notably, while BKPyV and JCPyV are frequently detected in human sewage, the presence of SV40 has not been reported.[31] In addition, while some human sera are reactive against SV40 Vp1, suggesting a past infection, most of this activity can be depleted by preincubation with BKPyV or JCPyV Vp1.[163,278]

Avian Polyomavirus and Disease

Hemorrhagic nephritis and enteritis of geese develop rapidly after infection with GHPyV. Typical symptoms of infected birds include generalized edema, gout, hemorrhagic enteritis, interstitial nephritis following infection of the kidney tubular epithelium, and disruption of lung, feather follicle, and endothelial cells. Lymphoid tissues can become depleted of most

lymphocytes. These features have been observed in naturally and experimentally infected birds.[179,254] In addition to GHPyV, infection with APyV, FPyV, and CPyV are associated with fatal disease often including hepatitis, ascites, enteritis, and nephritis.[153]

PERSPECTIVE

Since Ludwig Gross first described MPyV in 1953, polyomaviruses have proven to be relevant model systems for understanding fundamental biological processes in eukaryotic cells. In addition to the insights that have contributed to our understanding of transcription factors and enhancers, RNA splicing and polyadenylation, and DNA replication, the study of polyomaviruses has enriched our understanding of tumor suppressors, oncogenes, tyrosine kinase signaling, immunity, and tumorigenesis. The study of polyomavirus cell receptors, entry, and trafficking through the cell has brought remarkable insights that have challenged previously held models. Importantly, the information gained by study of polyomaviruses has enabled critical insights of human disease. As the population of immunosuppressed individuals increased due to HIV/AIDS and developments in transplantation medicine and the therapy of autoimmune diseases, the incidence of polyomavirus diseases continues to rise. A dramatic example of this has been the occurrence of JCPyV-induced PML in patients with multiple sclerosis or Crohn disease who were treated with an antibody that blocked lymphocytes from binding the VLA4 receptor through the α4 integrin molecule.

Continued investigation into the interaction between polyomaviruses and their hosts will be crucial for improving our ability to prevent and treat polyomavirus diseases in the future. Given new technology and model systems, it should be possible to develop high-throughput screens to identify more effective compounds that inhibit the viral life cycle. It is imperative that evidence-based clinical studies, guided by impeccable cellular and molecular studies, are implemented to benefit immunocompromised patients at risk for and suffering with polyomavirus diseases.

The contribution of MCPyV to MCC deserves special mention. To date, all studies indicate that expression of the MCPyV STag and a truncated form of LTag is present in approximately 80% of all MCCs. Consistent with the large body of literature on polyomavirus-mediated transformation, MCPyV is clonally integrated into the MCC cells in a manner that enables persistent expression of the T antigens. There are many questions that remain unanswered regarding the role of MCPyV T antigens in MCC. In addition, it is not understood what the contributions of age, UV exposure, and immunosuppression are to the risk for developing this cancer. Furthermore, it is not known what the normal host cell or tissue type for MCPyV is and what is the special relationship with Merkel cells. Also, the factors in the host and virus that sustain lifelong infection but permit reactivation of polyomavirus infection remain to be defined not only for MCPyV but also for all polyomaviruses.

The recent discoveries of new polyomaviruses in humans, primates, marsupials, and birds have brought renewed vigor to the field. It is likely that more polyomaviruses and related viral families will be discovered.[70] More importantly, it can be expected that further investigation of the new and previously studied polyomaviruses will continue to bring important new and fundamental insights into biology and disease. It can certainly be concluded that the

polyomaviruses have paid huge dividends in the amount of knowledge they have yielded. Consequently, the future seems to hold great promise that study of polyomaviruses will continue to help us demystify fundamental cellular processes and give direct benefits to patients whose polyomavirus infection becomes organ and life threatening.

INTRODUCTION

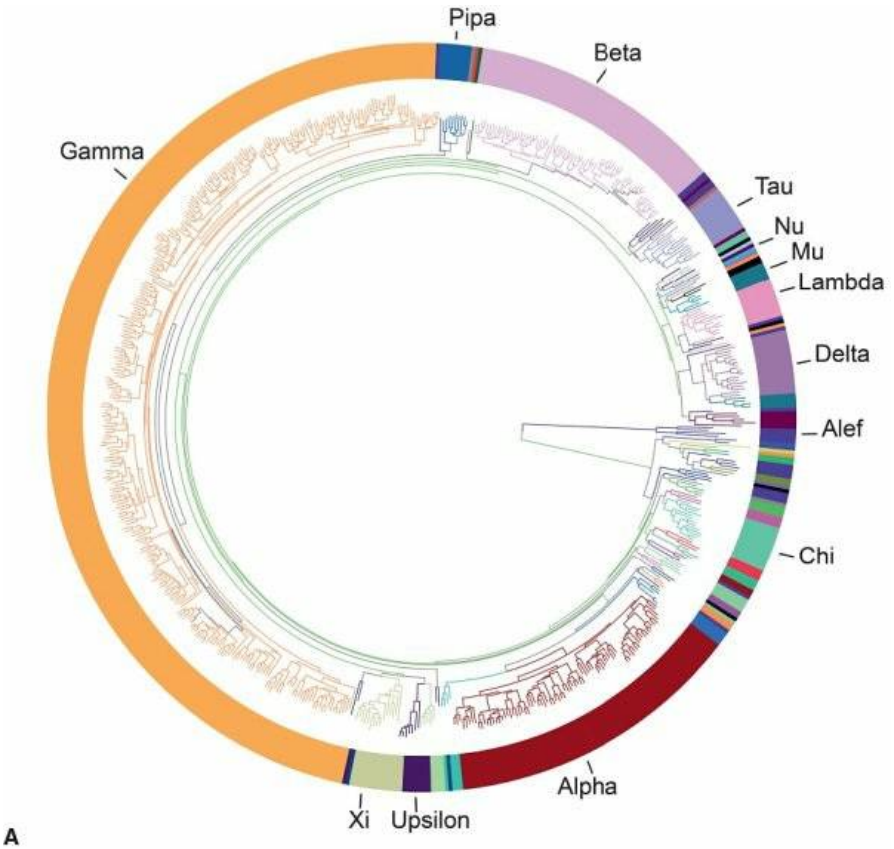
The Papillomaviruses (PVs) comprise a group of nonenveloped epitheliotropic DNA viruses that induce benign squamous epithelial lesions in a variety of higher vertebrates. Some PVs are associated with cancers in their natural hosts including some of the human papillomaviruses (HPVs) that are the cause of human cervical cancer, other tumors of the urogenital tract, and head and neck oropharyngeal cancers. Indeed, 5% of human cancers are caused by oncogenic HPVs. In previous recent editions, the PVs were presented in a single chapter. Because of major advances in understanding the fundamental biology of the papillomaviruses, as well as advances due to the success of the preventive VLP-based vaccines, the PVs are covered by two separate chapters in this 7th Edition. This chapter will focus on fundamental aspects of the molecular biology and replication of the PVs and Chapter 3 by Schiller and Lowy will deal with more clinical aspects of the HPVs.

HISTORY

Warts were known to the ancient Greeks and Romans. Their infectious nature was recognized, but until the nineteenth century, genital warts were usually considered to be a form of syphilis or gonorrhea. The viral nature of human warts was demonstrated in the early 1900s when cell-free filtrates from lesions were shown to transmit the disease.[48] PVs were subsequently identified in a variety of vertebrate species in addition to humans.

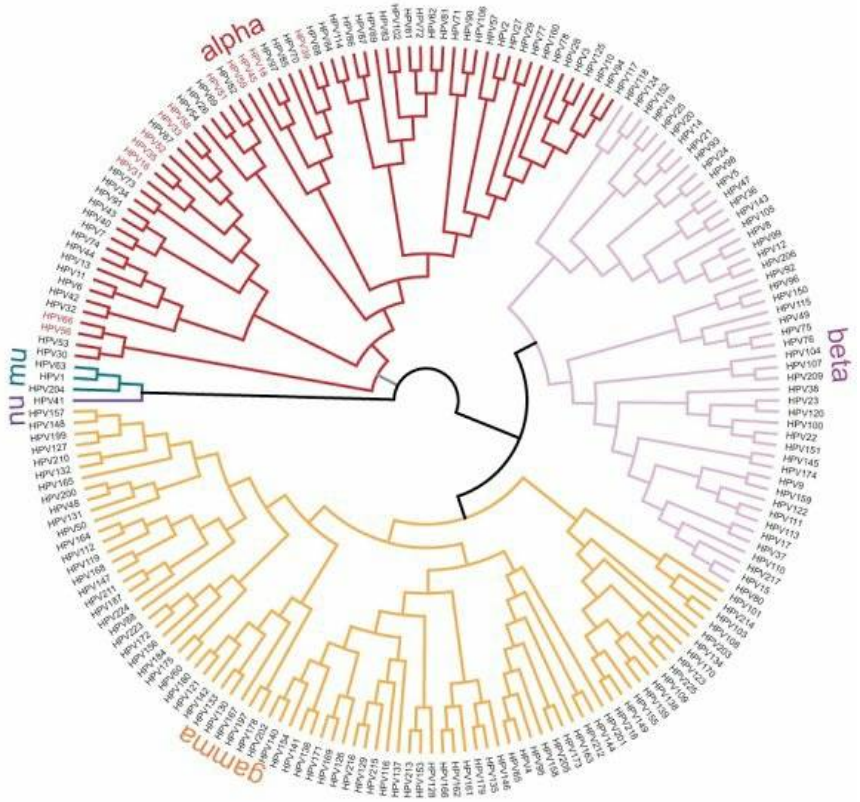
The first animal PV was identified in the 1930s by Richard Shope, who characterized the transmissible nature of cutaneous papillomas arising in wild cottontail rabbits.[235] The Shope papillomavirus, now officially designated as *Sylvilagus floridanus* Papillomavirus 1 (SfPV1) but commonly called cottontail rabbit papillomavirus (CRPV), was the first DNA tumor virus identified. Shope's research also showed that although systemic injection with papilloma suspensions did not produce detectable infection, it could induce serum-neutralizing antibodies and protect rabbits against high-dose cutaneous viral challenge.[234] These findings laid the groundwork for believing that a preventive vaccine against a PV could be based on the induction of humoral immunity. In addition to causing benign papillomas, some warts induced by SfPV1/CRPV were observed to undergo malignant progression,[215,254] and for the next two decades, SfPV1/CRPV was an important model for the fundamental study of viral tumorigenesis.[143,253] However, its use as a model tumor virus was largely supplanted by the discovery in the late 1950s of the polyomaviruses, which could replicate in cultured cells and induce morphologic transformation *in vitro*, in contrast to SfPV1/CRPV, and were tumorigenic in experimental animals.

Although the PVs were studied less intensively in the 1950s and 1960s, that period was associated with some important advances, including the physicochemical analysis of PV virions, and the demonstration that PV replication was associated with the differentiation process of the infected epithelium.[216] However, it was the advent of molecular cloning in the 1970s that initiated more extensive studies of PVs. The cloning and sequencing of PV genomes led to the identification of open reading frames (ORFs) as putative viral genes and permitted investigators to determine the function of viral genes by reverse genetics, resulting in a much wider interest in PV research.[42,53,54] The bovine papillomavirus type 1 (BPV1) was the standard PV used for these studies because the virus induced focal transformation of established rodent cell lines.[21,74] The molecular cloning of the HPV genomes also led to the recognition that there were multiple HPV genotypes, and that a subset of these types was closely associated with human cancers. These included cervical cancer[25,73,190] and skin cancers in individuals with the primary immunodeficiency, epidermodysplasia verruciformis (EV).[190, p.461] The appreciation of their medical importance, combined with improved tools for analyzing PVs, further enhanced the utility of PVs as a model of viral tumorigenesis. Although the study of animal PVs continues to bring new information to the field, the medical importance of HPVs has shifted emphasis toward the analysis of HPV, especially when it was established that the biochemical properties of some nonstructural viral proteins differed from those of their BPV1 counterparts.



CLASSIFICATION

Initially, the PVs were classified together with the polyomaviruses as a single family, the *Papovaviridae*. Although the viruses share many similarities, including a double-stranded circular DNA genome, an icosahedral capsid composed of 72 pentamers, a nonenveloped virion, and the nucleus as the site of viral replication and virion assembly, they are genetically distinct virus families.



Hundreds of PVs (655 to date) have been isolated from diverse mammalian host species, birds, reptiles and fish, but thus far they have not been identified in nonvertebrates. PVs are species specific, and many different PV types can infect a given host species. HPVs have been analyzed most intensively; currently 440 different HPV types have been identified and classified, and there are likely more to be discovered (https://pave.niaid.nih.gov/).

PVs are named according to the host species they infect and are classified as individual types based on the DNA sequence of the L1 gene. The current International Committee on Taxonomy of Viruses (ICTV) classifies the *Papillomaviridae* family into two subfamilies, the *Firstpapillomavirinae* with more than 50 genera and 130 species, and the *Secondpapillomavirinae*, with a single genus containing fish papillomaviruses.[271, p.462] Within the PV community, the viruses are divided into the categories: subfamily, genus, species, type, and variant. The broadest category is a *genus*. PVs are divided into greater than 50 genera, each of which is designated by a letter of the Greek alphabet. Within a given *genus*, the L1 genes of all members share more than 60% identity. A *species* is designated for those PVs that share 60% to 70% identity within a given genus. A viral *type* has 71% to 89% identity with other types within the species, or conversely has an L1 DNA sequence that is at least 10% different from that of all other PV types. Within a type, there can be *variants*, which share more than 98% identity.[35] These variants have been studied intensively for viruses such as HPV16 because of its medical importance.[45,176]

The PV types can be organized into a phylogenetic tree based on the comparative homology of the L1 DNA sequence (Fig. 2.1). Similar (though not identical) phylogenetic relationships are also seen when homologies among other regions of the genome are compared. This is because different PV types appear to have arisen primarily from point mutations scattered throughout the genome, rather than from recombination between PVs.[41] These similarities are consistent with the conclusion that PVs have accompanied their host species during evolution and have evolved with them.[19,270]

FIGURE 2.1 Phylogenetic trees demonstrating the evolutionary relationship among PVs. A: Phylogenetic tree based on the L1 sequence of 655 PVs characterized to date. This contains animal PVs, Reference HPVs (officially named by the HPV Reference center https://ki.se/en/labmed/international-hpv-reference-center) and Non-reference HPVs. The more common genera are indicated. **B:** Phylogenetic tree based on the L1 sequence of the Reference HPVs. HPVs are contained in five genera and each of them has different epithelial tropisms and disease associations. The *Alphapapillomavirus* HPVs include the low-risk mucosal types that cause genital warts, and the high-risk mucosal types associated with anogenital cancers (indicated in red text). Some *Betapapillomavirus* HPV types have been associated with nonmelanoma skin cancers (NMSC) in immunosuppressed individuals, and in individuals with epidermodysplasia verruciformis (EV).

Using this classification, HPVs are clustered among five of the greater than 50 genera: *Alpha-*, *Beta-*, *Gamma-*, *Mu-*, and *Nupapillomavirus*, while the other genera are occupied exclusively by animal PVs. The host species associated with each PV genus tend to be closely related evolutionarily. Thus, PVs that infect nonhuman primates are found within the genera that include HPVs, and some HPVs are more closely related to nonhuman primate viruses than to some of the other HPVs in the genus. The HPVs of greatest medical importance, that is, those that are associated with genital and mucosal cancers, are members of the *Alphapapillomavirus* genus. Most *Alphapapillomavirus* types primarily infect genital and nongenital mucosal surfaces and the external genitalia. This group of PVs is often referred to collectively as the “mucosal” types. The types that are associated with cervical cancer, often designated as high-risk types, are found in species 5, 6, 7, 9, and 11. HPV16, the type found most frequently in cervical cancer, is a member of species 9, while the next most common cancer-associated type, HPV18, is a member of species 7. HPV6, which causes most cutaneous genital warts, is a species 10 member.

In contrast to most species of the *Alphapapillomavirus* genus, members of *Alphapapillomavirus* species 4 (HPV2, 27, and 57) are primarily infectious for nongenital skin. The *Beta-*, *Gamma-*, *Mu*, and *Nupapillomavirus* viruses also infect nongenital skin. The *Betapapillomavirus* HPVs include those that are often designated EV specific, because they cause lesions, and cutaneous squamous cell carcinomas, mainly in patients with EV, a genetic susceptibility to widespread nongenital HPV lesions. Some PVs, including many members of the beta and gamma species, may behave as commensal agents, as they are frequently isolated from normal skin or plucked hair from humans and animals.[8,26]

The PVs in the *Deltapapillomavirus* genus, which includes BPV1 and other PVs of ungulates, cause fibropapillomas, rather than papillomas. This distinct pathology results from a proliferative dermal fibroblastic component under the epithelial portion of the lesion, because members of this genus induce nonproductive transformation of the fibroblasts, in addition to the productive infection of the overlying epithelium. The ability to transform nonepithelial cells is not species specific. This property can lead to the induction of nonproductive fibroblastic tumors in heterologous hosts under natural conditions, as in equine sarcoid of horses (from BPV1 or BPV2), or experimental hosts, such as hamsters. It also endows viruses such as BPV1 and BPV2 with the ability to induce focal transformation of cultured rodent cells.

VIRION STRUCTURE

PVs are small, nonenveloped, icosahedral DNA viruses that replicate in the nucleus of squamous epithelial cells. The PV particles are approximately 60 nanometers in diameter (Fig. 2.2). The virion particles consist of a single molecule of double-stranded circular DNA of about 8,000 base pairs (bp) in size, contained within a spherical protein coat, or capsid, composed of two viral proteins, L1, the major capsid protein, and L2, the minor capsid protein. The DNA constitutes approximately 12% of the virion by weight, accounting for their density in cesium chloride of 1.34 g/mL.[52]

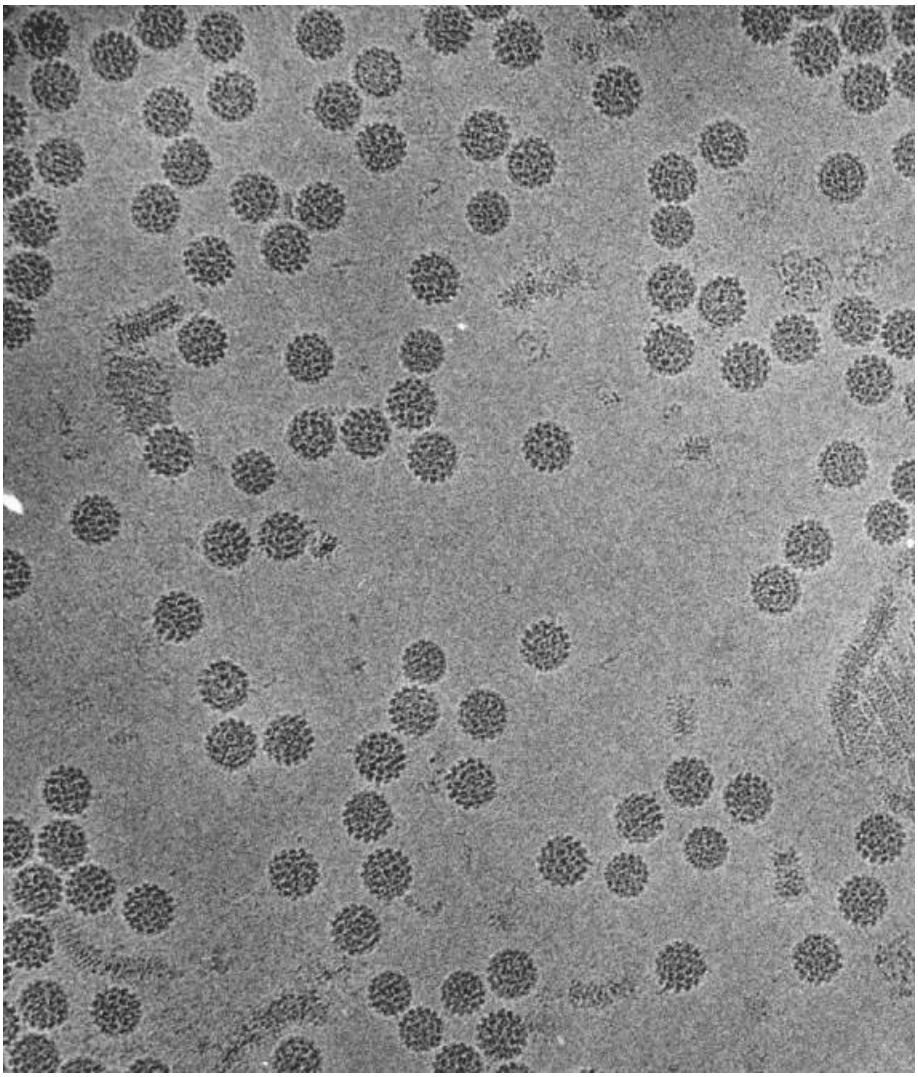

FIGURE 2.2 Electron micrograph of BPV1 virion particles (55 nm in diameter). (Reprinted from Baker TS, Newcomb WW, Olson NH, et al. Structures of bovine and human papillomaviruses—analysis by cryoelectron microscopy and three-dimensional image reconstruction. *Biophys J* 1991;60:1445–1456. Copyright © 1991 The

Biophysical Society. With permission.)

Structural analysis by cryo-electron microscopy (cryo-EM) and three-dimensional image reconstruction techniques revealed that the viruses consist of 72 pentameric capsomers arranged on a $T = 7$ surface lattice.[10,267] The capsomers are composed of five L1 molecules with one L2 molecule occupying the axial lumen.[33] As with the polyomavirus capsids, the capsomers exist in two environments, one capable of making contact with six neighbors as observed in the 60 hexavalent capsomers and the other with 5 neighbors in the 12 pentavalent vertex capsomers (Fig. 2.3). Analysis of proteins in the virus particle showed that the viral DNA is associated with cellular histones to form a chromatin-like complex.[81,200]

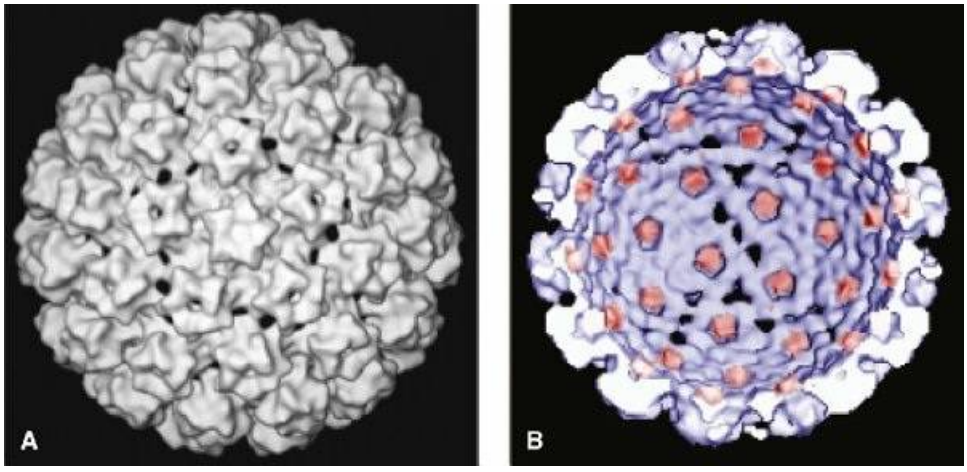

FIGURE 2.3 A: 3-D reconstruction of a BPV virion viewed down a 5-fold axis.[267] **B:** 3-D reconstruction of an interior/cutaway view of an HPV L1/L2 VLP with the L2 specific density shown in red. (Adapted from Buck CB, Cheng N, Thompson CD, et al. Arrangement of L2 within the papillomavirus capsid. *J Virol* 2008;82(11):5190–5197. Copyright © 2008 American Society for Microbiology. Amended with permission from American Society for Microbiology.)

Virus-like particles (VLPs) can be produced from different PVs by expressing L1 alone using mammalian or nonmammalian expression systems,[103,136,214] and these are the basis for the highly successful HPV vaccine (Chapter 3). The morphology of VLPs containing only L1 appears identical to intact virus particles in low resolution cryo-EM reconstructions,[102] but near atomic reconstructions reveal the putative location of the L2 protein.[100] The structure of a truncated $T = 1$ HPV16 L1 VLP containing 12 pentamers has been solved by x-ray crystallography to 3.5 Å resolution.[44] The structure of full-size BPV1 virions has been solved to 3.6 Å resolution using cryo-EM.[289]

GENOME STRUCTURE AND

ORGANIZATION

To date, over 650 human and animal papillomavirus genomes have been sequenced in their entirety, and the overall genomic organization of each is very similar (https://pave.niaid.nih.gov/).[272] Each virus contains a regulatory region, approximately one kilobase in size, which contains the replication origin, transcriptional enhancers and repressor elements, and promoters. This region has been alternatively named the upstream regulatory region (URR), the long control region (LCR), or the noncoding region (NCR). The remainder of the genome is divided into the early and late coding regions. All viral ORFs are located on one strand, which serves as a template for transcription. The organization of an *Alphapapillomavirus* HPV genome is shown in Figure 2.4.

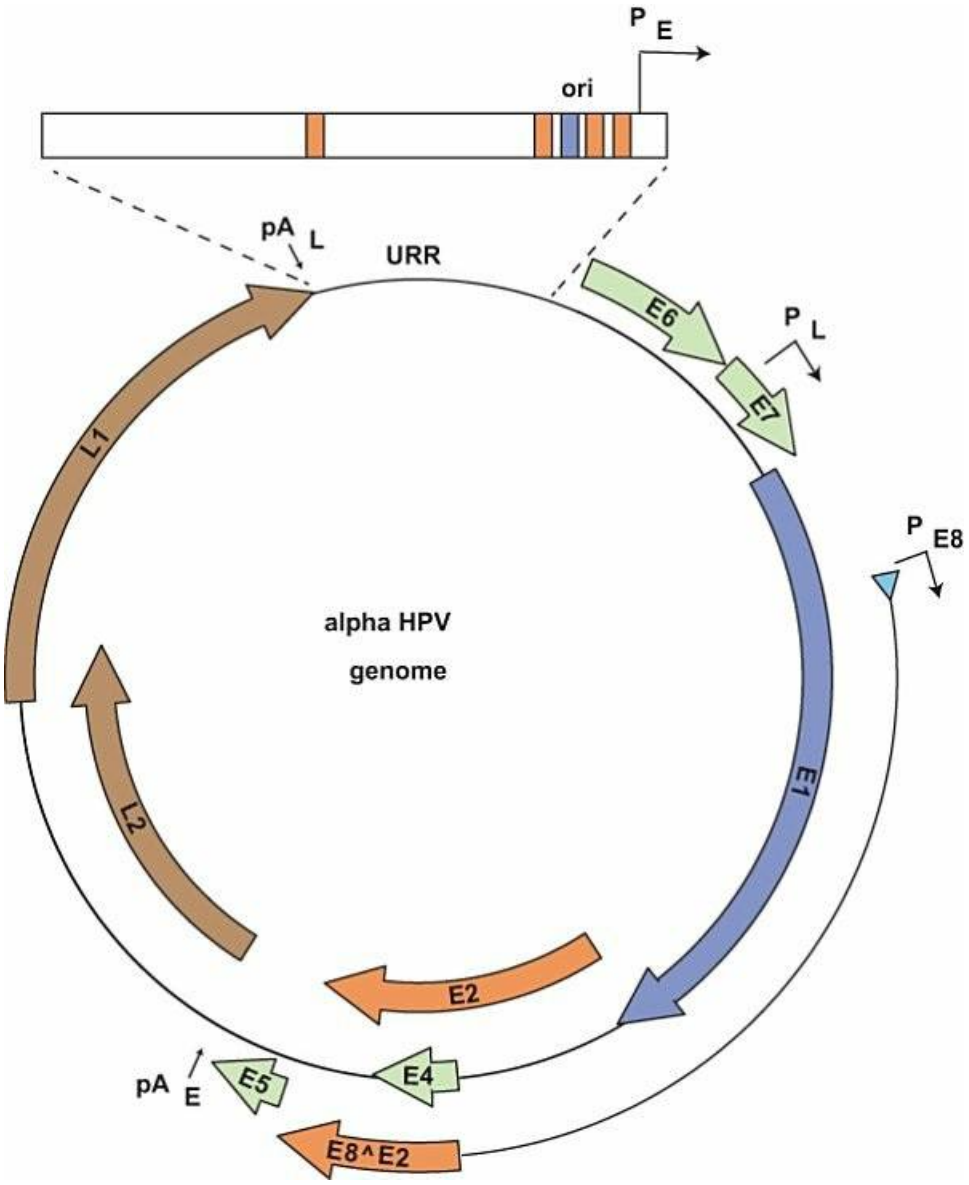

FIGURE 2.4 Oncogenic *Alphapapillomavirus* HPV genomic map. All HPVs have a circular dsDNA genome of approximately 7,000 to 8,000 bp. The location of early (E) and late (L) ORFs are shown. Only one strand is transcribed, and transcription initiates in the clockwise direction from three viral promoters P_E (early), P_{E8} (E8), and P_L (late) and terminates at one of two polyadenylation sites pA_E and pA_L. The URR is the Upstream Regulatory Region and contains the origin of DNA replication (ori). The orange boxes in the URR represent the four E2 binding sites and the blue box is the E1 binding site.

All PV genomes encode four core proteins; these are the replication proteins E1 and E2 (encoded in the early region), and the L1 and L2 capsid proteins (encoded by the late region, and expressed only in productively infected cells). Also encoded by almost all PVs are two fusion proteins expressed from spliced early mRNAs. E8^E2 contains a few amino acids encoded by the E8 ORF (overlaps E1) fused to the C-terminal half of the E2 protein. E1^E4 contains a few amino acids encoded by the E1 ORF fused to E4, an ORF that overlaps the central portion of the E2 ORF.

Other PV genes (E5, E6, E7) are not encoded by all PVs and are likely evolutionary embellishments; these proteins help condition the cellular environment for optimal viral persistence and production. The functions of the individual ORFs are described in more detail in the relevant sections of this chapter. The E5 proteins are short hydrophobic polypeptides expressed from the ELR (early to late region) between the E2 and L2 ORFs. Notably, among the five genera of HPVs, only the *Alphapapillomavirus* HPVs encode E5 proteins. The E5 proteins encoded by different PVs can be evolutionarily unrelated, and occasionally more than one E5 is encoded by this region.[28] However, a few diverse PVs encode a hydrophobic E5-like protein that either replaces or overprints the E6 protein.[273] To avoid confusion with other ORFS, these have been designated E10 in the Papillomavirus Episteme.[272]

VIRUS REPLICATION

Papillomaviruses are highly species specific and have a specific tropism for squamous epithelial cells (reviewed in Ref.[66]). Productive infection of cells by the PVs can be divided into early, intermediate, and late stages, which are linked to the differentiation state of the epithelial cell. The tropism of the papillomaviruses for squamous epithelial cells is evidenced by the restriction of the late viral replication functions, such as vegetative viral DNA synthesis, the production of viral capsid proteins, and the assembly of virions, to differentiated epithelial cells. The close link of the papillomavirus life cycle with the differentiation program of the squamous epithelium is depicted in Figure 2.5.

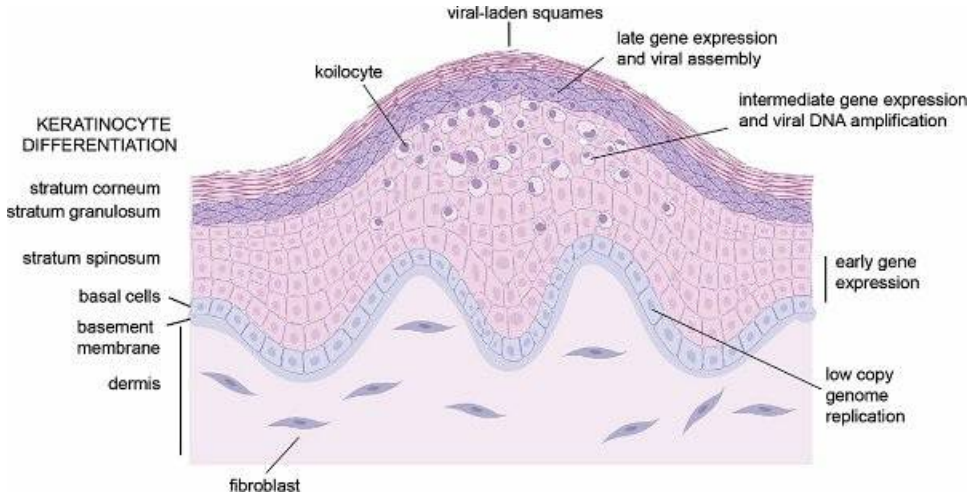

FIGURE 2.5 PV infection of cutaneous epithelia. Differentiation of normal and infected cutaneous squamous epithelium. The various epithelial strata are indicated on the left and the viral activities in the corresponding strata during productive infection are indicated. Koilocytes are atypical cells that are indicative of PV infection. Figure created with BioRender.com.

The basal cell is the only cell in the squamous epithelium capable of undergoing sustained cell division. Thus, the virus must infect the basal cell to establish a long-term, persistent infection. Only very low levels of viral DNA are found in the basal cells, but viral transcripts have been detected,[248] and at least some early viral proteins are found in basal cells.[4] Late gene expression, synthesis of capsid proteins, vegetative viral DNA synthesis, and assembly of virions occur only in terminally differentiating squamous epithelial cells.

Virion Attachment, Entry, and Trafficking

As noted above, persistent papillomavirus infection requires infection of the basal layer cells of the epithelium (reviewed in Ref.[66]). Because of the complex nature of the PV life cycle, most studies on viral entry have used *in vitro* generated virus and the following is a summary of those studies. To achieve selective infection of basal keratinocytes, the virions preferentially bind initially to heparan sulfate proteoglycans (HSPGs) on the basement membrane exposed at sites of epithelial trauma (Fig. 2.6).[127,212] This binding induces a conformational change in the capsid that exposes an N-terminal L2 peptide to cleavage by furin.[211] In one model, cleavage induces a conformational change that exposes a capsid-binding site (probably on an L1 surface) for a secondary, presently unknown, cell surface entry receptor on keratinocytes.[134] Alternatively, virions coated with HSPGs and growth factors interact with growth factor receptors, and this is essential for both cell entry and signaling of keratinocytes.[252]

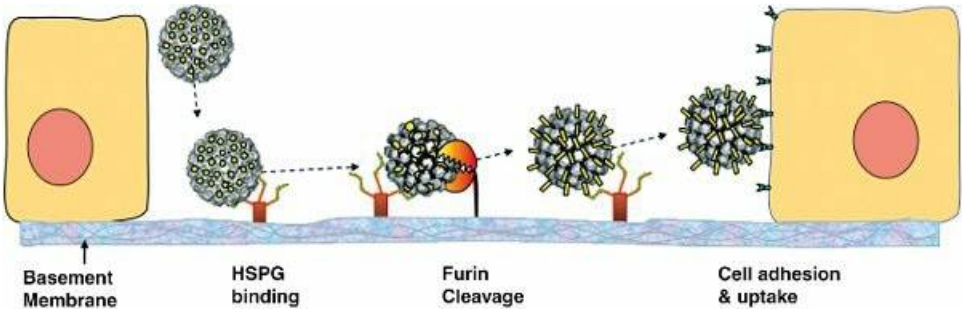

FIGURE 2.6 Model of *in vivo* papillomavirus infection. The virion first binds to HSPGs on the basement membrane exposed after disruption. This induces a conformational change exposing a site on L2 (depicted in *yellow*) susceptible to proprotein convertase (furin or PC5/6) cleavage. After L2 cleavage, an L2 neutralizing epitope is exposed and a previously unexposed region of L1 binds to an unidentified secondary receptor on the invading edge of the epithelial cells.

Virions are internalized by endocytosis, and it was originally thought that low pH in the endosomal pathway caused disassembly of the capsid (Fig. 2.7). Recent findings, however, show that the capsid-bound L2 protein undergoes further conformational changes and translocates across the endosomal membrane, resulting in intact virions enclosed in membrane vesicles.[130] The cytoplasmically exposed portion of L2 interacts with the retromer complex to traffic the viral containing vesicles to the trans-Golgi network (TGN).[61,205]

Entry of the HPV-containing vesicles into the nucleus requires nuclear envelope breakdown during mitosis, rather than active transport through nuclear pores.[208] During mitosis, the virion-containing membrane vesicles bind to condensed host mitotic chromosomes,[61] presumably to retain them in the nucleus until after the nuclear membrane reforms and prevent detection of cytoplasmic viral DNA by innate immune sensors. After cell division, specific nuclear condensates called PML nuclear bodies (PML-NBs) reform in association with the HPV containing vesicles.[101] PML-NBs are commonly hijacked by DNA viruses, and this localization promotes transcription of the HPV genome,[55] even though these structures contain antiviral factors that repress replication and transcription of incoming DNA viruses.[228] Not surprisingly, viruses counteract these repressive factors, and correspondingly HPV L2 displaces Sp100 repressors from the PML-NBs.[87]

Viral Transcription

Animal PV transcription has been studied extensively in a variety of different systems such as BPV1-infected bovine wart tissue, BPV1-infected rodent cells, MmuPV1-infected wart tissue, and SfPV1-induced lesions in cottontail rabbits. Viral transcripts have also been mapped in *Mupapillomavirus* HPVs (HPV1) and *Betapapillomavirus* HPVs (HPV5 and 8). However, best studied are those of the *Alphapapillomavirus* HPVs associated with genital tract lesions such as HPV11, HPV16, HPV18, and HPV31. Transcripts representing all stages of the infectious cycle have been identified in cervical carcinoma cell lines, differentiated organotypic culture systems, infected xenograft tissue in nude mice, and HPV-positive clinical lesions. Transcript maps for all papillomaviruses can be found at (https://pave.niaid.nih.gov/#explore/transcript_maps) (Fig.

2.8).

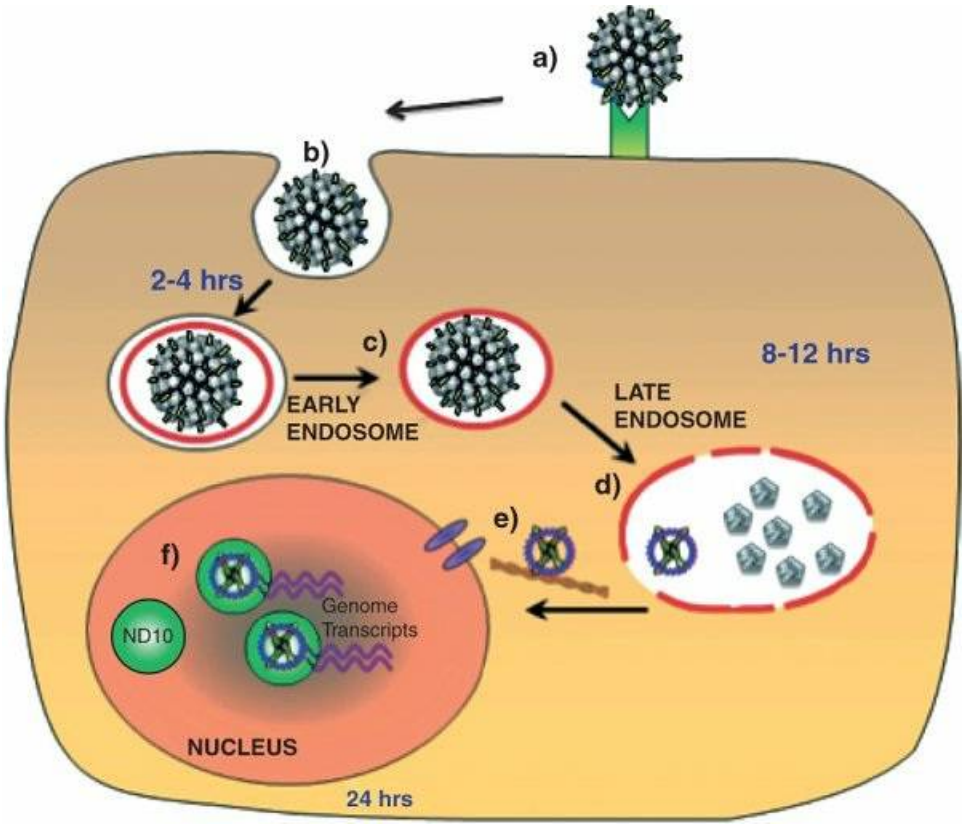

FIGURE 2.7 Infectious process after cell binding. After binding to a cell surface receptor (*a*), the virus enters the cell via an endocytic pathway (*b*) and within 4 hours localizes in the early endosome (*c*). By 12 hours, the virus uncoats within the late endosome and the viral genome complexed with L2 is released (*d*). The L2–genome complex traffics through the cytoplasm, perhaps via microtubules, and enters the nucleus by 24 hours (*e*). After nuclear entry, the complex colocalizes with ND10 and viral genome transcription begins (*f*).

Viral RNAs and Promoters

Papillomavirus transcription is complex due to the presence of multiple promoters, alternate and multiple splice patterns, and the temporal synthesis of different mRNA species in differentiated cells (reviewed in Ref.[99]). In the oncogenic *Alphapapillomavirus* HPVs, transcription occurs in early, intermediate, and late phases, each dependent on the differentiation stage of the host keratinocyte. Early transcription occurs in the lower layers of a papilloma, intermediate transcription coincides with productive DNA replication, and late transcription generates the capsid proteins. A transcription map of an HPV is shown in Figure 2.8 and additional transcript maps for other PVs can be found at http://pave.niaid.nih.gov/#explore/transcript_maps.

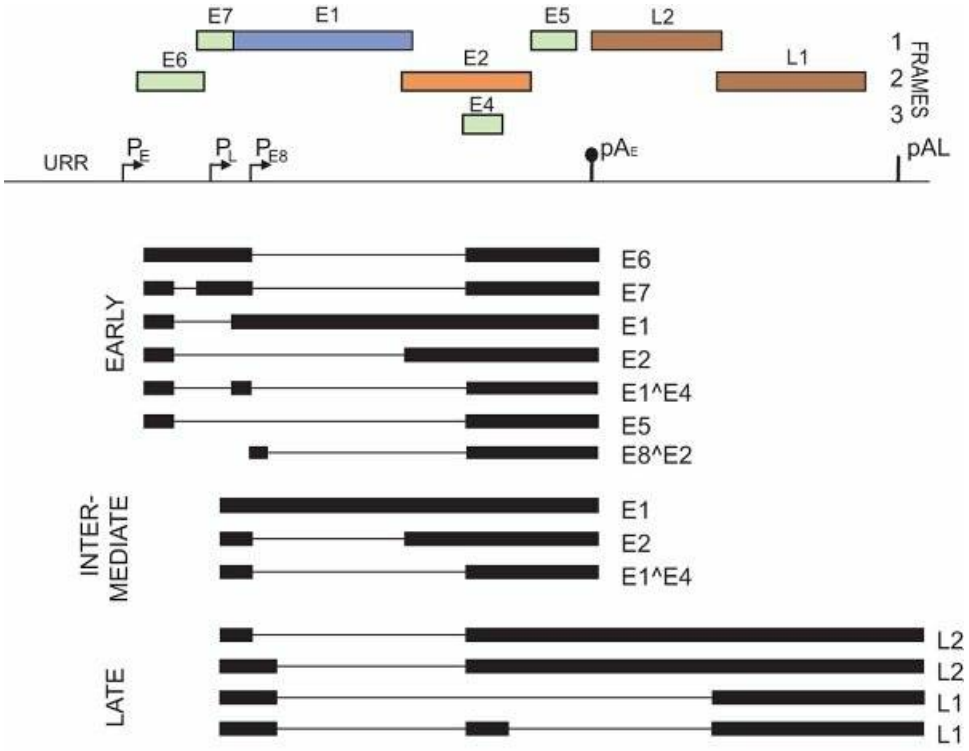

FIGURE 2.8 Transcription map of an oncogenic *Alphapapillomavirus* HPV. A linearized version of the viral genome is shown at the top. There are three phases of transcription depending on the differentiation status of the infected cells: Early transcripts use the early promoter (P_E) and polyadenylation site (pA_E); Intermediate transcripts use the late promoter (P_L) and early polyadenylation site (pA_E); and late transcripts use the late promoter and polyadenylation sites (P_L and pA_L).

The oncogenic *Alphapapillomavirus* HPV genomes contain three promoters, P_E (early), P_{E8} (expresses the E8^E2 repressor), and P_L (late) as well as two polyadenylation sites, A_E (early) and A_L (late).[126] Multiple alternatively spliced early transcripts initiate from P_E and terminate at A_E; these express E6 and E7 as well as other early gene products. P_E is active immediately after infection whereas P_{E8} activity is delayed for several days, suggesting that E8^E2 expression might be important for maintaining low-level early transcription.[20] In the mid-layers of a papilloma, the late promoter, P_L, is activated but still uses the early polyadenylation site. This generates a series of intermediate transcripts that express high levels of E1, E2, and E4 to promote viral genome amplification.[126] At later stages of differentiation, the late promoter transcribes mRNAs that use the late polyadenylation site and encode the L1 and L2 capsid proteins.[126] Figure 2.5 shows these stages in a cutaneous papilloma.

There is an important difference in the structure and expression of the E6 and E7 mRNAs encoded by the “high-risk” and “low-risk” *Alphapapillomavirus* HPV types. The high-risk HPVs, such as HPV16 and HPV18, use a single promoter to synthesize alternatively spliced mRNAs that express E6, or E6*, and E7 proteins (Figs. 2.4 and 2.8). The E6-encoding mRNA is not able to synthesize E7 since there is insufficient spacing for translation reinitiation. The

spliced E6* mRNA introduces a stop codon that allows reinitiation and translation of the E7 ORF. In contrast, the E6 and E7 genes of the low-risk HPVs such as HPV6 and HPV11 are expressed from two independent promoters.[241]

Regulation of Transcription (Cis Elements)

The URR (also known as LCR or NCR) of PVs contains enhancer elements that are responsive to cellular factors as well as to virally encoded transcriptional regulators. Each viral URR contains constitutive enhancer elements that determine tissue or cell type specificity. These constitutive enhancer elements play an important role in the initial expression of the viral genes after viral infection and may also be important for tissue tropism and maintenance of viral latency. A number of transcription factor binding sites have been identified in the URRs of multiple PVs, such as AP1, SP1, Oct-1, and YY1 (reviewed in Ref.[18]). In addition to the binding sites for cellular transcription factors, the URR contains binding sites for the virally encoded E2 proteins as well as the origin of DNA replication that contains binding sites for the E1 and E2 proteins.

E2 Regulatory Proteins

The papillomavirus E2 proteins regulate viral transcription and DNA replication and support long-term plasmid maintenance. E2 was first described as a transcriptional activator[244] capable of activating viral transcription through E2 responsive elements located within the viral genome. All E2 proteins contain two conserved domains: an N-terminal transactivation domain and a C-terminal sequence-specific DNA-binding and dimerization domain (reviewed in Ref.[168]). These domains are linked by a hinge region that is not well conserved in length or amino acid composition among different papillomaviruses. The dimeric E2 proteins bind the consensus sequence, $ACCN_6GGT$,[6,153] and regulate transcription from promoters containing E2 binding sites (reviewed in Ref.[168]).

The structure of the dimeric DNA-binding domain of E2 has been solved for many papillomaviruses and forms a previously unobserved DNA-binding fold of a dimeric antiparallel β barrel.[110] The structure of the N-terminal transactivation domain has also been solved for several PVs (https://pave.niaid.nih.gov/#explore/proteins/protein_structure_viewer/table_of_available_protein It forms a cashew-shaped structure; the N-terminal portion consists of three antiparallel alpha-helices and is joined to a C-terminal antiparallel β-sheet structure by a region called the fulcrum[9] as shown in Figure 2.9.

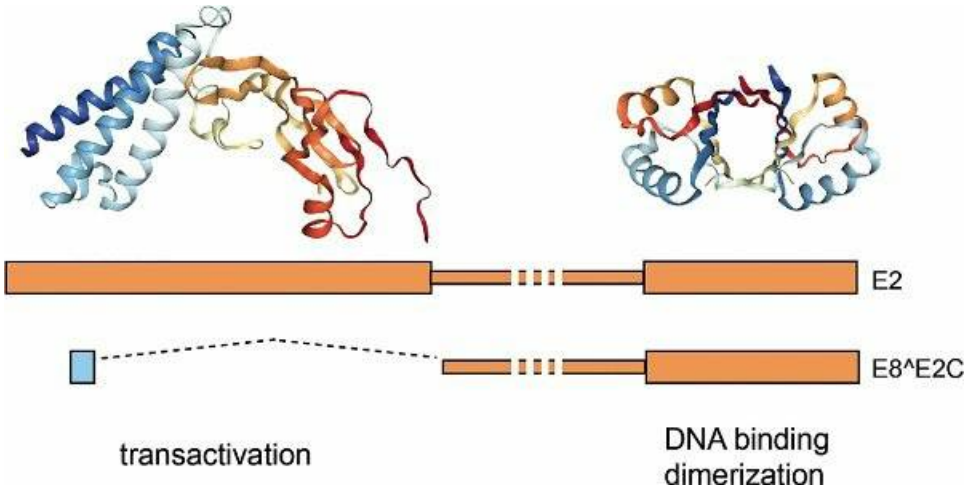

FIGURE 2.9 Structure of the E2 proteins. The structures of the HPV E2 and E8^E2 proteins are shown. The N-terminal transactivation domain is approximately 200 amino acids and is only present in the full-length form of E2 (HPV16 structure shown from 1DTO[9]).The C-terminal DNA-binding and dimerization domain is approximately 100 amino acids (HPV16 structure is shown Ref.[110]). These conserved domains are linked by a less well-conserved hinge of variable length and sequence.

In addition to the full-length E2 protein, all PVs encode a shorter repressor E2 protein named E8^E2 (reviewed in Refs.[69,168]). E8^E2 consists of a few amino acids encoded by the E8 ORF (overlaps E1) fused to the hinge and C-terminal domain of E2 (Fig. 2.9). These proteins antagonize both the replication and transcriptional regulatory functions by competing for DNA-binding sites and by forming inactive heterodimers with the full-length transactivator protein. E8^E2 proteins also recruit cellular corepressor complexes such as NCoR and SMRT.[68,207] The repressor functions of E8^E2 are important for maintaining low-level DNA replication and transcription as viruses that are mutated to eliminate E8^E2 expression spontaneously replicate to high copy number and synthesize high levels of viral DNA.[69] Some PVs, such as BPV1, encode two E2 repressor proteins, E2-TR and E8^E2.[69]

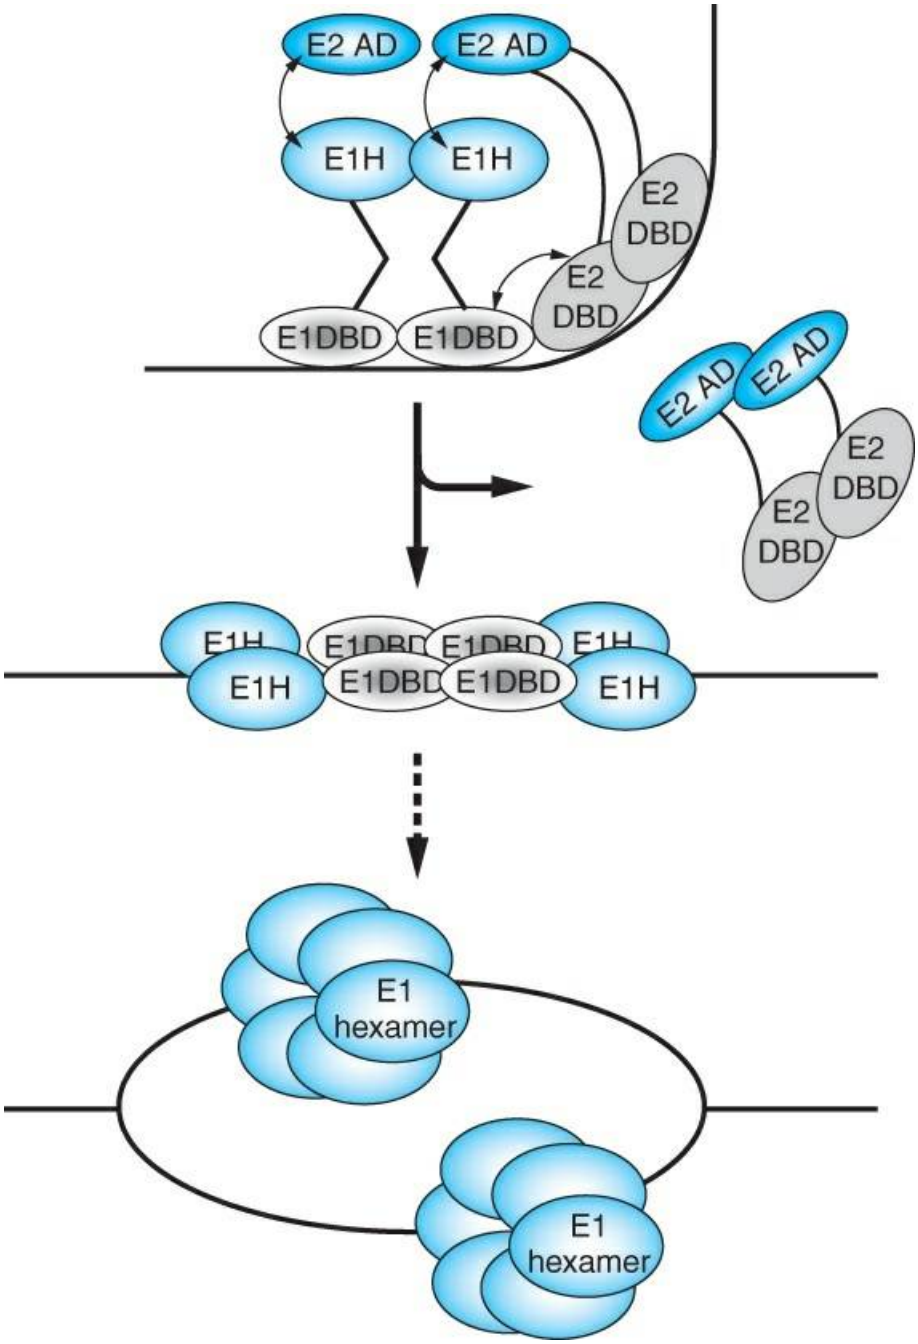

FIGURE 2.10 Proposed pathway for the assembly of an initiation-competent complex at the BPV origin of DNA replication. The E1 initiator binds cooperatively with E2 to the ori forming a specific $E1_2E2_2$–DNA complex. As a consequence of the interaction between the E1 and E2 DNA binding domains (DBDs), a sharp bend is induced in the ori DNA. The bend promotes the interaction between the E1 helicase domain (E1H) and the E2 transactivation domain (E2AD). The resulting highly sequence-specific complex serves to recognize the ori. In a reaction requiring ATP hydrolysis, E2 is displaced and additional E1 molecules are added to the complex, resulting in the formation of a complex where four molecules of E1 are bound to the ori. This complex can distort the DNA duplex and give rise to partially single stranded

regions. Subsequently, additional E1 molecules are added. In a final step, E1 is assembled onto the exposed single strands forming a hexameric ring-like structure that constitutes the replicative helicase. This figure was graciously provided by Arne Stenlund and represents a modified version of a published figure.[79]

Full-length E2 proteins both activate and repress viral transcription, and this depends on the position of the cognate DNA-binding sites with respect to other promoter and enhancer elements. In the high-risk *Alphapapillomavirus* HPVs, there are four E2-binding sites in the URR that mediate this regulation (Fig. 2.4). The binding of *Alphapapillomavirus* HPV E2 to binding sites adjacent to the major early promoter results in its down-regulation.[259] Notably, this repression requires factors that interact with the transactivation domain of the full-length E2 protein, such as the Brd4 protein,[240,293] as well as the histone demethylase SMCX and components of the TIP60 complex including EP400.[240]

The interaction of E2 with Brd4 is also required for the transcriptional activation function of all PV E2 proteins.[120] Brd4 is a member of the BET family, proteins containing two bromodomains and one extra-terminal (ET) domain; the bromodomains bind acetylated lysines in histones and regulate transcriptional initiation and elongation.[63] Two highly conserved amino acid residues in the E2 transactivation domain interact with Brd4 and are required for E2 transactivation.

In addition to its role as a transcriptional regulator, E2 has critical roles in the initiation of viral DNA replication and long-term extrachromosomal maintenance of viral genomes within replicating cells, and this is described in detail below. The multiple functions of E2 are mediated by interactions with specific cellular factors, the best studied of which are listed in Table 2.1.

The late promoter (located in the E7 ORF in high-risk *Alphapapillomavirus* HPVs) is activated in early differentiating cells to generate transcripts that express high levels of E1^E4 and the E1 and E2 replication proteins. The late promoter is regulated by cellular activators and repressors that are modulated during keratinocyte differentiation.[39,291] Transcriptional elongation factors such as Brd4 provide further regulation of the late promoter.[243] The viral minichromosome contains a chromatin loop, mediated by CTCF and YY1, that suppresses viral enhancer activity.[197] Differentiation-dependent down-regulation of YY1 disrupts this loop and relieves suppression of the enhancer.[197]

Activation of late viral transcription occurs in terminally differentiated keratinocytes to express mRNA encoding the capsid proteins.[126] In fact, regulation of read-through of the early polyadenylation site constitutes the major switch from early to late gene expression.[126] True late mRNAs initiate at P_L and terminate at the late polyadenylation site, A_L. Late HPV mRNAs contain negative regulatory elements that reduce mRNA stability and inhibit RNA processing in undifferentiated cells (reviewed in Ref.[99]), and keratinocyte differentiation reduces levels of repressor proteins that bind these elements.

Virion Assembly and Release

Virion assembly takes place in the nuclei of terminally differentiated keratinocytes after vegetative viral genome amplification and expression of the capsid proteins.[64] *In vitro*, the L1 protein can self-assemble into VLPs, but L2 enhances packaging of viral DNA.[136,300] The viral genome does not require a sequence-specific packaging signal[34] and is assembled with host histones into a chromatinized minichromosome.[81] The capsids are further stabilized by the formation of disulfide bonds between conserved cysteines on adjacent L1 monomers induced by the oxidizing environment in the upper layers of a terminally differentiated squamous epithelium.[50] PVs are not cytolytic, and virions are released in squames that slough off the surface of the epithelium. E4-mediated collapse of cytokeratin filaments in these terminally differentiated cells might assist in virion release.[65]

Viral DNA Replication

The differentiation-dependent PV life cycle requires different modes of viral DNA replication at different stages (reviewed in Ref.[169]). Following infection of a basal keratinocyte, there is a limited amplification of the viral genome, which then becomes established as a stable, low copy plasmid. The viral genomes are maintained at a constant copy number in dividing cells and replicate on average once per cell cycle during S phase, in synchrony with host DNA replication.[96] This ensures persistent infection in the basal cells of the epidermis. Vegetative DNA replication occurs in the more differentiated cells of the infected epithelium. Such differentiated cells have exited the cell cycle and are no longer capable of supporting cellular DNA synthesis. Therefore, the virus activates the DNA damage response and uses DNA repair machinery to support vegetative viral DNA synthesis producing the genomes to be packaged into progeny virions.[179]

Origin of DNA Replication

Papillomavirus DNA replication requires the origin of DNA replication in cis and the viral E1 and E2 proteins in trans. The minimal origin of DNA replication contains an A/T rich region, an E1 binding site, and an E2 binding site.[269] E1 is an ATP-dependent helicase that binds and unwinds DNA at the replication origin.[80] E2 is a helicase loader that binds to E1 and facilitates binding of an E1–E2 complex to the replication origin.[247]

The E1 Protein

The E1 protein is well conserved among the PVs and is an origin-binding, ATP-dependent helicase. E1 contains four domains: an N-terminal regulatory domain, an origin DNA-binding domain, an oligomerization domain, and a helicase/ATPase domain and a C-terminal tail.[17,80] E1 binds to its cognate site in the origin with weak affinity; however, this binding is enhanced through its interaction with E2, which binds to adjacent DNA-binding motifs.[178,269] In addition to its interaction with E2, E1 has been shown to bind a number of cellular proteins such as Replication Protein A (RPA), DNA polymerase α-primase and DNA topoisomerase I (topo I) and thereby recruits the cellular DNA replication initiation machinery to the viral replication origin (reviewed in Ref.[17]). After the E1/E2 complex binds the origin, E2 is displaced, and E1 ultimately forms a double hexameric structure that bidirectionally unwinds DNA (Fig. 2-10). The expression and intracellular localization of E1 is tightly regulated in dividing cells. The N-terminal domain contains nucleo–cytoplasmic shuttling elements that are regulated by phosphorylation to ensure that E1 localizes to the nucleus in a cell cycle–dependent manner (reviewed in Ref.[17]).

E2 Protein Replication Functions

E2 serves as an auxiliary factor that fosters the assembly of the preinitiation complex at the origin, but E2 itself plays no intrinsic role in viral DNA replication. E2 cooperatively binds with E1 to the replication origin (reviewed in Ref.[168]) and interacts with many cellular factors that can support and promote viral DNA replication (see Table 2.1).

Plasmid Maintenance Replication

E2 plays a critical role in viral DNA replication by supporting long-term maintenance of extrachromosomal viral genomes. This was first defined for BPV1, where it was shown that genome maintenance requires, in addition to the replication origin, a minichromosome maintenance element from the URR containing multiple E2-binding sites.[203] Both the E2 protein and viral genomes are observed in association with host mitotic chromosomes, leading to the model that E2 facilitates viral genome partitioning by interacting simultaneously with condensed mitotic chromatin and the viral genomes, thereby ensuring that viral genomes are contained within the nuclear envelope when it reforms during telophase.[121,238] The cellular protein Brd4 mediates the association of BPV1 E2 with mitotic chromosomes. The TA domain of BPV1 E2 associates with mitotic chromosomes and mutations that abrogate Brd4 binding also disrupt the tethering of E2 and viral genomes.[2,13,295] Brd4 may also be the tethering factor for some other PVs. Binding of E2 to Brd4 is conserved among all the papillomaviruses and plays an important

role in the transcriptional activity of E2.[123,230,295]

Additional cellular factors are likely to be involved in E2-mediated tethering to mitotic chromosomes and PV genome maintenance. For instance, ChlR1 has been shown to be important for loading E2 onto mitotic chromosomes.[191] Also, the E2 proteins of some *Alphapapillomavirus* HPV types have been observed in association with the mitotic spindle rather than the chromosomes.[275] Finally, some E2 proteins bind at the ribosomal DNA loci on the short arm of acrocentric chromosomes.[189,204] Thus, the precise mechanism that ensure the stable maintenance of HPV genomes in host cells is still unresolved and will be a fruitful area for additional studies (reviewed in Ref.[51]).

Vegetative Viral DNA Replication

Vegetative replication of papillomavirus occurs only in the infected terminally differentiated keratinocytes and generates progeny genomes destined to be packaged in virions. These differentiated cells are no longer in S phase and need an alternative mode to synthesize DNA. Therefore, the virus expresses high levels of E1 and E2 and induces a DNA damage response that recruits numerous replication and repair factors to viral replication foci in the nucleus of infected cells.[88,179,221] There is evidence that replication switches from a bidirectional theta mode to a rolling circle, or recombination-directed replication mode late in infection.[86,220]

VIRAL TRANSFORMATION

BPV1 Transformation

Certain papillomaviruses are capable of inducing cellular transformation in tissue culture. The best studied of the transforming papillomaviruses is BPV1. Morphologic transformation in tissue culture was first described for BPV in the early 1960's.[21,23,262] In the late 1970's, a focus assay was developed using established cell lines to study BPV1 transformation.[74] In general, investigators have relied upon mouse C127 cells and NIH 3T3 cells for these transformation studies, although a variety of other rodent cells, including hamster and rat cells, are susceptible to BPV1-mediated transformation. Transformation of mouse C127 cells by BPV1 causes alterations in morphology, loss of contact inhibition, anchorage independence, and tumorigenicity in nude mice.[74]

One notable characteristic of BPV1-transformed rodent cells is that the viral DNA is maintained as a stable multicopy plasmid.[150] Integration of the viral genome is not required for either the initiation or maintenance of the transformed state. However, transformation is dependent upon the continued expression of viral genes as evidenced by the loss of the transformed phenotype in mouse cells that have been "cured" of the viral DNA by treatment with interferon.[268] Genetic studies mapped the BPV1 transforming genes to E5, E6, and E7.

BPV1 E5

The E5 gene is the major transforming gene of BPV1 in transformed cells. E5 encodes a small (44 amino acid) integral membrane protein that is sufficient for the transformation of certain established rodent cells in culture. E5 is highly conserved among the group of papillomaviruses that induce fibropapillomas in their natural host and have the capacity to induce fibroblastic tumors in hamsters. The E5 gene is believed to be responsible for the proliferation of dermal fibroblasts in fibropapillomas.

The E5 protein does not possess intrinsic enzymatic activity, and functions by altering the activity of cellular membrane proteins involved in proliferation. The first evidence that BPV1 E5 could activate growth factor receptors came from experiments that showed that E5 could cooperate with exogenously introduced EGF receptor or CSF1 receptor in the transformation of NIH3T3 cells.[163] Subsequent studies established the β-receptor for the platelet derived growth factor (PDGF) as the endogenous target for the BPV1 E5 protein in fibroblasts.[62,198] E5 activates the PDGF β receptor and transforms cells in a ligand-independent manner.[198,199] The mechanism of E5 activation of the PDGF β receptor involves complex formation with the receptor, thereby inducing receptor dimerization, trans-phosphorylation of tyrosine residues in the cytoplasmic domain of the receptor, and recruitment of cellular SH2 domain–containing proteins into a signal transduction complex.[62] Two transmembrane dimers of E5 clamp the PDGF β receptor in an active dimeric conformation.[132]

BPV1 E5 has also been shown to form a complex with the 16 kDa transmembrane channel-forming subunit of the vacuolar H^+-ATPase,[98] an abundant cellular protein located in the membranes of intracytoplasmic membranes and plasma membranes. Golgi acidification has been found to be impaired in cells transformed by the BPV1 E5 protein, due to the inhibition of the vacuolar H^+-ATPase.[223] It has not yet been shown directly that Golgi alkalinization plays a role in cellular transformation, but there is a good genetic correlation between the ability of specific E5 mutants to transform cells and Golgi alkalization.[223] Since many important growth regulatory proteins, including the PDGF β-receptor, transit through the Golgi apparatus, it is possible that the ability of E5 to perturb the pH of intracellular organelles might affect the activity of some of these proteins and in so doing, contribute to the transformed phenotype. It is additionally possible that the BPV1-mediated Golgi alkalinization may affect cellular functions unrelated to transformation that are important in the life cycle of the virus.

BPV1 E6

The BPV1 E6 and E7 genes also encode proteins with transforming activities. In mouse cells, the full transformed phenotype requires the expression of the E6 and E7 genes as well as E5.[184] The E6 and E7 genes of all the papillomaviruses encode proteins with conserved structural motifs. They contain domains of almost identically spaced CYS-X-X-CYS motifs (four in E6 and two in the carboxy-terminal portion of E7), that are involved in binding zinc.

No intrinsic enzymatic activities have been identified for BPV1 E6, and, like the oncogenic HPV E6 proteins, it likely functions through binding cellular targets. Several different cellular proteins have been found to interact with BPV1 E6 but the physiologic significance of a number of these putative cellular interacting proteins has not been established and may represent artifacts due to overexpression. There is, however, a good correlation between the transforming activities of BPV1 E6 and the binding to the focal adhesion protein paxillin.[265,276] This binding has also been shown to correlate with the disruption of the cellular actin cytoskeleton, a characteristic of

transformed cells.[266] E6 binds to charged leucine motifs in paxillin known as LD motifs and in doing so competes with the ability of paxillin to bind to vinculin and the focal adhesion kinase.[266,276] Another cellular target of BPV1 E6 revealed by systematic proteomic studies is Mastermind-like 1 (MAML1).[32,217,256] MAML1 is a core component of the transcriptional activation complex that mediates the effects of the canonical Notch signaling pathway.[292] BPV1 as well as the *Betapapillomavirus* HPV E6 proteins repress Notch transcriptional activation, and this repression is dependent on an interaction with MAML1. Furthermore, the expression levels of endogenous Notch target genes are repressed by E6 proteins[256] interfering with keratinocyte differentiation.[175]

BPV1 E7

The E7 gene encodes a 127 amino acid zinc-binding protein that potentates the transforming activities of other BPV1 oncogenes. By itself, BPV1 E7 does not induce focus formation or anchorage independence, but enhances the transformation activity of BPV1 E5 and BPV1 E6.[22] When BPV1 E7 is coexpressed with either E5 or E6, it synergizes with these oncogenes to boost transformation efficiency four- to tenfold. Unlike the HPV E7 proteins, BPV1 E7 does not contain an LxCxE motif for binding the retinoblastoma tumor suppressor gene product (pRB), and it does not share the property of pRB binding and inactivation with the HPV E7 proteins.

BPV1 E7 binds the N-end rule E3 ligase UBR4 (initially referred to as p600),[59] and subsequently E7 binding to UBR4 was shown to be a characteristic of all the human HPVs.[286] For BPV1, the interaction between UBR4 and E7 correlates with the ability of E7 to enhance E6-mediated transformation.[58] BPV1 E7, similar to the HPV E7 proteins, also binds the nonreceptor protein tyrosine phosphatase PTPN14.[285] Similar to the HPV E7 proteins, BPV1 E7 causes the degradation of PTPN14, a process that is mediated by UBR-4.[285] This process and the cellular consequences are discussed below under the HPV E7 proteins.

HPV Immortalization and Transformation

The HPV16 and HPV18 genomes are not efficient at inducing transformation of established rodent cells; however, immortalization assays employing primary rodent cells, primary human fibroblast, and/or primary human keratinocytes have provided assays for studying their immortalization/transformation functions. In such assays, the high-risk HPVs, such as HPV16 and HPV18, are positive for immortalization or transformation, whereas the low-risk viruses, such as HPV6 and HPV11, are not.[229,249] These assays permitted the mapping of the E6 and E7 as viral oncogenes for the high-risk HPV types.

HPV E6

The HPV E6 proteins are approximately 150 amino acids in size and contain four Cys-X-X-Cys motifs that are involved in binding zinc. The first transforming activity identified for the high-risk alpha genus HPV E6 proteins (such as HPVs 16 and 18) was the ability to complement E7 in the immortalization of human keratinocytes.[109,182] This activity is explained at least in part by its ability to complex p53,[283] a property not possessed by the low-risk alpha genus HPV E6 proteins. The protein levels of p53 are generally quite low in HPV positive carcinoma cell lines

and in cells immortalized by the HPV oncoproteins,[225] since high-risk HPV E6 proteins promote the ubiquitin-dependent degradation of p53.[227] Indeed the half-life of p53 is dramatically decreased in E6-expressing cells, and E6 dampens the p53 response when cells are challenged with genotoxic agents.[114,225] In targeting p53, the high-risk HPV E6 proteins inhibit DNA damage and oncogene-mediated cell death signals.[78,129,133]

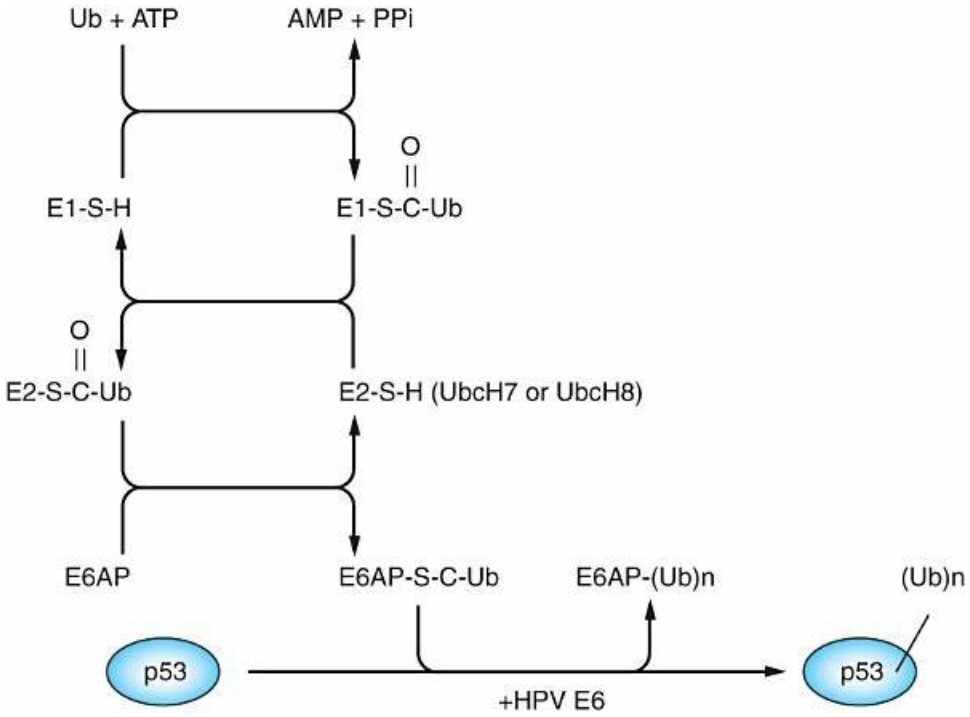

FIGURE 2.11 A ubiquitin thiolester cascade model for the HPV E6-dependent ubiquitination of p53. The E6 protein binds to the cellular protein E6-AP, and the complex together functions as an E3 (ubiquitin protein ligase) in facilitating the ubiquitination of p53.[224] The ubiquitination of a protein involves three cellular activities: E1 (ubiquitin activating enzyme), E2 (ubiquitin conjugating enzyme), and E3 (ubiquitin protein ligase). Ubiquitin is activated in an ATP-dependent manner and forms a high-energy thiolester with E1, which can then be transferred to the E2 through a thiolester linkage. Ubiquitin can then be transferred to a cysteine within the Hect domain of E6AP, again as a thiolester linkage,[226] through the direct binding of E6AP with UbcH7 or UbcH8.[148] In conjunction with HPV16 E6, E6AP then recognizes p53 and catalyses the formation of an isopeptide bond between the carboxy-terminal glycine of ubiquitin and a lysine side chain of p53.

HPV16 E6 induces p53 degradation by forming a complex with the cellular ubiquitin–protein ligase E6AP,[117,118] which is then able to bind and ubiquitylate p53 (Fig. 2.11).[224] E6AP is the founding member of a class of ubiquitin–protein ligases called HECT E3 proteins, which directly transfer ubiquitin to their substrates.[226] The catalytic domain of HECT proteins is a conserved 350 amino acid region defined by its *h*omology to the *E*6AP *c*arboxy *t*erminus

(HECT).[116] The HECT domain binds to specific E2 enzymes and contains an active site cysteine residue that forms a thiolester bond with ubiquitin.[116,226] Structure studies have determined that the HECT domain is a bilobed structure, with a larger N-terminal lobe that interacts with the ubiquitin-conjugating enzyme, and a smaller C-terminal lobe containing the catalytic cysteine residue.[113]

Levels of p53 in E6 immortalized cells or in HPV-positive cervical carcinoma cells are, on average, two to three fold lower compared to primary cells.[225] In normal, non–HPV expressing cells, intracellular p53 levels increase significantly in response to DNA damage or genotoxic stress. Expression of the high-risk E7 proteins and their engagement of the pRB family of proteins causes a replication stress resulting in an increase in p53 protein levels within cells, which in turn transcriptionally activates the expression of cell cycle arrest genes and proapoptotic genes.[1,129] E7 also creates a signal that increases p53 levels by up-regulating expression of the long noncoding RNA DINO.[233] Higher levels of p53 can result in a G_1 growth arrest or apoptosis, as part of a cell defense mechanism that allows for either the repair of the DNA damage prior to the initiation of a new round of DNA replication or cell death. E6-expressing cells however do not manifest a p53-mediated cellular response to DNA damage,[133] indicating the ability of E6 to promote the degradation of p53 and prevent the p53 level to rise above a certain threshold level (Fig. 2.12). Under DNA-damaging conditions, the E6-stimulated degradation of p53 abrogates the negative growth regulatory effects of p53 and as such contributes to genomic instability. E6 hijacks E6AP to form a ternary complex with p53. E6AP does not normally regulate p53 protein stability in non–E6 expressing cells. Mdm2 is the major E3 ubiquitin ligase responsible for p53 degradation in the absence of E6.[108,145]

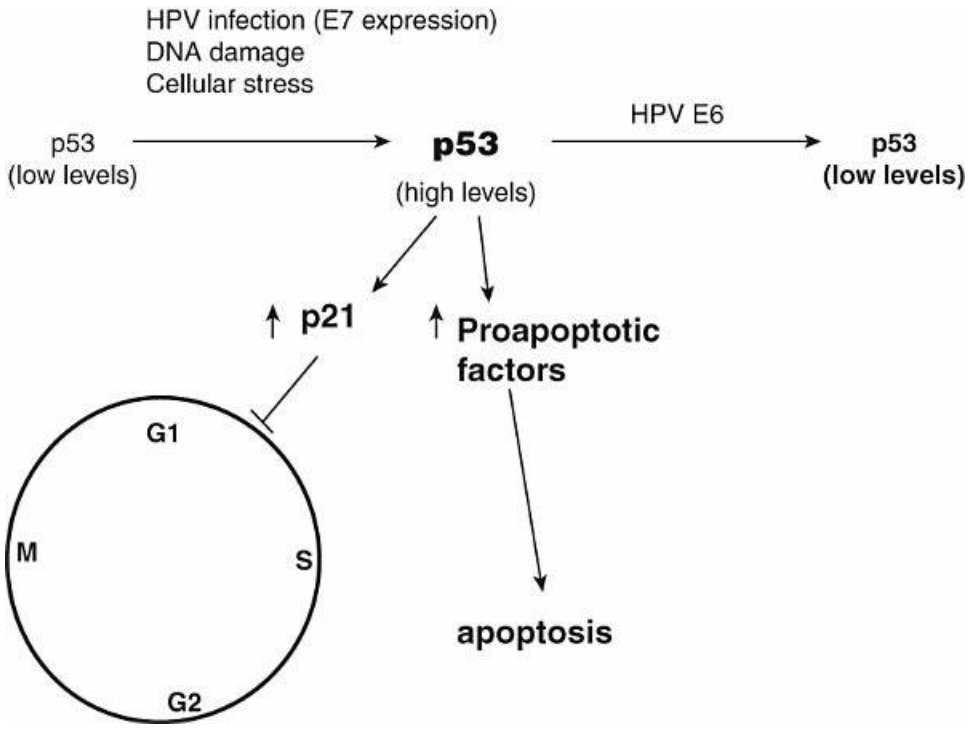

FIGURE 2.12 The level of p53 in primary cells is generally low. DNA damaging agents, viral infection, and expression of E7 increase the level of p53. Elevated levels

of p53 can lead to either apoptosis or a cell cycle checkpoint arrest in G1 through the transcriptional activation of proapoptotic genes or $p21^{cip1}$. Viral oncoproteins may interfere with this negative growth regulatory function of p53, either by sequestering p53 into a stable, but nonfunctional complex (such as with SV40 TAg or the Ad5 55 kDa E1B protein) or by ubiquitylation and enhanced proteolysis as observed with the high-risk HPV E6 proteins.

The E6AP protein is encoded by the UBE3A gene that is located in an imprinted region on chromosome 15q11-q13, and it has been linked to Angelman syndrome, a neurogenetic disorder characterized by severe mental retardation, ataxia, loss of speech, seizures, and other abnormalities.[137,167] An increase in UBE3A gene dosage has also been linked to autism spectrum disorders.[187] Although a number of E6AP interacting proteins and potential substrates, including RAD23A, UBQLN1/2, and the estrogen receptor have been described, the physiological relevance of some of these E6AP interactions is often uncertain.[140,149,152] E6AP is a component of a number of cellular complexes, including the proteasome and a 2MDa HUN complex that contains Herc2 and Neurl4.[164] E6 is recruited to each of these complexes by E6AP.

The crystal structure of the E6 protein bound to the 12-amino acid alpha helical LxxLL containing peptide of E6AP and the DNA binding domain of p53 was solved.[165] The binding of E6 to E6AP activates its E3 ligase activity and induces E6AP self-ubiquitylation.[131,257] The binding of E6 to E6AP causes a conformational change positioning E6 and p53 in the immediate vicinity of the catalytic center of E6AP.[219]

E6 encodes a number of p53-independent functions that are relevant to cellular transformation and immortalization. There are HPV16 E6 mutations that separate p53 degradation from cellular immortalization,[138,156] and it is possible that some of these p53-independent activities are still mediated by E6AP. One such function is its ability to activate telomerase in keratinocytes[141] through the transcriptional up-regulation of the rate-limiting catalytic subunit of human telomerase (hTERT).[138,188,277] Maintenance of telomere length is an important step in cellular immortalization and transformation, which occurs either through the transcriptional activation of hTERT expression or through the activation of the ALT recombination pathway. The mechanism of hTERT promoter activation by E6 is complex and controversial. Some studies have implicated c-Myc binding and activating the hTert promoter, and others show the E6AP-dependent degradation of the NFX1-91 transcriptional repressor of the hTERT promoter.[94,95] Interactions of E6 with E6AP as well as c-Myc have been shown to be important in the transcriptional activation of the hTERT promoter.[154,155,278,294]

Of note, the high-risk E6 oncoproteins contain a X-(S/T)-X-(V/I/L)-COOH motif at the extreme C-terminus that mediates binding with cellular PDZ domain–containing proteins. This PDZ binding motif (PBM) is unique in the high-risk HPV E6 proteins and is not present in the E6 proteins of the low-risk alpha genus HPV types. Although E6 could serve as a molecular bridge between these PDZ domain proteins and E6AP, facilitating their ubiquitylation and mediating their proteolysis, there is some evidence that the degradation of the PDZ domain–containing proteins may be E6AP independent.[166] Among the PDZ domain proteins implicated as E6 targets are hDlg, the human homologue of the Drosophila melanogaster Discs large tumor suppressor, and hScrib, the human homologue of the Drosophila Scribble tumor suppressor.[90,183]

Additional PDZ domain proteins shown to be capable of binding to E6 are MAGI-1, MAGI-2, MAGI-3, MUPP1, and TIP-2/GIPC.[82,97,151,263] Several of the PDZ–containing proteins have been shown to be involved in negatively regulating cellular proliferation. Therefore, some of the p53-independent transforming activities of the high-risk E6 oncoproteins may be linked to their ability to bind and degrade some of these PDZ motif–containing proteins.[139,185]

Other activities of the hrHPV E6 proteins include the induction of genomic instability,[210,284] the maintenance of stable episomal replication during the viral life cycle,[194] and the immortalization of human mammary epithelial cells.[11,232] E6 has also been shown to up-regulate the expression of the innate immune DNA cytosine deaminase APOBEC3B.[279] The up-regulation of APOBEC3B is likely a significant source of genomic mutagenesis observed in multiple human cancers, including HPV-associated cancers. Recently, DNA damage response pathways have been shown to directly signal to the E6 PBM, resulting in Chk1- and Chk2-driven phosphorylation that can result in the enhanced ability of E6 to inhibit p53 transcriptional activity,[258] thus providing a link between the PBM and E6 regulation of p53 functions.

HPV16 E6 has also been reported to bind the transcriptional coactivator p300/CBP, a target also of Ad E1A and SV40 large T-antigen.[196,301] This interaction is limited to E6 proteins of high-risk HPVs associated with cervical cancer that have the capacity to repress p53-dependent transcription. The repression of p53 transcriptional activity by targeting the p53 coactivator CBP/p300 provides a second mechanism by which p53 can be inhibited. A subsequent study has shown that *in vitro*, E6 can inhibit p300-mediated acetylation on p53 and nucleosomal core histones.[264] A variety of other E6 cellular targets have been identified (Table **2.2**); however, the physiologic relevance to the life cycle of the virus or to transformation or immortalization functions has not yet been elucidated for some of these interactions. Other p53-independent activities for the alpha genus HPV E6 proteins have been described in the literature, including the activation of cap-dependent translation.[245] Some recent reviews of HPV E6 will provide further details of these interactions.[104,111,281]

TABLE 2.2 Cellular targets of the papillomavirus E6 oncoproteins

E6-associated protein (E6AP) (alpha genus HPVs)	Ubiquitylation of associated proteins Ubiquitylation of E6	[224] [131]
MAML1 (beta genus HPVs)	Repress Notch transcription and signaling	[32,217,254]
p53	E6AP-dependent ubiquitylation and proteolysis	[227,283]
E6BP (Erc55)	Unknown	[43]
Paxillin	Disruption of the actin cytoskeleton	[246,276]
PDZ domain–containing proteins: HDlg, MUPP1, and hScrib (HR HPVs only)	E6AP-dependent ubiquitination and proteolysis	[90,151,183]
NHERF1	Degradation with activation of Wnt/β-catenin signaling	[70]
IRF-3	Inhibition of β-interferon induction	[213]
Clathrin adaptor complex AP-1	Unknown	[245]
Bak	Inhibition of Bak-induced apoptosis	[261]
CBP/p300	Inhibition of p53 transcriptional activity	[196,301]
Myc	Activation of cellular telomerase	[155]
NFX1-91	Activation of cellular telomerase	[94,95]
USP15	Stabilization of E6 Innate immune signaling	[280] [47]
USP46	Stabilization of Cdt2	[135]
ADA3	Transcriptional regulation	[146]
FADD/Caspase 8	Block apoptosis	[84,91]

Most studies thus far on the molecular biology of the HPV E6 proteins have been on the alpha genus high-risk HPV types. Studies of the cutaneous HPVs are more limited, and less is known about the cellular activities of the cutaneous HPVs of the beta genus. Recently, the beta HPV E6 types as well as BPV1 E6 have been shown to bind Mastermind-like 1 (MAML1) and other members of the Notch transcription complex.[32,217,256] MAML1 and E6AP each complex E6 through LXXLL motifs, and the binding of MAML1 and E6AP to the various PV E6 proteins is mutually exclusive.[31,256] MAML1 is a core component of the transcriptional activation complex that mediates the effects of the canonical Notch signaling pathway. BPV1 and *Betapapillomavirus* HPV E6 repress Notch transcriptional activation, and this repression is dependent on an interaction with MAML1. Furthermore, the expression levels of endogenous Notch target genes are repressed by *Betapapillomavirus* HPV E6 proteins.[175,256]

Notch-dependent transcriptional programs are critical in the differentiation and cell cycle arrest of keratinocytes.[160,209] In addition, inactivating Notch pathway mutations have been recently reported in squamous cell carcinomas of the head and neck,[3,251] and the skin,[282] consistent with the notion that Notch signaling is a tumor suppressor pathway in squamous epithelial cells.[67] E6 binding to MAML1 provides novel mechanism of viral antagonism of the Notch signaling, and suggests that Notch signaling is an important epithelial cell pathway target for the *Betapapillomavirus* HPVs.

Interestingly, although most studies have focused on the high-risk alpha genus HPV, the cellular Na+/H+ Exchanger Regulatory Factor 1 (NHERF1) protein was found to bind E6 proteins of both high and low-risk E6 proteins as well as from diverse nonprimate mammalian species. The binding results in the degradation of NHERF1 resulting in the activation of canonical Wnt/β-catenin signaling, a key pathway that regulates cell growth and proliferation.[70]

HPV E7

The E7 protein encoded by the “high-risk” HPVs is a small nuclear protein of about 100 amino acids, has been shown to bind zinc, and is phosphorylated by casein kinase II (CK II). E7 is a multifunctional protein that shares some functional similarities with adenovirus (Ad) 12S E1A.[202] The HPV proteins also share important amino acid sequence similarity with portions of the AdE1A proteins and the SV40 large tumor antigen (TAg) (Fig. 2.13). These conserved regions are critical for some of the transforming activities in all three viral oncoproteins, and participate in the binding to the product of the retinoblastoma tumor suppressor gene pRB, and the related pocket proteins, p107 and p130.[56,76,287]

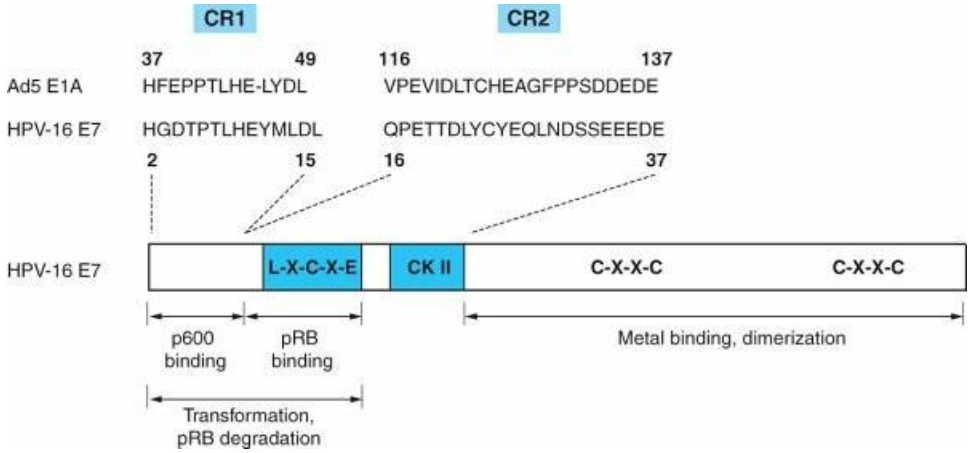

FIGURE 2.13 Amino acid sequence similarity between portions of conserved regions 1 and 2 (CR1, CR2) of the Ad5 E1A proteins and the amino terminal 38 amino acids of HPV16 E7. CR2 contains the pRB binding site and the casein kinase II (CKII) phosphorylation site of HPV16 E7.

The retinoblastoma protein is a member of a family of cellular proteins that also includes p107 and p130, which are homologous in their binding "pockets" for E7, AdE1A, and SV40 TAg. The phosphorylation state of pRB is regulated through the cell cycle, being hypophosphorylated in G_0 and G_1 and phosphorylated during S, G_2, and M. pRB becomes phosphorylated at multiple serine residues by cyclin-dependent kinases at the G1/S boundary and remains phosphorylated until late M, when it becomes hypophosphorylated again through the action of a specific phosphatase (Fig. 2.14). The hypophosphorylated form represents the active form with respect to its ability to inhibit cell cycle progression. HPV16 E7, like SV40 TAg, binds preferentially to the hypophosphorylated form of pRB, resulting in the functional inactivation of pRB through the release of E2F transcription factors thus permitting progression S phase cell cycle progression. This property of the viral oncoproteins to complex pRB accounts, at least in part, for their ability to induce DNA synthesis and cellular proliferation.

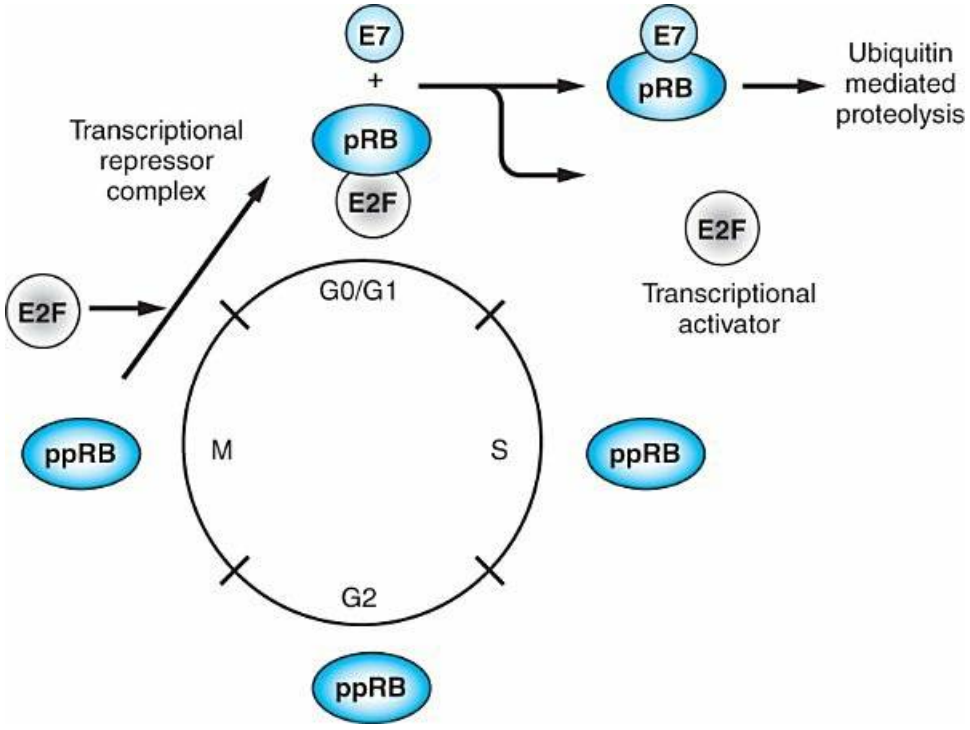

FIGURE 2.14 E7 abrogates the cell cycle regulation mediated by pRB (as well as the related proteins p107 and p130) by complex formation. During the cell cycle, pRB is differentially phosphorylated, and the underphosphorylated form is detected only in the G0/G1 phase. This underphosphorylated form is the active form of pRB, acting as a negative regulator of the cell cycle. During the transition to the S-phase, pRB is phosphorylated by cyclin-dependent kinases (cdk), resulting in the inactivation of its cell cycle regulatory functions. Members of the E2F family of cellular transcription factors are preferentially bound to the underphosphorylated form of pRB, and in complex with pRB cannot activate transcription. Phosphorylation of pRB or complex formation with E7 results in the release of the E2F factors allowing them to function as a transcriptional activators of cellular genes involved in cellular DNA synthesis and progression into the S phase of the cell cycle.

The high-risk HPV E7 proteins associate with the pocket proteins and induce their proteasomal degradation.[27,129] The LXCXE motif within the CR2 homology domain of E7 is sufficient for pocket protein binding,[77,182] but additional sequences located in the immediate amino terminal CR1 homology domain of E7 are required for pocket protein degradation[129] and these sequences are also necessary for the transforming activities of E7.[201]

E7 targeting the pocket proteins, including pRB, is not sufficient to account for its immortalization and transforming functions, indicating that there are additional cellular targets of E7 that are relevant to cellular transformation.[124] Other E7 binding proteins that are important to its transformation activities are the E3 ligase UBR4 and protein tyrosine phosphatase PTPN14. Although all E7 proteins bind both these cellular proteins,[286] the high-risk HPV E7 proteins target the ubiquitin-dependent degradation of PTPN14 through its interaction with UBR4.[255,285] The degradation of PTPN14 by E7 impairs keratinocyte differentiation thus contributing to its

oncogenic activity independent of its ability to target pRB.[106,107] The binding to UBR4 is also important in mediating some of the pRB independent functions of E7 such as modulating anoikis.[58] E7 can interact with cyclin-dependent kinase inhibitors. HPV16 E7 interacts with and abrogates the inhibitory activity of $p27^{kip1}$[95] and associates with $p21^{cip1}$ and abrogates its inhibition of cdks as well as its inhibition of PCNA-dependent DNA replication.[89,128] $p21^{cip1}$ is normally induced during keratinocyte differentiation,[177] and its inhibition by E7 may be critical in allowing papillomavirus viral DNA replication in differentiated squamous epithelial cells.[46]

Table 2.3 provides a list of various cellular targets with which HPV E7 has been shown to bind, although the physiologic relevance of some of these interactions remains unclear. Some recent reviews on E7 provide additional details of some of these interactions.[104,111,242]

E7 is necessary for the stable maintenance of HPV episomes in epithelial cells,[85,260] and sequences in E7 that contribute to cellular transformation are also important for the functions in the viral life cycle.[158,260] Hence, the ability of E7 proteins to induce DNA replication through the release of E2F transcription factor complexes and the inactivation of $p21^{CIP1}$[89,128] and $p27^{KIP1}$[96] is an essential component of the HPV replication strategy.

The high-risk HPV E7 proteins causes genomic instability in normal human cells.[284] HPV16 E7 induces G1/S and mitotic cell cycle checkpoint defects and uncouples synthesis of centrosomes from the cell division cycle.[181] This causes formation of abnormal multipolar mitoses, leading to chromosome mis-segregation and aneuploidy.[71] Moreover, there is an increased incidence of double-strand DNA breaks and anaphase bridges, suggesting that in addition to numerical abnormalities, high-risk E7 proteins also induce structural chromosome aberrations.[72] Abnormal centrosome duplication rapidly results in genomic instability and aneuploidy, one of the hallmarks of a cancer cell. This activity is therefore likely to be functionally relevant to the contribution of high-risk HPV to malignant progression.

The high-risk HPV E7 proteins have also been shown to reprogram cellular transcriptional programs.[172] The repressive H3K27 marks, which are necessary for binding of polycomb repressive complexes, are decreased in HPV16 E7-expressing cells due to the transcriptional induction of the KDM6A and KDM6B H3K27-specific demethylases.[170] The HPV16 E7-

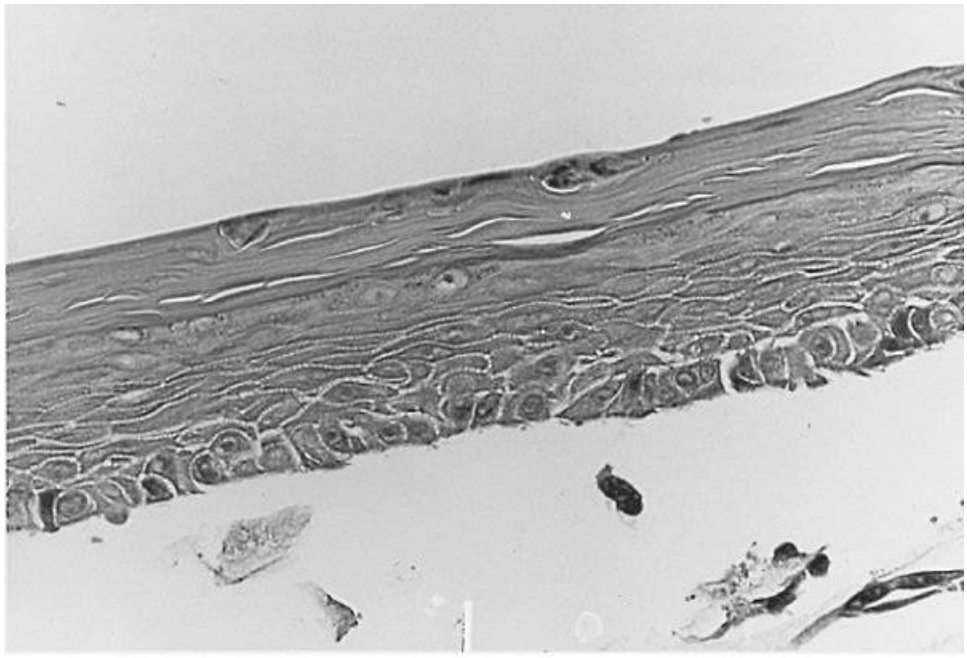
induction of p16(INK4A) is mediated by KDM6B.[170] Moreover, KDM6A- and KDM6B-responsive Homeobox genes are expressed at significantly higher levels, indicating that HPV16 E7 results in reprogramming of host epithelial cells. These effects are independent of the ability of E7 to inhibit the retinoblastoma tumor suppressor protein.

What are the roles of the E6 and E7 oncoproteins in the normal life cycle of an HPV infection? It is likely that they function to allow the replication of the viral DNA. The viral E1 and E2 proteins are necessary for the initiation of viral DNA replication, but the virus is otherwise totally dependent on host cell factors, including DNA polymerase α, thymidine kinase, PCNA, etc. for the replication of its DNA. These are proteins that are normally only expressed in S phase during cellular DNA replication in cycling cells. Vegetative DNA replication for the papillomaviruses, however, occurs only in the more differentiated cells of the epithelium that are no longer cycling (see Fig. 2.5). Thus, the papillomaviruses have evolved a mechanism similar to that of the polyomaviruses and the adenoviruses, to activate the cellular genes necessary for the replication of their own DNA in otherwise quiescent cells. These viruses may do so through the E7 proteins and their ability to release the E2F transcription factors by binding the pocket proteins including pRB (Fig. 2.13). In addition, E7 binds and inhibits the cdk inhibitor $p21^{cip1}$ that is normally induced during keratinocyte differentiation, again presumably for the purpose of permitting viral DNA replication in a differentiated cell. The high-risk HPV E7 proteins, when expressed in the absence of E6, result in increased levels of p53 resulting in either a G1-mediated cell cycle arrest or apoptosis, depending upon the cell type. E7 creates a signal that increases p53 levels. E6, by promoting the degradation of p53, counters this activity of E7 and permits the E7-dependent activation of the cellular DNA replication genes required for viral DNA replication.

HPV E5

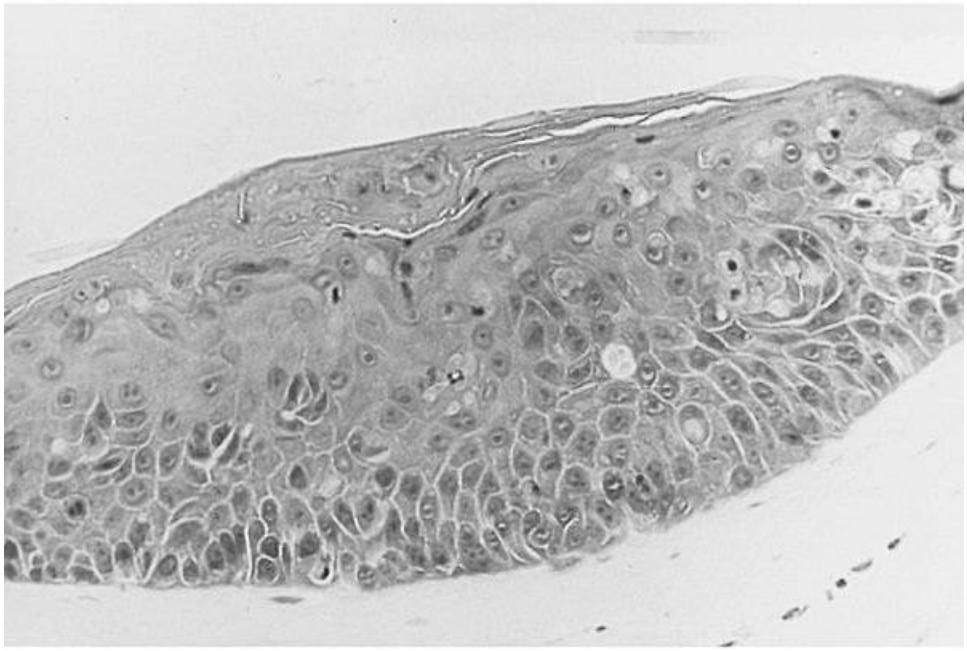
Many of the papillomaviruses that induce purely epithelial papillomas (such as CRPV and the HPVs) contain E5 genes with the potential to encode short hydrophobic peptides. The similarity of these peptides to the BPV1 E5 protein has prompted studies of the potential transforming activities of the HPV E5 genes. The E5 proteins of the HPVs are required for optimal growth.[83,92] In tissue culture, various HPV E5 genes have been shown to have some modest transforming activities and in transgenic mice HPV16 E5 expressed in basal keratinocytes can alter the growth and differentiation of stratified epithelia and induce epithelial tumors at a high frequency.[93] Furthermore, E5 has recently been implicated in the up-regulation of Met in human keratinocytes.[231]

Although the biochemical mechanisms by which the E5 genes of the epitheliotropic papillomaviruses exert their growth stimulatory effects have not yet been fully elaborated, they may involve interactions with the EGF receptor or the 16kD subunit of the vacuolar ATPase, each of which has been shown to bind HPV E5 proteins.[49,93,119,250,298] HPV E5 has also been shown to bind the A4 endoplasmic reticulum protein to regulate cellular proliferative activity.[142]



It should be noted, however, that the E5 gene is not expressed in most HPV-positive cancers, suggesting that if the E5 protein does stimulate cell proliferation *in vivo*, it presumably functions in benign papillomas and not in the cancers. It might also participate in the initiation of the carcinogenic process or in some other aspects of the viral/host cell interaction relevant to the pathogenesis of the HPV infection. Indeed there is also a report that would implicate E5 in the down-regulation of MHC class II antigen expression.[297]

Propagation and Assay in Cell Culture



PVs have proved difficult to propagate *in vitro* because the complete life cycle requires a stratified squamous epithelium, which is not mimicked in monolayer cultures. Most clinical identifications of PV infection, therefore, rely on techniques that identify the viral DNA, such as the polymerase chain reaction (PCR) or molecular hybridization, rather than isolation and assay of viral particles in cell culture.

Early to intermediate stages of the life cycle of many PVs can be studied in cells transfected with viral genomes derived from recombinant DNA. BPV1 can replicate in and transform mouse fibroblasts, though this species promiscuity is very unusual and because BPV1 is a fibropapillomavirus (a virus that replicates nonproductively in dermal fibroblasts as well as productively in the overlying keratinocytes). Human keratinocytes will support replication of transfected *Alphapapillomavirus* HPV genomes; HPVs from the Beta and Mu genera are more refractory to replication because of the strong repressive function of their viral E8^E2 protein.[69] HPV genome-containing keratinocytes can be induced to differentiate by treatment with high levels of calcium,[14] or by suspension in semisolid medium.[218] These treatments stimulate intermediate gene expression, viral DNA amplification, and some late gene expression but not the production of viral particles

The complete virus life cycle can be recapitulated in cultured keratinocytes using an organotypic “raft” culture system. In this system, keratinocytes containing an HPV genome are cultured at the air–liquid interface on the surface of a dermal equivalent (e.g., a collagen gel containing fibroblasts).[174] This induces the formation of a completely stratified squamous epithelium that can be used to analyze various aspects of PV biology, genetics, and biochemistry, and to produce HPV virions (Fig. 2.15).

A

B

FIGURE 2.15 Raft cultures showing normal keratinocytes **(A)** and keratinocytes transfected with the full-length HPV16 genome **(B)**. The normal keratinocytes stratify and differentiate with an increase in the cytoplasmic–nuclear ratio in cells of the upper half of the epithelium and a prominent granular layer. In keratinocytes transfected with HPV16, while stratification takes place, differentiation is abnormal. There is hyperplasia of cells in the parabasal layer, and mitotic figures are observed in the upper half of the epithelium. No granular layer is seen, and the cytoplasmic–nuclear ratio

does not change throughout the stratified epithelium. This morphology is similar to cervical intraepithelial neoplasia (CIN). Courtesy of D. McCance.

The species specificity of PVs has limited the study of HPV in animal models, but an early approach for HPV propagation was to expose primary cultured epithelial cells to virus and place them under the renal capsule of nude mice.[112] This immunologically protected site can support the growth of heterologous cells and foster formation of a multilayer epithelium that resembles a stratified squamous epithelium. The xenograft approach led to the successful propagation of several HPV types, although it is too cumbersome for routine virus isolation or for the molecular or biochemical analysis of virus replication.

Papillomavirus gene transfer vectors, also known as pseudovirions, have been developed and are widely used for studies of viral entry and *in vitro* neutralization assays.[34] The most widely employed procedure involves cotransfection of plasmids expressing codon-modified L1 and L2 genes along with a reporter plasmid containing the SV40 origin of replication into SV40 T antigen expressing cells (usually 293TT). The L1 and L2 proteins efficiently package the amplified reporter plasmids, and the purified pseudoviruses (expressing marker genes such as GFP or secreted alkaline phosphatase) are widely used for studying the infectious process.

An extension of this technique is to transfect 293TT cells with recombinant papillomavirus genomes in addition to the L1 and L2 expression vector. The resulting viral particles contain HPV genomes and are called “quasivirus”.[206] Quasiviruses can be used as a substitute for lesion-derived virions in basic virologic studies; they have the added advantage that they can contain mutated genomes and could not otherwise be produced.

Marker-PV genomes are related to both pseudoviruses and quasiviruses. These are recombinant PV genomes in which the late region has been replaced by genes encoding GFP, drug selectable markers, or shRNA.[57,274] Early and persistent stages of infection can be studied in cells infected or transfected with these genomes, but they are unable to complete the viral life cycle in the absence of the late genes.

PAPILLOMAVIRUS INFECTION OF EXPERIMENTAL ANIMALS

The species-specific nature of PV has thus far prevented adaptation of authentic HPV infection to experimental animals. However animal PV models have been played important roles in understanding PV pathogenesis.

Wild cottontail rabbits (*Sylvilagus floridanus*) represent the natural host for the CRPV.[235] Experimental studies of SfPV1/CRPV can be carried out in the natural host, but difficulties in maintaining cottontail rabbits under typical cage conditions have led to most SfPV1/CRPV studies being carried out in closely related domestic rabbits (*Oryctolagus cuniculus*).[30] SfPV1/CRPV can readily induce papillomas in domestic rabbits, where their persistence and progression to cutaneous cancer occurs more frequently than in cottontails. Although papillomas

in cottontails usually contain large amounts of infectious SfPV1/CRPV, the lesions in domestic rabbits contain little or no infectious virus. Papillomas can also be induced by application of naked SfPV1/CRPV genomic DNA, permitting mutational analyses of the viral life cycle in this model.[144] SfPV1/CRPV genomes have also been incorporated into the L1/L2 capsids of other papillomavirus types and the resulting pseudovirions used to assess the protective capacity of HPV prophylactic vaccines.[173]

Rabbit oral papillomavirus (OcPV1) is a mucosotropic PV that was isolated from domestic rabbits.[195,288] Although SfPV1/CRPV and OcPV1/ROPV are closely related phylogenetically, they are sufficiently distinct antigenically that resistance to one virus does not confer resistance to the other. The canine oral papillomavirus (CPV1 or COPV) is another mucosotropic PV that has been studied.[186] CPV1 papillomas usually regress one to two months after infection, which makes this model well suited to studying aspects of host defense mechanisms against PV infection.[122]

Bovine PV1 (BPV1) is the prototype of a group of animal PVs, found in ungulates, that cause fibropapillomas.[36] The ability of these PVs to induce nonproductive transformation of dermal fibroblasts leads to their having a wider host range than other PVs, although the increased host range may be limited to fibroblasts. Benign dermal tumors known as equine sarcoid appear to arise following accidental dermal infection of horses with BPV1 or BPV2.[40] An experimental counterpart is the ability to induce nonneuronal tumors in hamsters inoculated intracerebrally with BPV1.

Bovine PV4 can induce oral mucosal lesions in cattle, as well as esophageal papillomas.[36] When cattle are fed bracken fern that contains chemical carcinogens, it can lead to esophageal cancers. One interesting feature of these cancers is that, although the BPV4 infection plays a role in their induction, the tumors themselves do not contain detectable BPV4 DNA.[37] This represents a rare instance of virally induced tumors that arise via a “hit-and-run” mechanism.

A rhesus papillomavirus (MmPV1/RhPV1) has been described that appears to be sexually transmitted between monkeys and to be associated with the development of cervical cancer.[290] MmPV1 and HPV16 are highly homologous, which suggests this animal model might have many similarities with human cervical infection with HPV. Infectious RhPV has not yet been isolated or propagated, however, severely limiting experimental analysis of this potentially useful model. The ability to generate RhPV quasivirions in cultured cells might increase the utility of this model.

Cervicovaginal infection by mucosatropic HPVs can be assessed using a pseudovirus-based mouse intravaginal challenge model.[212] Infection is generally monitored by whole animal luminescence imaging after inoculation with luciferase-expressing pseudovirions. Similar models have been developed to examine cutaneous infection.[5]

The first and only laboratory mouse PV, designated MmuPV1, was identified in a colony of immunodeficient inbred mice that spontaneously developed papillomas at cutaneous surfaces near the mucocutaneous junctions of the nose and mouth.[125] This has been an important advance in the field as it provides an infection-based model to study papillomavirus disease pathogenesis. Although phylogenetically distinct from the HPVs as a member of the *Pipapillomavirus* genus, MmuPV1 affords opportunities to study malignant progression following infection and the immunologic responses to infections in the mouse.[246] Another animal model that has received

some attention is the African rodent *Mastomys coucha* that offers a model for skin-related cancers.[105]

Prevention
- Interruption of transmission
- Prophylactic vaccination

The Papillomaviruses (PVs) comprise a widely dispersed group of nonenveloped epitheliotropic viruses of vertebrates that characteristically induce benign hyperproliferative lesions of the skin (warts) and mucous membranes (condylomata).[100] More than 200 genotypes (types) have been identified in humans.[43] All PVs have small double-stranded circular DNA genomes of approximately 8 kilobases, and all transcripts are derived from the same DNA strand (Fig. 3.1). They generally contain about eight distinct protein coding regions, which through alternatively spliced mRNAs can generate multiple protein species. The proteins function as virion structural proteins (L1 and L2), as regulators of viral genome transcription and replication (E1 and E2), and as determinants that perturb the normal physiology of host cell in ways that promote the

virus productive life cycle (E4, E5, E6, E7, and E8). Productive infection occurs only in a stratified squamous epithelium, with the highly regulated expression of the viral genes being closely tied to the differentiation state of the keratinocytes (Fig. 3.2). In rare cases, the normal viral life cycle of a small subset of PV types goes awry, leading to the development of various epithelial malignancies, which are manifested in humans as cancer of the uterine cervix, as well as other cancers in the anogenital tract and the upper airway. An accompanying chapter details the basic molecular biology of PVs. This chapter will focus primarily on the epidemiology of human papillomaviruses (HPVs), the neoplastic diseases that they cause, and interventions to prevent or treat these diseases.

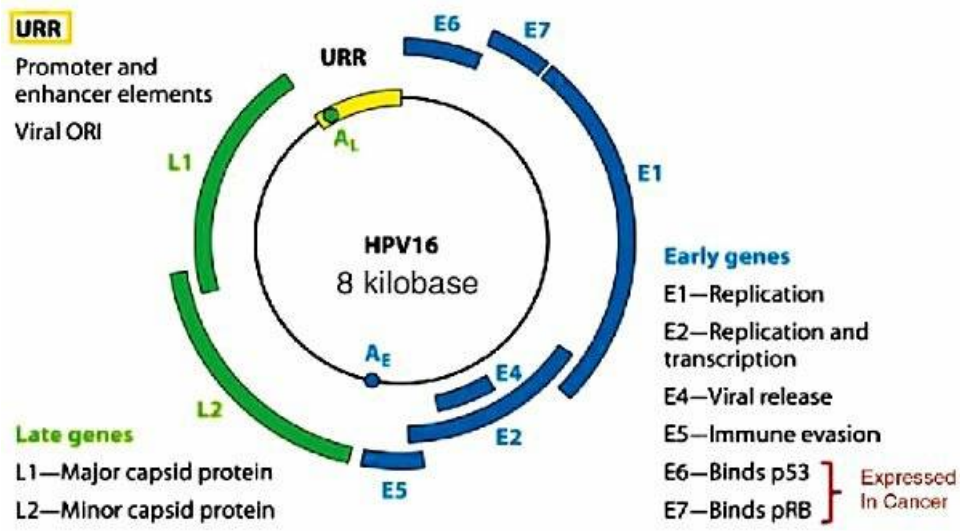

FIGURE 3.1 Schematic of the 8 kilobase double-stranded DNA genome of HPV-16. The open reading frames encoding viral polypeptides are shown in blue and green. The upstream regulatory region (URR) is depicted in yellow. A_E and A_L are the polyadenylation sites for the early and late transcripts, respectively. E6 and E7 bind multiple cellular proteins, in addition to p53 and pRB. (Figure from Stanley MA. Epithelial cell responses to infection with human papillomavirus. *Clin Microbiol Rev* 2012;25:215–222. PAPILLOMAVIRUSES AND CANCER

Whereas most PVs do not appear to have oncogenic potential, a subset of PV is clearly implicated in the development of malignancy in humans and animals[403] (Table 3.1). In humans, approximately 5% of all cancers are attributable to HPV infection, with cervical cancer being the most important from a global public health perspective (Fig. 3.3).[81] HPVs are also implicated in other anogenital cancers, including anal cancer, vulvar cancer, and penile cancer, as well as in oropharyngeal and laryngeal cancers (Fig. 3.3). HPV infection is associated with virtually all cases of cervical cancer, the vast majority of cases of anal cancer, and many of the other forms of cancer (Fig. 3.3).[81,82] There may be concordant HPV infection at multiple mucosal sites,[58] and patients who have had one HPV-associated cancer may have an increased risk of a second HPV-associated cancer.[59]

TABLE 3.1 Major clinical associations of HPVs by type

Clinical Association	Viral Type(s)
Skin	
Common warts	HPV-2, 27, 57
Plantar and palmar warts	HPV-1a**, 2, 27, 57
Flat warts	HPV-3, 10
Squamous cell cancer	HPV-5*, 8*
Genital tract	
Exophytic condyloma (any site)	HPV-6, 11
Flat condyloma (especially cervix)	HPV-6, 11, 16, 18, 31
Bowenoid papulosis	HPV-16, 18
Giant condyloma	HPV-6, 11
Cervical cancer	
Strong association	HPV-16, 18, 31, 45
Moderate association	HPV-33, 35, 39, 51, 52, 56, 58, 59, 68
Weak or no association	HPV-6, 11, 26, 42, 43, 44, 53, 54, 55, 62, 66
Vulvar and vaginal cancer	HPV-16
Penile cancer	HPV-16
Anal cancer	HPV-16
Recurrent respiratory papillomas	HPV-6, 11
Conjunctival papillomas	HPV-6, 11
Oral cavity	
Focal epithelial hyperplasia	HPV-13, 32
Infection with genital HPV	HPV-6, 11, 16
Lesions on lip	HPV-2
Oropharyngeal cancer	HPV-16

All list types belong to the Alpha genus unless otherwise designated.* = Beta.** = Mu.

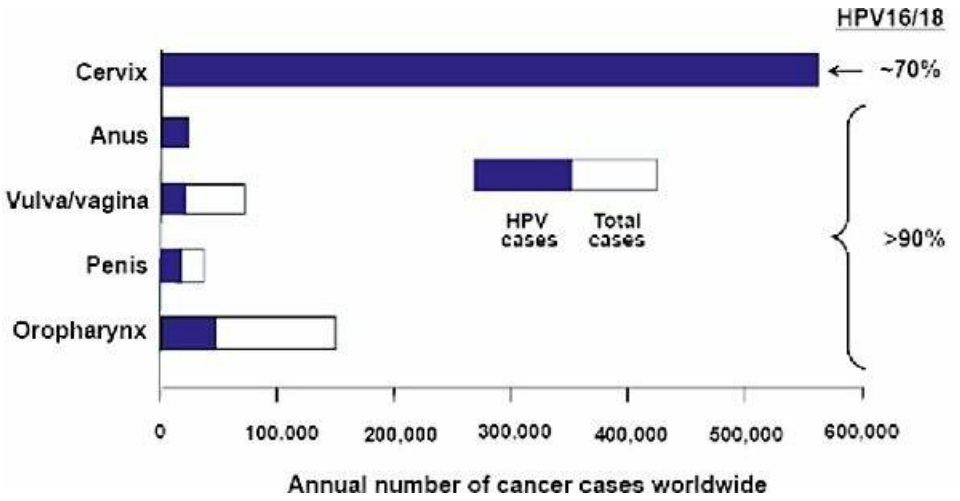

FIGURE 3.3 Worldwide annual incidence of HPV-associated cancers and attributable fraction of total cancers in 2018. The number of HPV-attributable cases is indicated in *blue* and HPV-independent cases in *white*. The approximate percent of attributable cases caused by HPV-16 or HPV-18 is indicated at the *right*. (Data derived from de Martel C, Georges D, Bray F, et al. Global burden of cancer attributable to infections in 2018: a worldwide incidence analysis. *Lancet Glob Health* 2020;8(2):e180–e190.)

In the developing world, cervical cancer accounts for more than 90% of the HPV-associated cancers,[81,82] while the noncervical cancers constitute at least one-half of the HPV-associated cancers in the United States and some other industrialized countries (Fig. 3.4).[320] This difference is attributable to substantial reductions in the incidence of cervical cancer brought about by Pap smear screening, as well as an increasing incidence of HPV-positive anal cancer and, especially, HPV-positive oropharyngeal cancer (OPC).[361] In the developing world, fewer than 10% of HPV-associated cancers occur in males,[81] while in the United States, more than 40% of them arise in males.[320]

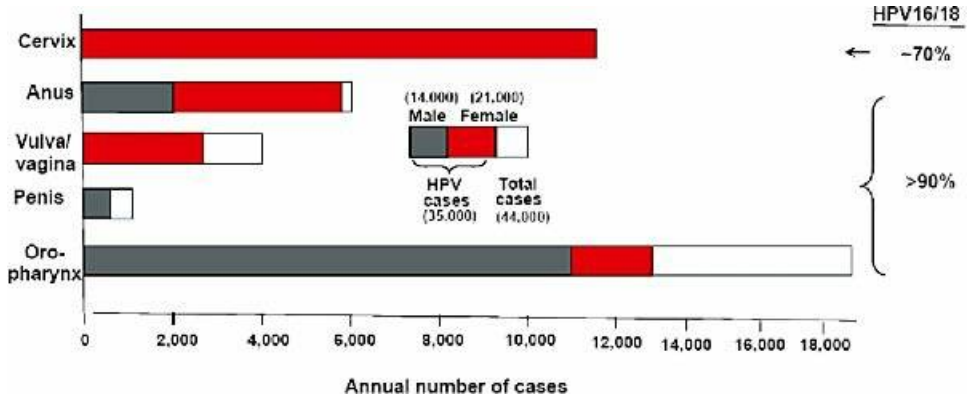

FIGURE 3.4 United States annual incidence of HPV-associated cancer in 2012–2016 and attributable fraction by gender. HPV-attributed cases in females are shown in *red*, HPV-attributable cases in males in *gray* and HPV-independent cases in

white. The approximate percent of attributable cases caused by HPV-16 or HPV-18 is indicated at the *right*. (Data derived from Senkomago V, Henley SJ, Thomas CC, et al. Human papillomavirus-attributable cancers—United States, 2012–2016. *MMWR Morb Mortal Wkly Rep* 2019;68:724–728.)

A subset of skin-tropic HPV, especially HPV-5 and 8, is involved in the cutaneous squamous cell cancers that develop in association with epidermodysplasia verruciformis (EV), a rare inherited genodermatosis characterized by excessive flat wart-like papules.[243] These same types have been implicated in cutaneous squamous cell cancers in the general population or in immunosuppressed individuals, but their contribution to skin cancers in these populations remains unclear.[328] Some claims have been made of an association of HPV with several other common cancers, including those of the lung, breast, esophagus, colon, rectum, and prostate, but a consistent causal relationship has not been demonstrated.[68] Where detected, the HPV genome copy number has generally been found to be much lower than one per cancer cell in these cancers. As HPVs have an exceptional tropism for infecting cancer cells compared to intact normal tissues,[179] the possibility of reverse causality, that is, that infection is the result rather than the cause of the cancer, should be considered in these cases.

In the most well-studied examples of human cancers attributable to HPV, the tumors develop in a stratified squamous epithelium, they do not occur until many years after the initial infection, persistent infection is required for progression to invasive cancer, and maintenance of the transformed phenotype depends on the continued expression of at least some viral genes, especially E6 and E7.[125] On the other hand, most infections, even those caused by the HPV types implicated in cancer, have a benign outcome, because they either are self-limited or do not progress to cancer even when they are persistent.

The long interval between the initial infection and the development of cancer implies that, in addition to persistent infection by an appropriate HPV type, additional environmental and/or host factors contribute to malignant progression. Immune status is one important host parameter, with impaired cellular immune function being associated with a greater risk of persistent infection and cancer.[340] Adult patients with Fanconi anemia, an inherited disease with defective DNA repair, have been reported to have a greater than 100-fold increased risk of developing HPV-associated tumors.[177] Exogenous exposure of PV-induced lesions to cocarcinogens may represent an environmental mechanism. For example, most cutaneous cancers in EV occur on sun-exposed skin, which implies that UV light is serving as a cocarcinogen.[352]

Most HPV-associated cancers appear to depend on the continuous expression of viral genes (e.g., E6 and E7). However, it remains possible that viral gene expression may not be obligatory at all stages for some HPV-induced cancers.[315] In a small minority of cervical cancers that contain HPV DNA, the viral oncogenes are not expressed. Development of esophageal cancer in cattle by BPV-4 and the carcinogen in bracken fern is associated with complete loss of the viral genome in the malignant tumors.[44] A hit-and-run mechanism has been postulated to explain the generally low viral copy number in skin carcinomas.[315] A hit-and-run phenomenon suggests that, in these instances, the virus is required for tumor induction, but that its continued presence is consistently selected against, either biologically or immunologically, in progressed lesions. One plausible scenario is that antiapoptotic viral activities allow genetically damaged cells to survive and proliferate, permitting further genetic and/or epigenetic changes to accumulate that

overcome the need for continued viral gene expression.

HUMAN PAPILLOMAVIRUS INFECTIONS OF THE GENITAL TRACT

HPV infection of the anogenital tract represents the most important medical burden from infection with this group of agents. In women, infection affects the genital skin and mucosa, including the vulva, vaginal tract, cervix, and anal canal. Most of these infections are sexually transmitted, which means that their prevalence is usually correlated with measures of sexual activity, such as the number of lifetime sexual partners, a recent change in sexual partner(s), and a history of other sexually transmitted infections.[40,327]

HPV infection of the anogenital tract is extremely common, with a wide range of clinical manifestations and outcomes, varying from asymptomatic and self-limited to persistent and associated with malignant progression. Viral factors and host factors each contribute to determining the outcome. The alpha-HPVs cause most anogenital infections, and the majority of oncogenic HPV types are from the alpha-7 and alpha-9 species, which together are often considered “high-risk” HPV types (Table 3.1).[310]

Cervical Cancer

Cervical cancer is the fourth most common malignancy among women worldwide, with an estimated 570,000 cases and 311,000 deaths in 2018.[9] Despite its worldwide distribution, the frequency of cervical cancer varies considerably, being about 10 times more common in some developing countries than in most industrialized ones.[82] More than 85% of cervical cancer occurs in developing countries, where it is frequently the most common cancer of women, accounting for as many as one-quarter of female cancers. Pap smear screening, which identifies cytologic abnormalities induced by persistent HPV infection, has dramatically decreased the frequency of cervical cancer in many industrialized countries. In the United States, approximately 10,000 new cases are diagnosed annually, and about one-third of these women will die of their malignant disease.[320] The incidence of cervical cancer in the United States varies considerably among ethnic and, especially, socioeconomic groups.[22]

More than 90% of these cancers occur in the transformation zone of the cervix, where the columnar cells of the endocervix form a junction with the stratified squamous epithelium of the exocervix[42] (Fig. 3.5). About 85% of cervical cancers are squamous cell cancers. Most of the other cases are adenocarcinomas, with a small number being small cell neuroendocrine tumors.

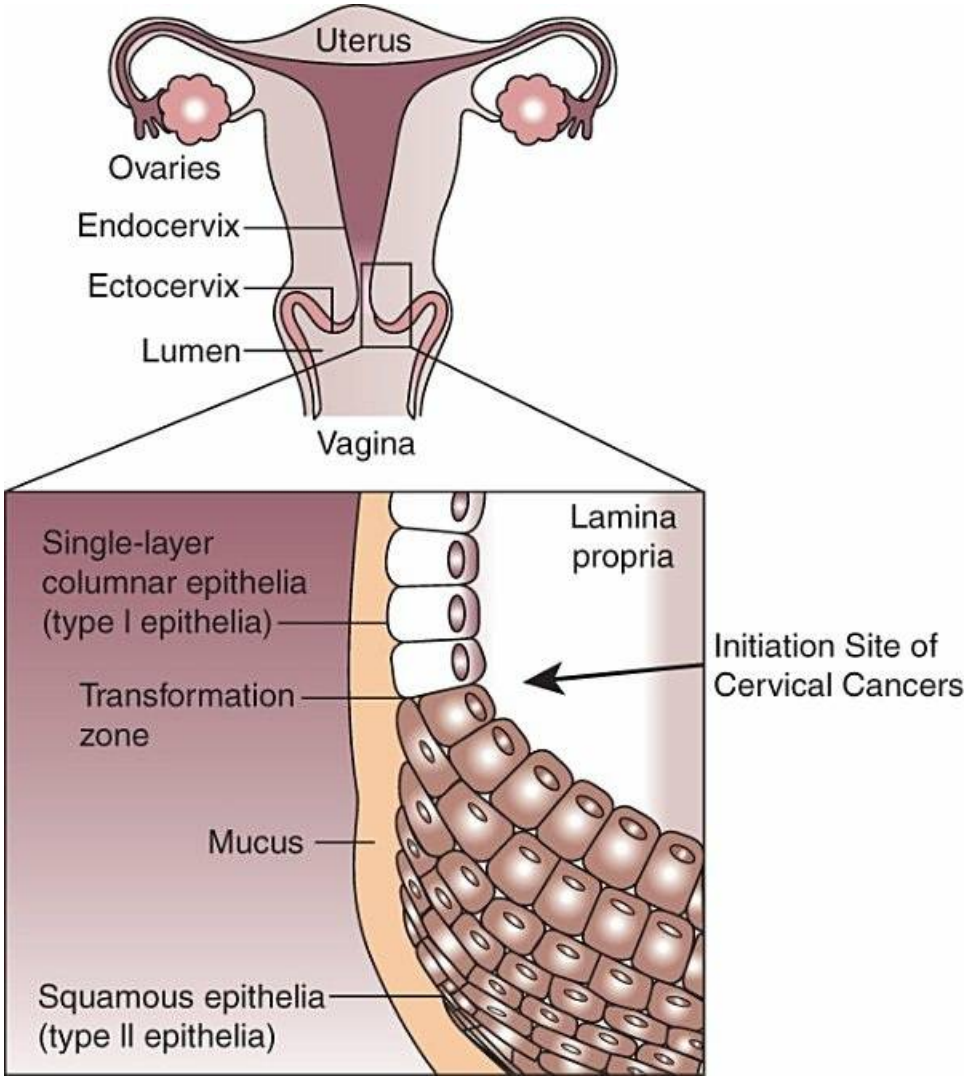

FIGURE 3.5 Female reproductive tract anatomy and histology. (Reprinted by permission from Nature: Iwasaki A. Antiviral immune responses in the genital tract: clues for vaccines. *Nat Rev Immunol* 2010;10:699–711. Copyright © 2010 Springer Nature. Ref.[164].)

Lesions that become malignant squamous cell carcinomas typically undergo a series of dysplastic changes over many years.[307] The severity of the lesion is determined by the degree to which the squamous epithelium is replaced by basaloid cells, with the entire thickness being replaced in the most severe dysplasias (Fig. 3.6). In the histologic classification of cervical intraepithelial dysplasia (CIN), grades 1, 2, and 3 correspond, respectively, to mild dysplasia, moderate dysplasia, and severe dysplasia or carcinoma *in situ*. The cervical dysplasias have their counterpart in the exfoliated cells present in the Papanicolaou (Pap) smear, as evidenced by the presence of koilocytes (evidence of virion production) and basaloid cells (evidence of dysplasia). In the binary cytologic Bethesda system,[196] abnormalities are classified as low-grade and high-grade squamous intraepithelial lesions (SIL), with low grade corresponding to mild cytologic abnormalities and high grade encompassing the more severe abnormalities (Fig. 3.6). CIN1 and

LSIL are now considered normal manifestations of productive HPV infection. Atypical squamous cytology of undetermined significance (ASCUS) is the cytologic designation for equivocal lesions; the risk of HPV-positive ASCUS lesions progressing to HSIL is similar to that of LSIL, while the risk of HPV-negative ASCUS lesions is about fourfold lower.[90]

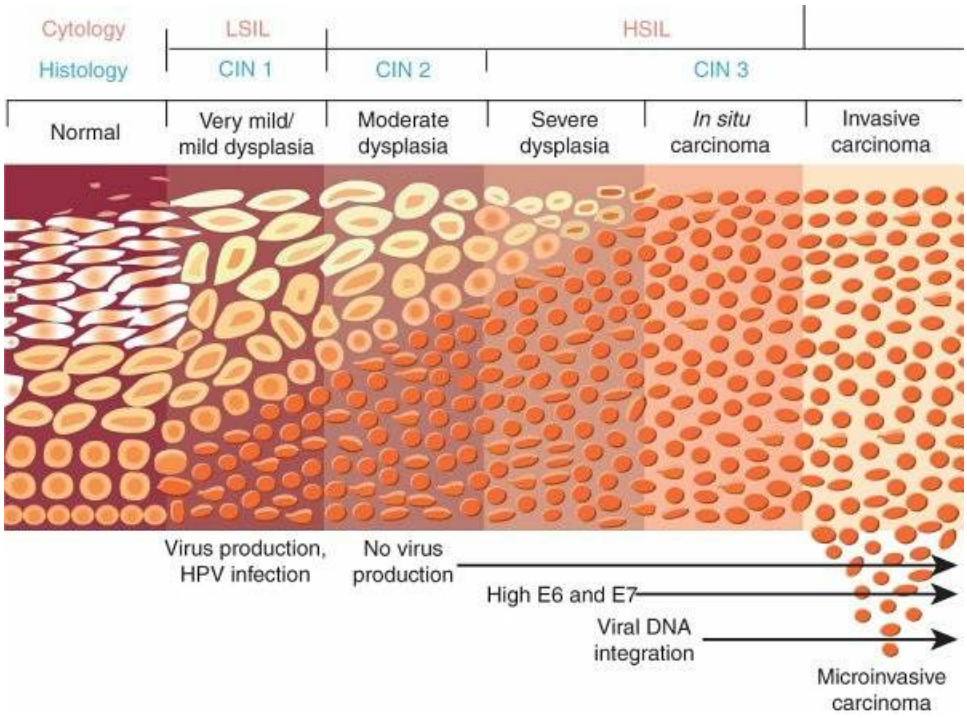

FIGURE 3.6 The histologic, cytologic, and virologic changes during progression from initial infection to cervical cancer. CIN, cervical intraepithelial neoplasia; LSIL, low-grade squamous intraepithelial neoplasia; HSIL, high-grade cervical intraepithelial neoplasia. (Modified with permission of American Society for Clinical Investigation from Lowy DR, Schiller JT. Prophylactic human papillomavirus vaccines. *J Clin Invest* 2006;116:1167–1173. Permission conveyed through Copyright Clearance Center, Inc. Ref.[214]).

Most dysplasias do not progress and, in fact, resolve spontaneously, but the likelihood of their resolution decreases with the severity of the dysplasia (Fig. 3.7). Severe dysplasias (also designated “precancers”), however, generally arise from less dysplastic lesions after several years,[210] although some precancers can develop rapidly, apparently without passing through a low-grade stage,[186] perhaps due to high-risk HPV infection of a uniquely susceptible subset of morphologically distinct cells residing in the squamocolumnar junction.[149] Because of the long interval between the development of cervical dysplasia and invasive cancer, follow-up of Pap smear abnormalities or positive results in newer virologic-based screens (discussed below) can identify most premalignant lesions. Appropriate follow-up of women with these abnormalities, together with appropriate treatment, can thereby prevent the development of most cases of cervical cancer.[89,276] In some countries with screening programs, however, the incidence of adenocarcinoma and adenosquamous cell carcinoma has been increasing, suggesting that Pap

smear screening has been less effective in identifying the precursors to these tumor types.[359]

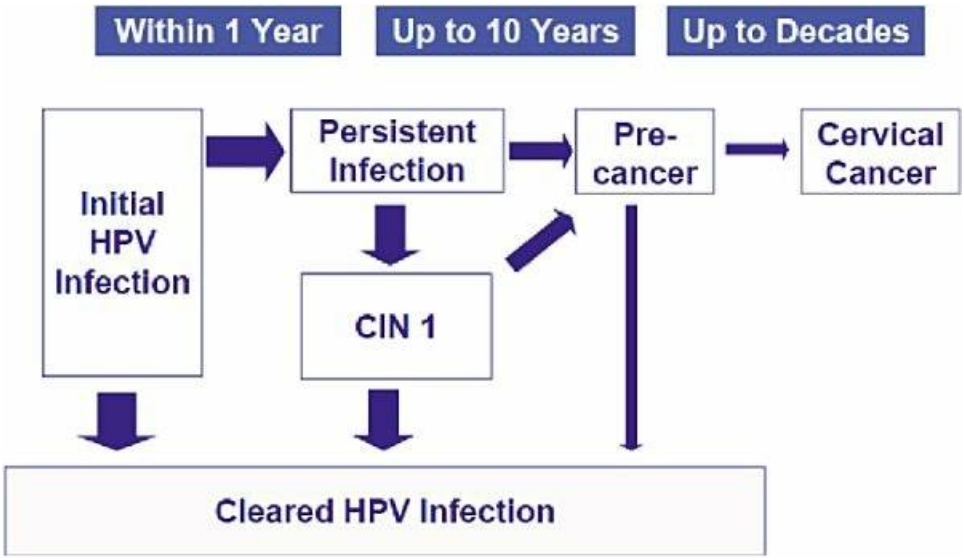

FIGURE 3.7 Natural history of oncogenic HPV infection and progression to cervical cancer. The bolder the *arrow*, the more frequent the transition between states. CIN 1, cervical intraepithelial neoplasia grade 1.

Role of HPV in Cervical Cancer

Cervical cancer was recognized for decades to behave as a sexually transmitted disease, long before sexually transmitted HPV infection was implicated in its pathogenesis. In the mid-1970s, Meisels and Fortin[231] recognized, on morphologic grounds, that HPV infection of the cervix occurred frequently, often with the histologic characteristics of mild CIN. These observations coincided with the proposal by zur Hausen[402] that HPV infection might be the putative sexually transmitted agent responsible for cervical cancer. During this period, the detection of HPV-5 or HPV-8 in skin cancer in patients with EV strongly suggested that some HPVs might have malignant potential.[257] Only a subset of the HPV types isolated from patients with EV was found in the skin cancers, implying that HPV types might vary in their oncogenicity. The molecular cloning of HPV-16 and HPV-18 from cervical cancer biopsies by zur Hausen and colleagues in the early 1980s[31,105] provided the field with the HPV types that were subsequently shown to be present in approximately two-thirds of cervical cancers worldwide. Using lower stringency hybridization techniques, other HPV types were later identified in cervical tumors.[403] Subsequent studies, carried out by many investigators, have sought to understand the natural history of HPV infection of the genital tract, determine the biological properties of different HPV types, elucidate the role of the virus in the pathogenesis of cervical disease, and identify nonviral factors that may influence the outcome of HPV infection.

More than 50 HPV types, mostly from the alpha genus, infect the genital tract.[317] Only a dozen of these types, however, are found regularly in cervical cancers, and in a higher proportion than in controls, leading these types to be designated as “high risk” (Table 3.1). On the other hand, HPV types that are detected relatively frequently in controls, but rarely in cancers, are

designated “low risk.” A worldwide study of almost 1,000 cervical cancers, from paraffin-embedded sections, indicated that more than 90% contain HPV DNA.[30] Although more than 20 HPV types were found in the tumors, two types from the alpha-7 (types 18 and 45) and two types from alpha-9 (types 16 and 31) species accounted for close to 80% of the HPV-positive cancers. Conversely, low-risk HPV (e.g., HPV-6 and HPV-11) was found in only two of these cancers. In all areas of the world, HPV-16 is the most common type found in the cancers. A follow-up evaluation of the cancers in this study that were initially believed to be HPV negative indicated either that they were false-negative results or that the DNA in the specimens was too degraded for the negative results to be deemed reliable.[372] The conclusion from this study was that at least 99.9% of cervical cancers contain HPV DNA and, therefore, that HPV infection is a necessary cause of cervical cancer, the first etiologic agent for a cancer to be so designated.

In a worldwide meta-analysis of 14,595 cervical cancers, of which 89.7% were HPV positive, HPV-16 and HPV-18 were detected in 70%, while no other type was found in no more than 4.4% (Fig. 3.8).[333] It seems likely that most cases reported as being HPV DNA negative represent false-negative findings. Some regional variation exists in the specific proportion of HPV types in cervical cancer, and also in CIN3, but this variation is relatively minor and is less than the wider variation that exists among asymptomatic infections or low-grade dysplasias.[49] In one recently identified racially associated susceptibility, HPV-35 appears to be more carcinogenic in women with African ancestry.[279]

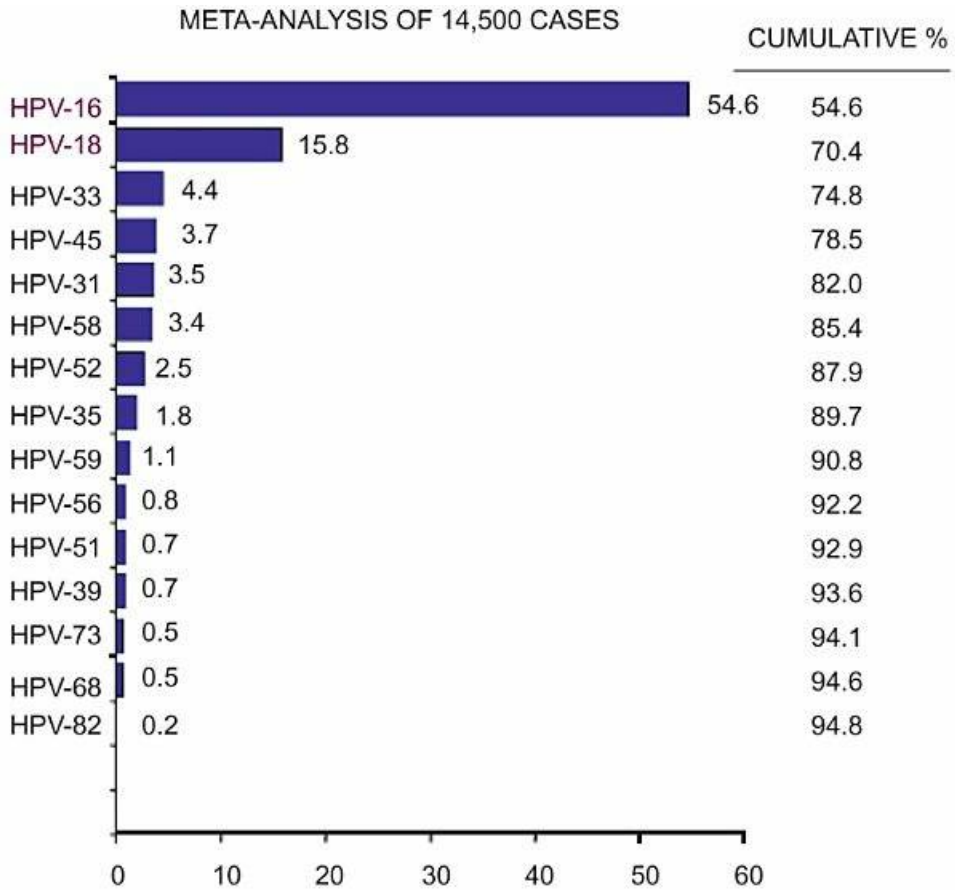

FIGURE 3.8 Worldwide percentages of cervical cancer attributed to the most

frequent HPV types. (Data from Smith JS, Lindsay L, Hoots B, et al. Human papillomavirus type distribution in invasive cervical cancer and high-grade cervical lesions: a meta-analysis update. *Int J Cancer* 2007;121:621–632.)

Prospective population-based studies that evaluated progression from asymptomatic infection to CIN3 or worse (CIN3+) confirmed that HPV-16 is the most oncogenic type. In a recent Danish study, the 8-year absolute risk of progression of a single persistent HPV-16 infection to CIN3 was 55%.[304] The next most virulent types appear to be HPV-33, -18, and -31 with absolute risks of 33%, 32%, and 31%, respectively (Fig. 3.9). By contrast, HPV-56, considered a high-risk type, had an absolute risk of progression to CIN3 of only 3%.

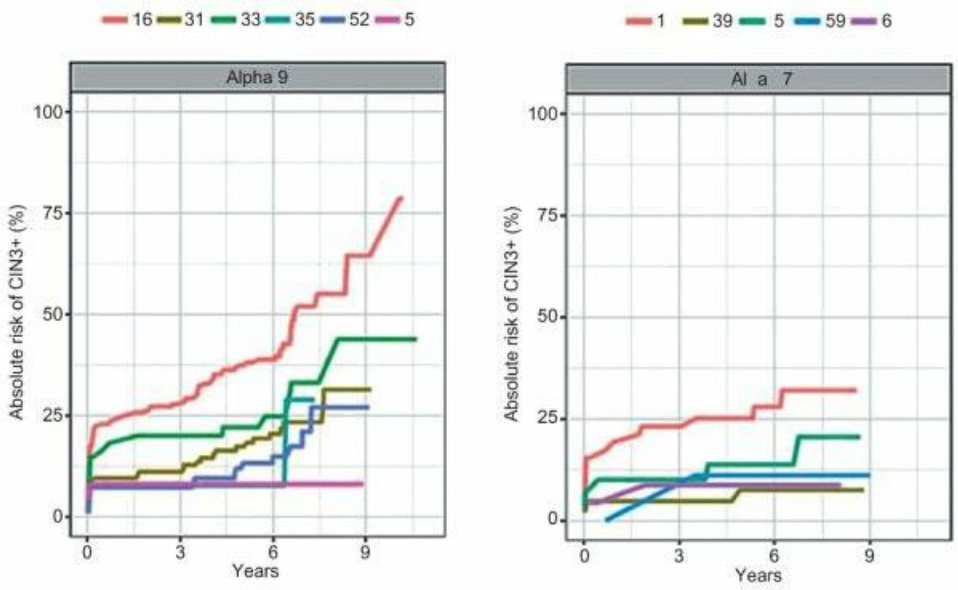

FIGURE 3.9 Absolute risk of a single persistent HPV infection progressing to CIN3 over time according to type. Alpha 9 and Alpha 7 refer to the two species of the genus that include the major oncogenic types.

Whereas most studies have focused on the more common squamous cell cancers, most cervical adenocarcinomas, adenosquamous carcinomas, and those carcinomas with neuroendocrine differentiation also contain HPV DNA. In an international analysis that pooled eight case–control studies, the adjusted odds ratio of adenocarcinoma for HPV-positive women was 81.3 (95% CI 42.0 to 157.1), and HPV-16 and HPV-18 accounted for 82% of these tumors.[50] A larger proportion of these tumors are associated with HPV-18, compared with squamous cell carcinomas, and in some studies, the number of HPV-18–associated tumors was greater than that associated with HPV-16. Low-risk HPV types may rarely be associated with cervical cancer and other cancers.[86] In addition, some HPV types, such as HPV-26, might be more oncogenic in an immunocompromised host.[141] It should also be recognized that this classification may not apply to HPV infections in all sites. For example, the Buschke-Löwenstein tumor, which is a low-grade squamous cell carcinoma of the external genitalia, is usually

associated with the low-risk HPV-6 or HPV-11.[137]

Natural History of Genital Human Papillomavirus Infection

Genital HPV infection is considered the most common sexually transmitted viral infection, with an estimated lifetime risk in U.S. women and men with at least one opposite sex partner of 85% and 91%, respectively.[61] The estimated prevalence of infection varies with the age of the population and depends on the sensitivity of the HPV assay employed. A population-based study of cervical infection in the United States, which used a very sensitive DNA-based test, found 42.5% of women 14 to 59 were HPV positive, with those 20 to 24 having the highest prevalence, 53.8%, decreasing to 38.8% in women 50 to 59.[142] The infections were divided approximately equally between high-risk and low-risk types. Since sexually active women 19 or younger acquire genital HPV infection at a high rate,[389] the comparatively low prevalence of 32.9% among those 14 to 19 probably arises because many in this age group are not yet sexually active. The decreasing prevalence of HPV infection beyond age 24 results from a combination of the self-limited nature of most infections, decreasing HPV exposure with age, and resistance to reinfection. It has been estimated that approximately 75% of the high-risk HPV infections leading to cervical cancer are acquired by age 30.[41] Genital HPVs can establish latency, but it is not clear whether reactivation from latency is a substantial risk factor for progression to cervical or other anogenital cancers.[131]

The natural history of genital HPV infection in men has been studied less systematically than that in women, with only one large prospective multicentric study.[327] As with women, infections in men are very common, and most are self-limited. In males, however, prevalence does not tend to decrease with age.[126] Penile infection is detected in 16% to 69% of healthy men depending on the population, sampling method, and HPV detection method.[95] When controlled for lifetime number of sexual partners, male circumcision has been identified as an important negative risk factor for prevalent penile infection in the men and for cervical cancer in their current sexual partners, although this association may be attenuated when multiple sites on the male genitalia are sampled.[5,6] Circumcision also reduced high-risk HPV acquisition and prevalence by approximately one-third in two randomized control trials in adult males.[132,351]

Although most women with HPV infection of the genital tract do not have detectable cytologic abnormalities, the epidemiology of genital HPV infection appears to account for the epidemiology of cervical neoplasia, including the dysplasias that precede cervical carcinoma (Fig. 3.6).[29] Following the development of validated HPV DNA assays in the early 1990s,[337] many studies have consistently shown that infection with high-risk HPV represents the major risk factor for high-grade cervical dysplasias and invasive cancer.[312] In cytologically normal women, being positive for a high-risk HPV places them at much higher risk for developing cytologic abnormalities compared with women who are HPV negative.[182,308] In addition, results of a serologic assay based on antibodies to HPV-16 L1 virus-like particles (VLPs) that can identify currently and previously infected individuals implicated HPV-16–related viruses prospectively in the development of cervical cancer.[138,204]

As noted above, most genital infections are self-limited, with the majority of incident infections clearing within 12 months and approximately 90% within 2 years, as operationally defined as the inability to detect HPV DNA in a sensitive assay.[240,386] Clearance of HPV

infection appears to return an individual to the same low risk of CIN3 or invasive cancer as an individual in whom HPV has not been detected previously. Low-grade dysplasia may be caused by infection with either low-risk or high-risk HPV. Persistent (i.e., long-term) infection with a high-risk HPV type, which occurs in a minority of infected women, is by far the single most important risk factor for developing CIN3 or invasive cancer (CIN3+). However, the magnitude of the risk depends on the HPV type (Fig. 3.9), and even on the variant within a given type.[235,311] In practical terms, persistence is usually defined as meaning that the same HPV type has been identified in two or more genital samples taken over a certain period, with the interval usually being at least 4 to 12 months. Persistent infections may clear spontaneously but are less likely to do so the longer they persist. Conversely, only some persistent infections progress to CIN3, and only some CIN3 progress to invasive cancer (Fig. 3.7). HPV-16 infections are more likely to persist than infection by other HPV types.[211] However, persistence *per se* is not sufficient for progression to high-grade dysplasia, because low-risk HPV types that persist are much less likely to progress than high-risk types.[309] The distinct biological activities of high-risk E6 and E7 (discussed in Chapter 2) are likely to represent at least partial explanations of the differences in the likelihood of progression.

Molecular Pathogenesis of Cervical Cancer

High-risk HPV types can infect the genital skin, the vaginal tract, or the cervix. If the cervix is not infected initially, the virus can spread locally, presumably by autoinoculation, to the cervix.[386] Cervical neoplastic lesions can be single or multiple. The production of progeny virions is usually limited to asymptomatic or low-grade lesions, as the full viral replication cycle is tied to the differentiation process (Fig. 3.2).[98,238] A subset of cuboidal cervical cells in the transformation zone that expresses specific embryologic markers may be particularly susceptible to malignant progression when they become infected (Fig. 3.5).[148,149]

In high-grade dysplasias and cancers, a restricted number of the viral genes are expressed, primarily E6 and E7, and their expression is now detected throughout the lesion, in contrast to most of their expression being in suprabasal cells during productive infection (Fig. 3.6).[98] Both genes are expressed from a single promoter, with alternate splicing determining their relative level of expression,[349] and progression to high-grade disease may be associated with a splicing pattern that favors E7 production. As discussed in detail in the accompanying chapter by McBride and Howley, E6 and E7 each interacts with multiple cellular factors, most notably p53 and pRb, respectively, to drive progression to high-grade dysplasia and cancer. Methylation of the HPV-16 viral genome appears to influence progression to moderate- and high-grade neoplasia, with methylation of CpG sites in L1, L2, and E2/E4 being associated with an increased risk of precancer, while methylation of upstream regulatory region (URR) sites is associated with a decreased risk.[33]

Integration of HPV DNA is strongly associated with malignant progression. In one study of 155 samples, integration was not detected in any asymptomatic infections or CIN1 lesions but was present in 5% of CIN2 lesions, in 16% of CIN3 lesions, and in 87% of invasive cancer.[184] The frequency of viral DNA integration may vary with the HPV type. In an analysis of The Cancer Genome Atlas (TCGA) data set, 76% of HPV-16–positive samples had integrated copies, whereas all HPV-18–positive cases had integrated viral genomes.[45] Viral DNA integration can occur at many sites throughout the genome, but it is clonal for a given lesion and is found

preferentially at transcriptionally active and genomically fragile sites. In a given lesion, it usually involves only one locus or a few loci, and the viral genome can be integrated as a single copy or as tandem repeats.[229] The conclusion that a proportion of cancers contains both extrachromosomal and integrated viral genomes has recently been challenged.[239] These cancers may instead harbor circular replicons containing both viral and host DNA segments.

Viral genome integration drives malignant progression primarily because it can increase the expression of the E6 and E7 oncogenes, which can occur via several mechanisms. Integration can disrupt the expression of E2, which is a negative regulator of E6/E7 transcription in undifferentiated cells. Alternatively, integration can generate E6/E7 transcripts with 3′ cellular sequences that stabilize the mRNAs,[107] or it can increase transcription by occurring in the vicinity of cellular enhancer elements.[229] Clonal outgrowth of cells with integrated viral genomes exemplifies the selective advantage conferred by E6/E7 overexpression in neoplastic progression, and studies in cervical cancer–derived cell lines indicate that continued expression of E6 and E7 is necessary for their continued viability and proliferative ability.[88] However, integration offers no selective vantage for the virus *per se*, since integrated genomes are unable to produce progeny virions. In cancers where only episomal copies are detected, E2 is often inactivated, frequently by mutation or epigenetic silencing, resulting in dysregulation of E6/E7 expression.[52]

It has been postulated that the viral genome can also contribute to carcinogenesis by insertional mutagenesis via integration in the vicinity of cellular protooncogenes or tumor suppressor genes, activating and repressing their expression, respectively. Viral DNA integration near the c-Myc proto-oncogene has been observed in up to 10% of cervical cancer in some case series and was associated with its increased expression.[104,376] However, current evidence suggests that insertional mutagenesis is not obligatory for malignant progression and functions in only a minority of cervical cancers.

It is noteworthy that HPV-16– and HPV-18–positive cell lines derived from cervical and anal cancers harbor wild-type versions of p53 and pRb, in contrast to HPV-negative tumor-derived cell lines, many of which have mutations in p53- and pRb-related pathways.[242] This observation implies that there is sufficient functional inactivation of p53 and pRb by HPV E6 and E7, respectively, and that there is virtually no selective pressure for the genetic inactivation of the *p53* and *pRb* genes. Another consistent feature of dysplasias and cancer is that most cells express the p16 tumor suppressor, as a cellular response to the E7-dependent inactivation of pRb,[25] again in contrast to many tumors not associated with HPV, in which p16 tends to be silenced. Immunostaining for p16 has frequently been used as a surrogate marker for elevated HPV E7 expression.

The E7s of high-risk HPVs stimulate DNA replication stress that leads to DNA breakage and chromosomal instability.[185] In addition, high-risk HPVs induce abnormal centrosome duplication, which can result in genomic instability and aneuploidy.[102] The deregulation of this mitotic event appears to depend on both E6 and E7, with the latter protein being more responsible for the effect.[185] In a study that compared the incidence of aneuploidy and viral DNA integration, both were associated with increasing dysplasia.[232] Although 95% (19/20) of lesions with integrated viral DNA were aneuploid, only 59% (19/32) of aneuploid lesions had integrated viral genomes. As aneuploidy was found significantly more frequently than integration, it was concluded that deregulated viral oncogene expression results first in chromosomal instability and

aneuploidization, which are subsequently followed by viral DNA integration.

Although the E5 gene, which can potentiate signaling through growth factor receptors and promote immune evasion (discussed below), is considered an oncogene, the studies mentioned above imply a central role for high-risk E6 and E7 in cervical cancer pathogenesis, and tumors that contain only integrated HPV DNA have usually lost expression of E5. However, some evidence suggests that, in HPV-16–associated tumors that retain extrachromosomal copies of the viral genome, E5 may also contribute to their pathogenesis. In one study, HPV-16 E5 protein was detected in 12/20 (60%) of invasive cancers.[53] A more recent study confirmed the loss of E5 transcription with integration of HPV-16 or HPV-18 genomes in cervical cancers and further found no association between E5 expression and overall survival of the patients.[19]

Cellular Events in Cervical Cancer

Although infection with high-risk HPV may be necessary for the development of cervical cancer, or other cancers attributable to HPV infection, it is clearly not sufficient. Cancers arise long after initial infection and only after other factors have collaborated with the infection. As discussed above, some changes (e.g., integration) may be virus specific. Other changes associated with progression include genetic and epigenetic alteration of cellular genes that complement the activities of high-risk HPV E6 and E7. A genomic characterization of 228 primary cervical cancers with whole genome sequencing and RNAseq analyses by The Cancer Genome Atlas (TCGA) Research Network found that mutations characteristic of ABOBEC3 cytidine deaminase activity predominated.[45] This finding is consistent with the observation that ABOBEC3, a mutagenic cellular antiviral protein, is activated in response to many viral infections, including HPV.[335] ABOBEC3B is consistently elevated in HPV-associated cancers. The mechanism of its activation by high-risk HPV infection is uncertain. It may involve the interactions of E6 with p53 and E7 with pRB, but infection by HPV pseudovirions, which do not encode the viral oncogenes or other viral genes, also induces ABOBEC3 expression.[275] It is also uncertain whether this induction has evolved primarily as a host strategy to limit HPV replication, a viral strategy to promote adaptation and immune escape by increasing sequence diversity in the viral genomes, a viral strategy to suppress virus induction of host LINE element transposition, or some combination thereof.[373] Regardless, it is clear that a cellular mechanism that has evolved to restrict replication of a broad range of viruses plays a key role in the progression of HPV-associated cancers.

The mutations, amplifications, and deletions observed in the TCGA analyses result in a spectrum of down-regulation of tumor suppressor and proapoptotic genes and up-regulation of proto-oncogenes and antiapoptotic genes. For example, potentially drug targetable activation in receptor tyrosine kinases, PI3 kinase, and MAP kinase pathways were frequently detected.[45] In addition, gene inactivation in pathways downstream of TGF beta, a growth-suppressive and proapoptotic factor in normal cells, was notably common, including inactivation of the TGF-beta receptor, CREB-binding protein, and the SMAD4 transcription factor. Epigenetic silencing, including DNA methylation and histone acetylation, of numerous genes is also seen in cervical cancers and has been reported to precede cancer development. For example, in one recent study, a cancer-like cellular DNA methylation pattern was detected in 72% of CIN3 and 55% of CIN2 but was virtually absent in high-risk HPV-positive asymptomatic infections.[363]

Other Cofactors in Cervical Cancer

Because only a small percentage of women infected with high-risk HPV have a malignant outcome, host and environmental factors have been examined for their possible influence on the incidence of cervical cancer and its precursor lesions.[55] When controlled for the presence of HPV infection, consistent association of increased risk has been found for smoking, oral contraceptives, early age of pregnancy, and multiparity.[51,162,163] Nutrition, micronutrients, and sexually transmitted diseases other than HPV were also associated with increased risk in some studies.[332,334] In addition, studies using next-generation sequencing of bacterial 16S rRNA have linked elements of the vaginal microbiome with persistence of HPV infection and progression to precancer or cancer.[198,358] In particular, increased disease severity was linked to increased bacterial diversity and low levels of *Lactobacillus* species.[236] In most instances, it is not clear how these cofactors contribute to dysplasia and carcinogenesis, or even if they are causally related. Possibilities include increasing the risk of establishing infection, decreasing local or systemic immunity, stimulating the growth of HPV-infected tissue, and inducing mutations in infected tissue. Furthermore, it is important to note that, where associations between these factors and cervical cancer were observed, the odds ratios were relatively low, generally in the range of 1.5 to 4.0. In comparison, the odds ratios associated with high-risk HPV infection were often over 100.[29]

Human Papillomavirus in Other Genital Sites

Anogenital Warts (Condylomas)

As with cervical HPV infection, condylomas, that is, anogenital warts (GW), are most prevalent among young, sexually active adults, and their frequency usually parallels that of other sexually transmitted conditions.[17,267] The estimated prevalence in the United States is 1% of the sexually active population aged 15 to 49, with about 7% of women and 4% of men giving history of at least one episode.[93] A survey conducted in the United Kingdom in 2010–2012 found that 3.8% and 4.6% of 16- to 44-year-old sexually experienced men and women, respectively, self-reported a GW diagnosis.[338] A similar proportion of reported GWs was found in a parallel survey in 1999–2001. In a worldwide survey, the median annual incidence of GW was 137 and 126 per 100,000 in men and women, respectively.[270] About 90% of genital warts are caused by HPV-6 or HPV-11, which are closely related to each other, with HPV-6 predominating.[106,133] Other HPV types, including HPV-16, may also be found in these lesions.

Condylomas are usually exophytic lesions that are frequently multiple. They can arise anywhere on the external genitalia and can be found simultaneously in multiple sites. In men, they occur most commonly on the penis and anus, and in women on the perineum and anus. The anus can develop multiple lesions that coalesce to surround the anal canal. Condylomas are usually self-limited, regressing spontaneously or after local treatment, but some lesions can persist for years.[272] As with other HPV infections, GWs, when they arise in patients with impaired cellular immunity, can be highly refractory to treatment. They can also increase in size and number during pregnancy and regress following delivery.[241] This sequence of events may be a reflection of the immune suppression associated with pregnancy.

GWs in children commonly result from virus inoculation at birth or from incidental spread from cutaneous warts,[233,345] although some GWs in children may be sexually transmitted, secondary to sexual abuse.[292] In contrast to anogenital lesions in adults, a significant proportion of GWs in children contain HPV types that are usually isolated from nongenital warts, perhaps because, compared with adults, the genital skin in children is more susceptible to infection with these nongenital HPV types.[167]

Bowenoid papulosis is a related entity.[134] The lesions usually consist of multiple small papules that histologically resemble Bowen disease or squamous cell carcinoma *in situ*. Most of these lesions contain HPV-16, but the rate of transition to frank malignancy appears to be much lower for the external genitalia than for the cervix.

Vulvar, Vaginal, and Penile Malignancy

Genital HPV can routinely infect other genital areas that contain stratified squamous epithelium. The risk of malignant progression associated with HPV infection at non-cervical sites is less than that of cervical infection, perhaps because these tissues lack a defined transformation zone from simple columnar to stratified squamous epithelium. High-risk HPVs, most often HPV-16, are associated with a subset of cancers of the vulva, vagina, and penis. Worldwide HPV attributable fractions for 2018 were estimated to be 25%, 78% and 53%, respectively (Fig. 3.3).[81] Giant condyloma acuminatum, also called the *Buschke-Löwenstein tumor*, is a low-grade, locally invasive squamous cell carcinoma that involves the external genitalia, most frequently the penis. It is associated with low-risk HPV types, such as 6 and 11.[137]

In squamous cell carcinoma of the vulva, most HPV-positive invasive tumors are designated morphologically as being warty or basaloid, tend to arise in younger women, and have a better prognosis than HPV-negative cancers, which tend to have a keratinizing morphology.[252,384] HPV-16 predominates in vulvar and vaginal cancers (>75%) and high-grade dysplasias (VIN2/3 and VAIN2/3), but a broader range of low-risk and high-risk types is detected in low-grade lesions (VIN1 and VAIN1).[87] Risk factors for vulvar and vaginal cancers are similar to those for cervical cancer and include immunosuppression, irradiation, smoking, and infection with herpes simplex virus type 2.[161] Vulvar and vaginal (and also anal) high-grade dysplasia and cancers occur more frequently in women with a previous history of cervical HPV infection or dysplasia.[27] Some evidence, based on virus–host DNA junction analysis, suggests that, in some instances, dysplastic cells may actually have been self-transplanted from the cervix to these sites.[368] Family history is also a risk factor for vulvar, vaginal, and penile cancer.[397]

The incidence of penile cancer, almost all of which are squamous cell carcinomas, is low in most highly developed countries, generally less than 1/100,000 but may be four times higher is some developing countries. In a systematic review in which 48% of penile cancer was HPV positive, the most frequently detected types were HPV-16 (30.8%), HPV-6 (6.7%), and HPV-18 (6.6%).[15] In addition to sexual activity, risk factors include smoking, phimosis, and lack of circumcision.[234]

Anal Cancer

Anal cancer shares important similarities with cervical cancer, as well as some differences. The disease is more frequent in women than in men, with about 19,000 HPV-attributable annual

cases in women and 9,000 annual cases in men worldwide.[81] Its incidence has been gradually increasing in the United States since the mid-1980s, with a similar rate of increase in men and women between 1992 and 2004.[169] Anal HPV infection appears to be sexually transmitted in most instances, and a history of receptive anal intercourse in women and of homosexual activity in men is associated with an increased risk for this cancer.[114] Such a history is often lacking, however, which makes it likely that many anal infections have spread from other genital areas. Consistent with this interpretation, simultaneous cervical and anal infection, often with the same HPV type, is common, and the prevalence and type distribution of anal infection by high-risk HPVs in women appears to be similar to that of cervical infection.[258] However, in spite of the fact that cervical cancer incidences have decreased dramatically in countries with comprehensive screening programs, the worldwide incidence of cervical cancer remains 30-fold higher than that of anal cancer.[81] As with cervical cancer, high-risk HPV has been found in almost all anal cancers, with an even greater preponderance of HPV-16 than in cervical cancer, and most anal cancers arise in the transition zone between columnar and squamous epithelium. However, the anal transformation zone does not harbor the distinctive monolayer of undifferentiated embryonic cells seen in the cervical transformation zone, which might make it less susceptible to malignant progression after high-risk HPV infection.[392]

The risk of anal cancer among individuals who are human immunodeficiency virus (HIV) positive is much greater than that in the general population, with especially high rates for HIV-positive men who have sex with men (MSMs).[69] In a U.S. study from 1996 to 2012, the standardized incidence ratio in HIV-positive individuals overall was 19.1, but was 38.7 for HIV-positive MSMs, which translates to an incidence rate of 89.0 per 100,000 person-years. This rate is approximately twice the rate of cervical cancer in women in high-incidence low-income countries that lack organized screening programs.[9] HIV-positive heterosexual males and females had incidence rates of 11.4 and 7.9, respectively. These differences largely reflect differences in the prevalence of high-risk HPV infection and associated dysplasia.[85]

HPV INFECTIONS OF THE AERODIGESTIVE TRACT

Infections of the Oral Cavity

Benign HPV infections of the oral cavity occur commonly.[123,346] They may be asymptomatic or associated with single or multiple lesions in any part of the oral cavity. Genital–mucosal HPV types, especially HPV-6, HPV-11, and HPV-16, have frequently been recovered from oral tissue. HPV is usually identified in at least one-half of papillomatous lesions in the oral cavity lesions. HPV-6 and HPV-11 seem to be responsible for most benign HPV oral lesions, although HPV-16 may also be found. In a systematic review, 4.5% of healthy subjects were positive for any HPV, 3.5% had high-risk HPV, and 1.3 % had HPV-16.[188] The overall detection rates were similar in men and women. Infections can be transmitted by multiple routes, including perinatal, saliva, and oral sex. The fraction of oral infections by genital mucosal high-risk types due to sexual versus nonsexual transmission is debatable and likely to vary across cohorts.[76,288]

Focal epithelial hyperplasia (FEH) is a familial disorder with autosomal-recessive inheritance that occurs only in the oral mucosa, most often in childhood and adolescence.[282] It is characterized by multiple benign papules, plaques, or nodules. Most cases of FEH are attributed to HPV-13 or HPV-32, two types that appear predominantly to infect the oral cavity.[302] FEH has a worldwide distribution, but it is most prevalent in the indigenous populations of Central and South America and of Alaska and Greenland. In Greenlandic Eskimos, the prevalence in different localities varied between 7% and 36%. By contrast, the prevalence among Caucasian residents in the same localities was less than 1 in 300.

Head and Neck Cancers

Cigarette smoking and alcohol consumption are two well-known risk factors for head and neck cancers. Although HPV does not appear to be involved in most cancers in the oral cavity, consistent data indicate that a subset of head and neck cancers are attributable to HPV infection, with HPV-16 accounting for about 90% of them.[48,189] The attributable fraction varies widely depending on the proportion of cancer from specific anatomical sites in the case series, country of origin, and the relative importance of other risk factors. Most of these HPV-associated cancers are located in the oropharynx, which includes the tonsils, tonsillar fossa, base of the tongue, and soft palette. It is not understood why the HPV-positive tumors preferentially develop in the oropharynx. The worldwide yearly cases attributed to HPV infection are 42,000, 5,900, and 4,100 for OPCs, other oral cancers, and laryngeal cancers, respectively.[81] In comparison to HPV-negative OPCs, HPV-positive cases tend to develop at an early age and respond better to treatment, although the prognostic advantage associated with HPV positivity attenuates with age.

There is accumulating evidence for a global time trend of increased OPC incidence, most notably in North America and northern Europe.[124] In the United Sates, the incidence of OPCs increased more than threefold between 1988 and 2004,[57] and these trends are expected to continue through the current decade.[353] Most of the increase has been in white men, who account for about three-quarters of OPC cases[124] (Fig. 3.10). Coupled with a decreasing incidence in cervical cancer (due to screening programs), there are now more OPCs than cervical cancer in the U.S. (18,900 vs. 11,800) and two-thirds of the OPCs are HPV positive,[361] although the incidence of oral high-risk HPV infection is an order of magnitude lower than that of anogenital infection.[123,142,278] The higher OPC rates in U.S. men than in women are correlated with the three- to fivefold higher prevalence of HPV-16 and other high-risk types in the oral cavity of men.[123] This difference in oral prevalence may be due to lower rates of seroconversion after genital infection in men than in women and therefore less protection against subsequent oral infections.[215]

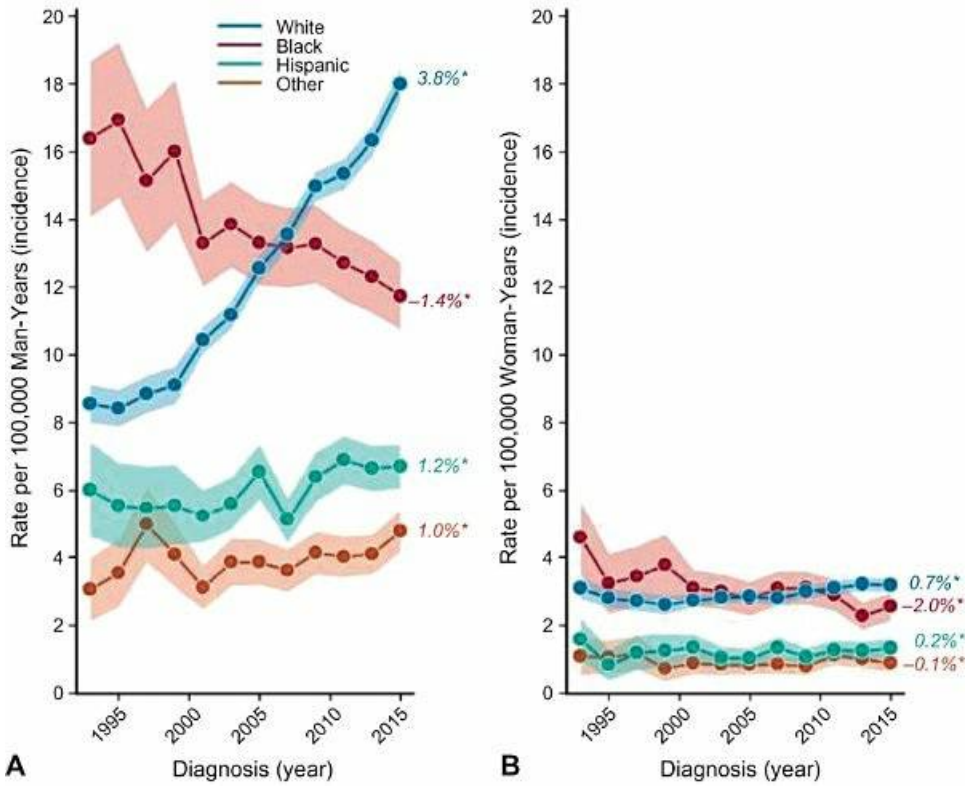

FIGURE 3.10 Incidence trends in oropharynx cancers in the United States stratified by race and sex. Panel A depicts incidence trends in men and **Panel B** the trends in women. (*) indicates statistically significant trend ($p < 0.05$). (Reprinted with permission from Tota JE, Best AF, Zumsteg ZS, et al. Evolution of the oropharynx cancer epidemic in the United States: moderation of increasing incidence in younger individuals and shift in the burden to older individuals. *J Clin Oncol* 2019;37:1538–1546. Copyright © 2019 by American Society of Clinical Oncology.)

Many behavioral risk factors for developing HPV-positive OPC are similar to those for anogenital HPV-positive cancers.[75] In addition, the risk of oral HPV positivity appears to be greatly influenced by the lifetime number of oral sex partners.[124,147] However, the alternative hypothesis that mother-to-child transmission *in utero* or early in life, leading to dysregulation of virus-specific T-cell immunity, is the primary risk factor was recently proposed.[347]

HPV-positive OPC tumors share many molecular features with those of HPV-positive anogenital tumors.[26] Specifically, they preferentially express E6 and E7, their p53 and pRb genes are usually wild type, and the vast majority of them express p16.[168] By contrast, the HPV-negative tumors tend to have mutant p53 and to be p16 negative. Most studies suggest that tobacco and alcohol increase the risk of both HPV-negative and HPV-positive tumors.[56] Despite the similarities with HPV-positive anogenital cancers, there is thus far no clearly identifiable premalignant oropharyngeal lesion for HPV-positive tumors, many of which may form deep in the tonsillar crypts. Interestingly, viral genome integration has been detected in only a minority of HPV-associated oropharyngeal cancers,[117,255] and some of the circular replicons consist of virus and human DNA hybrids.[239]

Recurrent Respiratory Papillomatosis (Laryngeal Papillomatosis)

Laryngeal papillomatosis, which is also called recurrent respiratory papillomatosis (RRP), is a rare condition whose papillomas can severely compromise the airway, particularly in young children.[110] Most lesions are caused by genital HPV types that are also associated with external genital warts, with HPV types 6 and 11 being responsible for more than 90%. High-risk HPV types, including 16, 18, 31, and 33, are infrequently detected in RRP. The vocal cords of the larynx are the site most commonly affected, but the papillomas can arise at other sites, including the trachea, lungs, nose, and oral cavity, even without laryngeal involvement.[348] Lesions can be single or multiple. Symptomatic papillomas are generally treated surgically, with the goal of debulking the lesion without damaging the normal tissue.[382] However, the recurrent nature of the disease means that periodic surgical treatment may be required. It is important to avoid the necessity of performing a tracheostomy in patients with RRP, because papillomas often grow along the tissues involved in the tracheostomy, resulting in severe morbidity. A number of case series have suggested that vaccination with the prophylactic HPV vaccines after surgery can decrease disease recurrence, decrease disease burden, and/or increase intersurgical intervals,[94] although these findings have not been verified in a randomized controlled trial.

Epidemiologic studies suggest that RRP can develop by at least two mechanisms.[200] One primarily affects young children and the other when RRP is first diagnosed in older individuals. The incidence of RRP is approximately 4 per 100,000 in children and 2 per 100,000 in adults.[110] RRP may occur at any age, but the risk of developing it decreases after 5 years of age. In children below this age, a maternal history of genital warts is a risk factor for RRP, and infection is thought to usually occur at birth during passage through an infected genital tract. In a population-based study in Denmark, close to 1% of children whose mothers had a history of genital warts developed RRP, which represented a 231 times higher risk of RRP relative to women without a history of genital warts.[330] *In utero* transmission also occurs but is uncommon, so RRP is extremely rare in children delivered by cesarean delivery.[321] First pregnancy and young age of the mother are associated with an increased risk, whereas cesarean section carries a lower risk.[322] HLA antigen class II polymorphism may also be a contributing factor.[118] A history of oral sex may be a risk factor in adult RRP.[200]

Although HPV-6 causes genital warts more frequently than HPV-11, the reverse is true of RRP, and HPV-11 infections tend to be more aggressive than RRP associated with HPV-6.[96,381] Patients less than 3 years of age also tend to have more extensive and aggressive disease. Given the presumed single exposure to HPV during vaginal delivery, the long and variable latent period of up to 5 years for childhood RRP remains to be explained. Latency has been shown in the larynx of patients with RRP who are in remission.[223]

RRP is associated with a low risk of spread to the bronchi and lungs, progression to severe dysplasia, and even to cancer.[121] The rates of malignant progression are estimated to be lower than 1% in children and 5% in adults. The risk of such progression is increased if the papillomas have been subjected to smoking, cytotoxic drugs, or X-irradiation, which was a common treatment of RRP in the 1940s.[110] In contrast to cervical cancer, HPV-6 and HPV-11 in RRP are clearly associated with severe dysplasia and cancer, with HPV-11 predominating, although most HPV-positive laryngeal cancers arise in patients without RRP and contain a high-risk HPV,

especially HPV-16.[103]

HUMAN PAPILLOMAVIRUS AND THE NONGENITAL SKIN

Nongenital Skin Warts

Three classes of nongenital skin papillomas are generally distinguished based on morphological criteria. Common warts (verruca vulgaris) are exophytic papules that are found on many skin surfaces, most often the dorsal hands and fingers.[115] Although many HPV types are detected in common warts, often more than one within a single lesion, a recent causal estimation based on viral loads has implicated types 2, 27, and 57 in about three-quarters of cases.[35] Plantar and palmar warts are generally endophytic papules, and, in recent studies, more than 90% of cases appear to be caused by HPV-1a, 2, 27, or 57[83] (Table 3.1). Both classes of papillomas occur frequently in older children and young adults, with a peak prevalence at 9 to 10 years and point prevalence estimates of 3% to 30%.[80,329] The third morphologic class consists of flat warts (verruca plana), which are slightly elevated smooth papules, most often on the upper extremities and the face, and are most often caused by HPV-3 or HPV-10.[393]

HPV can remain infectious in the environment for extended periods,[298] and transmission via fomites is thought to commonly occur.[119] Because of the apparent need for HPV to reach the basement membrane underlying the epithelium and subsequently infect basal cells at the time of inoculation,[290] maceration of the skin predisposes to cutaneous infection. Multiple lesions are most common, and they can be distributed symmetrically or be unilateral. Lesions involving apposing areas of skin or mucous membrane, as occurs frequently, probably develop by autoinoculation.

Most skin warts persist for several months and regress in the absence of treatment. A recent retrospective study in children found that 65% of common skin warts spontaneously regressed within 2 years and 80% within 4 years.[197] Regression of lesions is thought to be mediated immunologically. When most lesions regress spontaneously, there may be a mild mononuclear cell infiltrate, although regression of flat warts can be associated with an erythematous reaction around the lesions in association with an intense inflammatory infiltrate. The lower incidence of warts in older individuals[281] likely implies that immune mechanisms have rendered them relatively resistant to reinfection.

Epidermodysplasia Verruciformis

EV is a rare genodermatosis in which affected individuals have a unique susceptibility to cutaneous HPV infections.[219,256] More recently, an “acquired” form of EV has been reported in some immunocompromised patients. The warts in “genetic” EV usually develop in childhood, become widespread, do not tend to regress, and, in some instances, may progress to squamous cell cancers. Two predominant types of lesions are seen, which can occur in the same patient.

Some lesions have the appearance of flat warts, whereas others are flat, scaly, red-brown macules. The flat warts are caused by the same HPV types that induce flat warts in the general population, usually HPV-3 or HPV-10. The scaly lesions are associated with a range of beta-HPV types, especially HPV-5 and HPV-8. Patients with EV are frequently infected with several HPV types. The lesions in patients with EV are resistant to usual treatment modalities.

Genetic EV has been divided into "classical" and "nonclassical" categories.[157] Both classes display autosomal recessive inheritance and many families with EV have a history of parental consanguinity. Classical EV is associated with mutations in the EVER1/TMC6 or EVER2/TMC8 genes and accounts for three-quarters of genetic EV cases.[171] These genes are expressed in T cells and other leukocytes, and EV patients exhibit minor impairment in some cell-mediated immune functions such as cutaneous anergy to common skin test antigens.[273] The genes are also expressed in keratinocytes, where they control zinc efflux. The characteristic feature of classical EV is that patient pathologies are limited to increased susceptibility to clinical manifestations of skin infections by EV-associated HPV types but, surprisingly, they do not have increases in lesions caused by mucosatropic or common wart HPV types.

Nonclassical EV has been linked to mutations in a number of genes that have the common feature of impairing cell-mediated immunity, and patients often present with a variety of other infections and diseases.[157] Genes linked to nonclassical EV include RHOH, an atypical Rho GTPase specific for hematopoietic cells, MST1, a hepatocyte growth factor-like protein implicated in T-cell survival and migration, and CORO1A, an actin-binding protein involved in phagocytosis and a cause of severe combined immunodeficiency.[283] In addition, the genetic defect for a subset of EV patients remains to be determined.

Acquired EV is not associated with a family history of the disease or early onset but rather with immunosuppression, regardless of age, yet clinically, it closely resembles genetic EV. It was first described in organ transplant recipients on immunosuppressive drugs. It is also a rare manifestation of HIV infection, although, surprisingly, lesion development is not correlated with viral load or $CD4^+$ T-cell count.[166]

About one-third of EV patients develop skin cancers in association with their lesions. Most of the malignant tumors remain local, but regional and distant metastases may occur. The risk of malignant progression is limited to the pityriasis-like lesions, which are the lesions that contain the EV-associated types. HPV-5 and HPV-8 are considered the most oncogenic, because most of the skin cancers contain one of these two types.[256] The skin cancers usually develop on sun-exposed areas, implying that carcinoma develops in EV by a combination of infection by an oncogenic EV HPV type plus the cocarcinogenic effects of UV light. p53 mutations are common in EV-associated cancers,[261] in contrast to the mucosal cancers associated with alpha HPV types.

Nonmelanoma Skin Cancer

Nonmelanoma skin cancers (NMSC), which are extremely common, are generally subdivided into basal cell carcinomas (BCC) and squamous cell carcinomas (SCC). They generally arise on exposed areas of skin, most commonly in light-skinned individuals. Sunlight exposure is a predominant risk factor, and tumors associated with sun exposure are usually locally invasive, but only rarely metastasize. The skin of immunosuppressed individuals is at high risk of developing warts as well as premalignant lesions and NMSC, especially SCC, in sun-exposed

areas.[136,155]

The known oncogenic potential of at least some HPV types and the consistent finding of certain beta genus HPV types in SCC associated with EV make HPV infection an attractive etiologic agent for at least some NMSC in individuals who do not have EV.[293] Beta HPVs are known to encode E6 and E7 oncoproteins that can interfere with UV-induced apoptosis in cultured cells, which might allow keratinocytes with UV-induced mutations to survive and progress to carcinomas.[352] They also promote skin carcinogenesis in transgenic mouse models.[144,224,365]

Beta HPV DNA is frequently detected in SCC using sensitive PCR-based detection methods, but it is also frequently detected in normal skin.[32,374] Furthermore, the genome copy number is usually much lower than one copy per tumor cell, in contrast to HPV-associated anogenital and oral cancers. A study employing an unbiased analysis involving high-throughput sequencing of randomly primed mRNAs detected virtually no HPV transcripts in SCC specimens.[12] A recent prospective study evaluating the association between beta HPVs and SCC in over 500 organ transplant recipients for more than a decade found significant associations for detecting five or more beta types in plucked eyebrow hairs and for high beta HPV viral loads. However, the hazard ratios were rather weak, 1.7 and 1.8, respectively. In addition, there was no association between SCC and serum antibodies to beta HPV antigens.[32]

Overall, the association between HPV infection and NMSC in the absence of EV must be considered tentative at present, since continuous expression of predominant HPV types has not been as clearly identified in NMSC in the general population, as it is in EV-associated cancers or mucosal cancers associated with HPV. In addition, the HPV-positive tumors are not clinicopathologically distinct from the HPV-negative ones, in contrast to vulvar or oral cancer. Therefore, it remains possible that the detection of HPV DNA may be an epiphenomenon. This latter possibility needs to be seriously considered, because healthy skin often contains HPV DNA, especially beta types, and removal of the superficial layers of NMSC lesions has been reported to result in a drastic reduction in the proportion of HPV-positive tumors.[109]

However, it remains formally possible that cutaneous HPVs may induce SCC but are not required for their maintenance, secondary to a putative strong biological or immunological selection for their loss during progression.[122] This scenario is referred to as “hit-and-run” carcinogenesis. Interestingly, such a hit-and-run mechanism has been documented in the induction of alimentary carcinomas in cattle infected with bovine papillomavirus type 4 and in an HPV-38 E6/E7 transgenic mouse model, where skin expression of the oncoproteins (and long-term UV exposure) was required for SCC initiation but not for maintenance.[365] Based primarily on observations of reduced UV or chemical-induced skin carcinogenesis in mice colonized with MmuPV1, an alternative hypothesis that cell-mediated immunity to HPV infections of the skin might actually protect against skin cancers has been proposed.[341]

HUMAN IMMUNODEFICIENCY VIRUS AND HUMAN PAPILLOMAVIRUS INFECTIONS

The interaction between HIV and genital HPV infections centers on two interrelated questions. First, does HPV infection potentiate acquisition of HIV? Second, does HIV infection increase risk of HPV-induced cancers? The effect of HPV infection on risk of HIV acquisition remains uncertain. An increased risk of HIV seroconversion with existing or incident HPV infection was reported in two meta-analyses, but the association was not strong, as the odds ratio was 1.9, and it is difficult to exclude residual confounding biases, especially since the infections share the same primary risk factor, sexual transmission.[154,212] Two mechanisms have been proposed of how HPV infection would increase HIV acquisition. First, HPV infections can increase the local tissue concentration of T cells, including T helper cells, a primary target for HIV.[355] Second, *in vitro* studies have reported that HPV-16 E7 down-regulates E-cadherin, an epithelial adhesion molecule and might thereby increase HIV virion access to underlying dermal T cells that are thought to play a role in initiating infection in the anogenital tract.[203]

By contrast, there is considerable evidence that HIV infection potentiates HPV carcinogenesis. However, the magnitude of the increased risk is difficult to generalize, because CD4 T-cell counts inversely correlate with the magnitude of risk, and they vary considerably in study populations, primarily based on access to active retroviral therapy (ART).[174] In addition, more intense screening in HIV positives in some setting can increase the detection of premalignant lesions and subsequent treatment can decrease cancer incidences. Finally, the aforementioned common risk factors for acquisition of the two viruses can bias toward stronger associations. A large retrospective study of a U.S. cohort over the period from 1980 to 2004 (spanning the institution of ART) observed an increase in all major HPV-associated cancer in person diagnosed with HIV/AIDS. The standardized incident ratios (SIRs) and 95% CIs were 5.6 (4.8 to 6.5) for cervical cancer, 34.6 (20.8 to 38.8) for anal cancer, 8.4 (3.8 to 16.0) for vaginal or vulvar cancer, 4.4 (1.9 to 8.7) for penile cancer, and 1.6 (1.2 to 2.1) for OPC.[60]

There is biological plausibility, and mounting evidence, that HIV infection potentiates several steps in the process of HPV carcinogenesis, most notably persistence of infection and progression to cancer.[244] A higher prevalence of genital high-risk HPV infection, and particularly multiple infections, is generally observed in HIV positives versus negatives in a given population. For example, in a cohort of HIV-infected and uninfected Ghanaian women, the prevalence of genital HPV infection was 75.0% versus 42.6%, respectively.[254] Prevalence is a function of both acquisition rate and persistence of the HPV infections, and both parameters are higher in HIV-infected women. For example, in a U.S.-based cohort, the 8-year cumulative detection of cervical high-risk HPV DNA was 67% in HIV-seropositive women versus 36% for HIV-seronegative women ($p = 0.001$).[228] In a similar cohort, 24.1% of the HPV infections in HIV-positive women persisted, as defined by HPV DNA positivity in cervical samples taken 3 to 12 months apart, versus 3.9% in HIV-negative women.[343] Many subsequent studies have documented that cervical infections tend to persist longer in HIV-positive women.

HIV-positive women also progress from normal cytology or LSIL to HSIL more rapidly than do their HIV-negative counterparts. For example, in a 10-year U.S. study, the rate of progression to HSIL was 5.3 versus 1.3 per 1,000 person-years, respectively.[227] HIV status can also influence HPV type distribution in HSIL/CIN3, with HPV-16 infections less dominant in HIV-positive women (OR 0.6, 95% CI 0.4 to 0.7).[67]

As discussed below, it is likely that T cells play a critical role in clearing HPV infection, so the increased persistence and progression of HPV infection are likely attributable to the well-

documented T-cell dysfunction induced by HIV infection. Consistent with this conjecture, risk of cervical cancer tends to increase with decreases in CD4 counts. In a large North American study of HIV-infected women, the rate of invasive cervical cancer was 7.7, 3.0, and 2.3 times greater in women with CD4 counts of less than 200, 200 to 349, greater than 350 cell per mL, respectively, compared to HIV-uninfected women (p(trend) = 0.001).[1] There is evidence that initiation of antiretroviral therapies that improve CD4 counts modestly increases the rate of cervical lesion regression and decreases the rates of progression approximately twofold.[2]

Immunity

A defining feature of HPV infections is their persistence, implying that they successfully evade elimination by host immunity. Although some infections, particularly with some species of the HPV beta genus, may persist lifelong in an occult fashion, most HPV infections are nevertheless cleared, or controlled to undetectable levels, within months or years. For example, up to 90% of anogenital HPV infections clear within 2 years.[152] In addition, incident infection rates tend to decline with age after they peak, consistent with the acquisition of effective immunity, and adaptive T-cell immunity is implicated in clearance/control. Individuals with conditions that affect T-cell immunity, such as pregnancy, immunosuppressive chemotherapy, or HIV infection, are at increased risk of HPV infection that persists, as well as an increased risk of HPV-associated cancers.[11,113] At least some of these infections likely represent reactivation of latent infection, rather than being secondary to new exogenous exposure. Even benign HPV infections in immunosuppressed patients are notoriously difficult to treat, and reduction of the immune suppression may be associated with the spontaneous improvement of the HPV-induced lesions.[286] Consistent with the critical role of adaptive T-cell responses in control of HPV infections, specific class I and class II human leukocyte antigen (HLA) alleles have been associated with increased or decreased risk of persistent genital HPV infection, or progression to precancer and cancer.[260] By contrast, defects in B-cell immunity do not appear to greatly influence the course of HPV infections once established.

HPVs evade effective immune responses by three broad mechanisms: maintenance of immune ignorance, suppression of innate immune responses, and inhibition of effective adaptive immune responses.[217,379,399] As detailed in the accompanying chapter on basic PV biology, the PV life cycle appears to have evolved specifically to promote immune ignorance. It takes place entirely within a stratified epithelium, with no significant viremia to expose the viral antigens to the systemic immune system.[97] Furthermore, viral gene expression in the epithelium is regulated in a way that limits exposure to local intraepithelial immunity. Only low levels of the nonstructural proteins are expressed in the lower levels of epithelium where the infection is maintained and where immune surveillance is active. High-level expression of viral genes and production of virions occur only in the terminally differentiating keratinocytes of the upper layers of the epithelium, which are under limited immune monitoring (Fig. 3.2). Cell lysis is not induced during productive infection, so there is no release of cellular danger signals to alert the immune system of its presence. Rather the virions are released from or in the desquamating cells in the upper most layers of the epithelium. Low intrinsic immunogenicity of the viral proteins does not seem to play a role. For instance, the capsids can be highly immunogenic when exposed to the systemic immune system, as exemplified by the VLP vaccine studies discussed below.

In part because of this effective maintenance of ignorance, the immune responses to

infections are typically delayed and muted. Virion antibody responses have been best characterized for genital infections in women. Systemic antibodies are generally not detected until months after initial infection, and the titers induced are modest.[91] Responses may be somewhat more robust for genital wart types than high-risk types.[47] Many infections clear without the induction of a measurable systemic antibody response. The fact that PVs have evolved into hundreds of genotypes that are essentially distinct serotypes that cannot be effectively cross-neutralized by antibodies induced by natural infection or VLP vaccination strongly implies that such antibodies play an important role in virus/host interactions.[360] It is unlikely that virion antibodies play a role in clearing infections because the virion proteins are not expressed on the surface of living cells, so they are not susceptible to known antibody-mediated mechanism of immune regression, and virion antibodies at the time of detection of prevalent infection are not associated with persistent/clearance of genital HPV-16 infection.[354] However, neutralizing antibodies induced by infection likely play a role in preventing successive rounds of autoinoculation, reinfection from an external source, and perhaps spread to another host. The latter can be readily envisioned for female genital mucosal infections where the virions are shed into mucus that can also contain virion-neutralizing antibodies.[247]

There is some disagreement in the literature over whether virion antibodies measured after natural infection can protect from reinfection.[299,354,369] It seems quite likely that women with higher-than-average virion antibody titers to mucosal types in their serum are afforded at least partial protection from type-specific reinfection.[300] A meta-analysis of studies up to 2016 reported that antibodies to HPV-16 capsids were associated with protection in women (pooled RR, 0.65; 95% CI 0.50 to 0.80) but not in men (pooled RR, 1.22; 95% CI 0.67 to 1.77).[20] However, the interpretation of these studies is confounded by difficulties in distinguishing reinfection from reactivation of latent infection, in distinguishing low level of virion-specific from nonspecific antibodies, and by the possibility that antibody responses might often be a surrogate marker for protective cell-mediated immune responses.

Most adults are seropositive for L1 antibodies to one or more cutaneous HPVs, and the antibody responses tend to persist.[8] The role of these antibodies in the natural history of cutaneous HPV infection is not well understood.

Specific antibody responses to the early (nonstructural) viral proteins are seldom detected, except in the case of invasive cancers.[21] In cervical cancers, responses to E6 and/or E7 are detected in approximately half of the patients.[370] An exception appears to be HPV-16–associated OPCs, where approximately one-third of patients have detectable HPV-16 E6 antibodies up to 10 years prior to cancer diagnosis.[192] The preferential development of these cancers in tonsillar crypts juxtaposed to lymphoid tissues might explain the more frequent antibody response in subjects who subsequently develop OPC.

The cell-mediated immune effector mechanisms and viral antigens involved in lesion regression and prevention of reactivation are not well defined. Descriptive studies of cell-mediated immune responses have mostly focused on genital infections in women. Until recently, most studies have evaluated systemic responses, whereas local mucosal responses are likely to be the critical determinants. Many healthy individuals develop relatively strong systemic type 1 (IFNγ, TNFα, IL2 producing) T-cell responses to L1, but they are unlikely to be protective, since L1 is not detectably expressed in the basal layers of the epithelium, where the infection is maintained. More modest systemic CD4+ and CD8+ cytotoxic T-cell (CTL) responses to E6 and

E7 are often also detected in women with previous or current cervical genital HPV infections.[245] Interestingly, failure to clear HPV-16 infection was associated with lack of induction of CTL to E6, but not to E7.[246] In women with HPV-16–associated CIN1, CD4 T-cell responses to E2 and E6 were most frequently detected, and Th1-type CD4 responses to these viral proteins are also most frequently detected in women without infection.[79,375] In a prospective study, the presence of HPV-16 E2-specific responses in an IFNγ ELISPOT assay correlated with lack of progression of HPV-16–associated lesions.[388]

In some studies, the local tissue responses in regressing cervical lesions have also been characterized. Granzyme B–expressing CD8 T cells predominated, and a higher ratio of CD8 and Foxp3-negative CD4 cells over CD4 Foxp3-positive (regulatory) CD4 T cells was detected.[259,387] By contrast, the infiltrates in persistent and progressing lesions were associated with a suppressive environment, including granzyme B–negative and PD-1–expressing T cells (a sign of immune exhaustion) and high numbers of Foxp3+ Tregs, and macrophages.[140,165] There is a shift from a Th1 to a Th2 response in persistent infections, and a greater number of Th17 cells are seen in higher grade lesions. In a prospective study of high-grade HPV-16–associated CIN lesions, infiltration of CD8+ T cells into the epithelium was observed in lesions destined to regress.[355] They were excluded from the epithelium in lesions that persisted, although infiltrates in the submucosa adjacent to the lesions were frequently observed. The results suggest that dysregulation of T-cell trafficking and/or adhesion plays a role in viral immune evasion.

HPVs actively inhibit innate immune recognition of infected keratinocytes by multiple mechanisms. Suppression of innate immune responses to its double-stranded DNA genome occurs by at least three mechanisms. First, the viral genome appears to be shielded from host foreign DNA sensors by remaining enclosed in the virion coat proteins within a membrane-bound vesicle during infectious entry until it is delivered to the nucleus.[78] Second, viral proteins interfere with the activity of the DNA pattern recognition receptor (PRR) TLR9, which can trigger downstream inflammatory cascades. For example, HPV-16 E7 down-regulates TLR9 expression by recruiting histone demethylase JARID1B and histone deacetylase HDAC1 to the TLR9 promoter.[143] Third, the E7 proteins of both HPV-16 and HPV-18 have been shown to block the activity of STING, a cytosolic protein that induces inflammatory responses after recognition of cytosolic DNA that has been converted into cyclic diGMP/AMP by cyclic GMP/AMP synthase (cGAS).[201,216] Yet to be explained is why the latter mechanism has evolved if the viral genome replicates in the nucleus and seems to avoid cytoplasmic exposure during infectious entry. One possibility is that, during cell division, segregation of the multicopy viral genome to daughter nuclei is not always complete, leaving some copies in the cytoplasm where they would otherwise be recognized by the cGAS/STING sensing mechanism. In addition, the HPV E6 proteins of a number of high-risk and low-risk alpha HPVs, and also beta HPVs, inhibit activation of retinoic acid–inducible gene-1 (RIG-1), a cytoplasmic sensor of viral RNA that can activate the production of antiviral interferons.[62]

Viral proteins also more directly evade the innate immune activities of type 1 IFNs, mainly IFNα and IFNβ, by inhibiting their production and their activities. HPV-16 E6 binds to interferon regulatory factor (IRF)-3 and thereby prevents its ability to activate the IFN promoters,[296] while HPV-16 E7 inactivates IRF-1, also leading to inhibition of IFN gene transcription.[266] In addition, HPV infection induces up-regulation of the deubiquitinating enzyme ubiquitin C-terminal hydrolase L1 (UCHL1), which results in the inhibition of TRAF3, a protein that transmits the

signals from activated TLRs to the IRFs involved in type 1 IFN production. HPV E6 and E7 also inhibit the activities of the IFNs that are produced in response to infection by interfering with signaling through the IFNα/β receptor (IFNAR). They do this via multiple mechanisms focused on inhibiting the transcriptional activation of the IFN genes by STAT1 and/or STAT2 (Fig. 3.11) by decreasing their expression, phosphorylation, and nuclear translocation.[16,54,209,248]

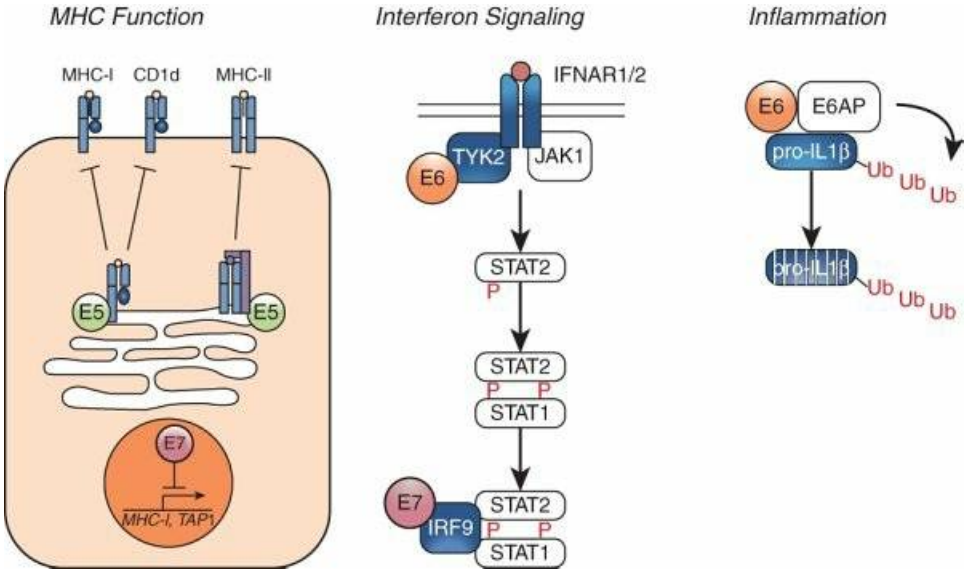

FIGURE 3.11 HPV oncoproteins inhibit immune responses by multiple mechanisms. Mechanisms that inhibit antigen presentation, type 1 interferon signaling, and degradation of proinflammatory cytokines are depicted from *left* to *right*. (Reprinted from Westrich JA, Warren CJ, Pyeon D. Evasion of host immune defenses by human papillomavirus. *Virus Res* 2017;231:21–33. Copyright © 2016 Elsevier. With permission.)

High-risk HPV infections also down-regulate the NF-κB pathway, a signaling pathway involved in activating the expression of multiple genes of innate immunity, such as IFNs, cytokines, and defensins, as well as genes involved in antigen presentation in adaptive immunity. As with the STATs, they do so by multiple mechanisms. Both E6 and E7 bind nuclear cofactors, for example p300 and CBP, that activate NF-κB.[158,269,401] In addition, up-regulation of UCHL1 leads to increased degradation of an essential modulator of NF-κB, which decreases NF-κB phosphorylation and its downstream signaling.[172]

Lastly, it was shown that HPV-16 E6 directly down-regulates protein levels of IL-1β, a key proinflammatory cytokine of innate immunity.[249] It does so by inducing the ubiquitin-dependent degradation of pro-IL-1β upon formation of a complex with it, p53, and E6-AP, the ubiquitin ligase involved in E6-mediated p53 degradation (Fig. 3.11).

HPVs have also evolved multiple mechanisms to evade recognition by the adaptive immune systems (Fig. 3.11).[18] E5 of multiple high-risk and low-risk types reduces cell surface expression of MHC I molecules on keratinocytes by interacting with their cellular transport proteins and thereby sequestering the MHC I molecules in the Golgi and ER, leading to reduced recognition

by CD8 T cells.[14,135] HPV-16 and HPV-6 E5 also sequester CD1d in the ER, which inhibits its cell surface expression. CD1d is the invariant MHC-like molecule that presents lipid antigens to natural killer cells (NKTs), suggesting that NKTs may function in controlling HPV infection.[237] High-risk E7s repress MHC expression by recruiting histone deacetylases to their promoter (Fig. 3.11).[120,208] By a similar mechanism, E7 also inhibits transcription of TAP1 and LMP2, which are critical components in loading peptides on MHC I molecules.[120]

HPVs of the alpha and several other genera decrease the local concentration of tissue Langerhans cells (LCs), a primary antigen-presenting cell type in the epithelium, which may create an environment permissive for viral persistence by helping to prevent the priming of an adaptive immune response to the virus.[207] Two explanations for the lower LC density in infected tissues have been proposed. First, E-cadherin is involved in retention of LC in the epithelium, and its expression is reduced in infected lesions.[159] Second, CCL20 is a chemokine that recruits LC to sites of inflammation, and E6 and E7 down-regulate its expression by the previously described inhibition of the NF-κB signaling pathways.

The above discussion on immune evasion was focused on immune deviation in normal keratinocytes during productive infections within an epithelium. However, the normal tissue architecture is disrupted in invasive HPV-induced cancers, and they are therefore subject to same selective pressures of systemic immunity as other carcinomas. Nevertheless, many of the mechanisms described above that reduce innate immunity and inhibit induction of adaptive immunity, especially those that are E6/E7 mediated, which have evolved to promote viral persistence during their normal life cycle, are also likely to function in inhibiting effective immune responses after progression to cancer. A presentation of the complexities of the immune responses observed in HPV-associated cancers is beyond the scope of this chapter, but they are critically discussed in several recent reviews.[336,357,399]

DIAGNOSIS AND TREATMENT

Human Papillomavirus Diagnosis

The approach used for the diagnosis of HPV infection may depend to a considerable degree on the underlying goal for making the diagnosis. These goals can include a determination of whether HPV is present, whether an active infection is present, which HPV type is associated with the infection, and the degree of cellular atypia associated with the infection. If routine *in vitro* propagation of HPV from clinical samples was available, its isolation from productive infections, theoretically, would be possible. No such assays exist, however, and their utility would be limited by the fact that high-grade dysplasias and cancers do not produce infectious virus. The potential use of virus-specific antibodies to detect infected cells in tissue sections or extracts is limited by analogous considerations. L1 and E4 proteins can be expressed at high levels in productive lesions, but not in high-grade dysplasias and cancers.[99] The expression of E6 or E7 proteins is higher in advanced lesions, and the clinical utility of detecting the E6 proteins of high-risk types remains an area of active investigation.[284]

Serologic assays in an ELISA format that monitor the antibody response to L1 in VLPs have

utility for population-based research studies to measure relative lifetime infection by specific types, although not all infected individuals seroconvert.[47,91,251] More recently, multiplex assays that permit simultaneous detection of antibodies to multiple HPV VLP types have been developed and employed in natural history studies and vaccine trials.[289] Various *in vitro* neutralization assays, based on L1/L2 pseudovirion transducing marker gene plasmids, have also been developed and exhibit sensitivities similar to ELISAs.[268,319] However, these assays, which measure both current and past infection, are not sufficiently sensitive to be used for routine clinical diagnosis. Invasive cervical cancers, but not the premalignant lesions, are associated with serum antibodies against E6 and/or E7; however, approximately one-third of patients were negative for antibodies to the type corresponding to the HPV DNA type in their cancer.[70] Unlike cervical cancer, virtually all patients with HPV-16–positive OPC have detectable anti-E6 serum antibodies.[153,199]

In contrast to serology, sensitive, reproducible, and robust molecular assays have been developed to detect HPV DNA and RNA in cervical swabs and biopsy samples, several of which have been approved by the FDA.[74,313,398] Approaches for such assays include PCR consensus primers (or alternative amplification systems) that can be used in conjunction with a reverse line blot for specific hybridization, synthetic RNA probes that capture viral DNA, real-time PCR, and microarrays. Some assays detect L1 DNA sequences, whereas others detect E6 or E7 DNA or RNA. More recently, assays based on high-throughput next-generation DNA sequencing have been developed and validated. Because they can determine the entire viral genome sequence, they provide variant, as well as type-specific, information.[371] The highest analytical sensitivity may be preferred if the goal is to detect as many infections as possible. However, as discussed below, a lower sensitivity threshold may be more useful clinically, as it can increase the specificity for identifying high-risk lesions.

CANCER SCREENING

For cervical cancer screening, the goal is to maximize identification of those infections associated with high-grade abnormalities (true positives), which usually should be treated, while excluding as many infections with no or only low-grade abnormalities (false positives) as possible, which should not be treated because most are destined to clear spontaneously (Fig. 3.7). Achieving this balance means that the signal used for screening must exceed a certain threshold, in order to reduce the number of false positives, while still identifying the vast majority of true positives.

Since its introduction in the 1950s, cytologic screening with Pap smears, whose goal is to prevent cancer by identifying premalignant lesions that can then be treated, has been the principal test for assessing cervical cancer risk.[23] Coupled with colposcopic follow-up of high-grade findings and ablation of histologically confirmed CIN2/3, its use has led to a greater than 70% reduction in cervical cancer mortality in developed countries with high-quality testing at regular intervals.[301] However, Pap-based screening has proven difficult to implement in most low-resource settings, because it is difficult to initially establish a program requiring well-trained cytologists, quality control can be challenging, and a single Pap test has relatively low sensitivity

in identifying premalignant lesions, which means the test must be repeated on a regular basis.

HPV-based assays have greater sensitivity than cytology, which gives them several advantages, including greater negative predictive value, which can permit longer intervals between screens, and a greater sensitivity in detecting cervical adenocarcinoma precursors, which cytologic screening tends to miss.[23,173,287,295] However, the specificity of HPV DNA for cervical precancer can be relatively low, particularly in younger women, because they generally have relatively high rates of infection and high rates of subsequent clearance. To avoid excessive follow-up and overtreatment of infections destined to regress, HPV-based testing is generally not recommended for younger women, under 30 in the United States. However, co-testing with cytology and HPV has been adopted for women over 25 to 30 in some countries. The U.S. Preventative Services Task Force cervical cancer screening guidelines now recommend cytology-based screening every 3 years for women 21 to 65 years of age or co-testing with cytology and an FDA-approved HPV test every 5 years for women 30 to 65.[318] HPV testing is also recommended for women with equivocal (ASCUS) Pap smears.

Hybrid Capture II (Digene), a signal amplification test, was the first HPV test approved by the FDA, in 2003. Since then, four additional signal and nucleic acid amplification–based tests have been approved: Cervista HPV HR (Hologic), Cervista HPV 16/18 (Hologic), Cobas HPV test (Roche Molecular Systems), and APTIMA HPV, which detects HPV E6/E7 mRNA (Gen-Probe). Some assays use a cocktail that can detect more than 10 high-risk HPV types in aggregate, while other assays report type-specific results. The greater oncogenicity of HPV-16, and HPV-18 and 45 to a lesser extent, argues for the importance of knowing whether a patient is infected with these HPV types. In 2014, the FDA approved the Roche Cobas test for primary screening in women starting at age 24. It is likely that primary HPV screening will become the standard of care in many countries in the coming decade.

Recent guidelines for follow-up of positive HPV tests, or co-tests with cytology, are based on estimates of the absolute risk that the result predicts a precancer (Fig. 3.12).[89,276] Therefore, follow-up varies by HPV type identified, based on the relative risk of the infection reflecting the presence of a precancer (Table 3.2). For example, the U.S. guidelines recommend immediate referral to colposcopy of HPV-16 or 18 DNA–positive results, while referral to cytology is recommended for positive results for other high-risk HPV types.[160]

TABLE 3.2 Risk of CIN3+ by HPV genotyping and cytology with no prior HPV testing history

Current HPV	Current Cytology	CIN3+ Immediate Risk, %	CIN3+ 5 Year Risk, %
HPV-16	NILM	5.3	8.8
HPV-18	NILM	3.0	4.5
HR12	NILM	1.3	2.2
HPV-16	LSIL	11	15
HPV-18	LSIL	3.1	3.9
HR12	LSIL	3.7	4.7
HPV-16	HSIL	60	64
HPV-18	HSIL	30	30
HR12	HSIL	35	37

NILM, negative for intraepithelial lesions or malignancy; LSIL, low-grade squamous intraepithelial neoplasia; HSIL, high-grade squamous intraepithelial neoplasia; HR12, 12 high-risk HPV types excluding HPV-16 and HPV-18.

Data extracted from Demarco M, Egemen D, Raine-Bennett TR, et al. A study of partial human papillomavirus genotyping in support of the 2019 ASCCP risk-based management consensus guidelines. *J Low Genit Tract Dis* 2020;24:144–147.

A challenge for the future will be to adjust screening recommendation in populations with high vaccine coverage.[178] The positive predictive value of programs will decrease as the number of true positives (CIN2+ detections) will decrease because of a large reduction in infection by the major high-risk HPV types, while the number of false positives will likely remain constant, particularly in the case of cytology-based screening.[342]

HPV-based assays have great potential for translation to low-resource settings, because they would require only one or two lifetime tests to substantially reduce cervical cancer death rates[305] and because self-sampling could be employed. Multiple studies have shown that patient and health care worker–collected samples generate comparable sensitivities and specificities.[145] Based on these considerations, the WHO currently recommends HPV testing, if feasible, over cytology as the primary screening method. The main impediments to implementation of HPV screening in low-resource settings are the cost of the tests and, because of its relative insensitivity for CIN2+, the need to follow up relatively large numbers of positive women. However, lower cost and rapid point of care tests have been and are being developed, including careHPV (QIAGEN) and Ampfire (Atila Bio Systems).[350]

A number of biomarkers, in addition to cytology, are being evaluated as triage tests, to distinguish between those HPV infections associated with precancer and those that are not. The most advanced test, which has been FDA approved, uses immunostaining for p16INK4a, which is elevated in response to the inactivation of pRb by E7 of high-risk viruses, plus costaining for the Ki67 cell cycle entry marker (CINtech Plus Cytology, Roche). Methylated viral DNA or methylation of specific cellular genes, as well as other markers, such as microRNA profiling, is also being evaluated.[73,213,325]

Visual inspection of the cervix after staining with acetic acid (VIA) or Lugol iodine (VILI) followed by ablation of suspicious lesions has been investigated in trials in multiple settings as a simple low-cost point of care "see-and-treat" approach.[306] VIA has now been implemented in national or regional cervical cancer prevention programs in several South Asian and sub-Saharan Africa countries.[3] However, the positive predictive value of VIA for CIN2+ is approximately 10%, which, in the absence of a triage test, results in considerable overtreatment. To address this issue, artificial intelligence–generated software has been developed based on a training set of photographs of histologically confirmed cervical lesions and was shown to markedly increase the positive predictive value of visual inspection.[156] The use of cell phones for digital imaging and data transmission to a central computer could make this approach amenable to many low-resource settings.

While population-wide screening efforts are directed toward cervical cancer, the more limited anal cancer screening activities have been focused on high-risk groups, including men who have sex with men, HIV-positive men and women, and patients with other forms of immunosuppression.[7] The high risk of anal cancer among HIV positives, especially MSMs, has led the CDC to recommend annual digital rectal exams in HIV positives, especially those with a history of receptive anal intercourse.[390] Visual inspection by anoscopy after application of acetic acid is currently considered the most sensitive and specific test for high-grade anal dysplasia but, as with cervical colposcopy, it is too expense to use as a primary screening tool. Therefore, anal cytology, similar to the cervical Pap smear test and available for high-risk populations at some clinical centers, is generally used as the initial test.[263] Recommendations for screening high-risk groups do not normally include HPV testing, because of the high prevalence of anal HPV infections in cytologically normal individuals in these populations and hence the relatively low predictive value for high-grade anal dysplasias.[367] At this time, treatment of anal HSIL has not been formally proven to reduce the incidence of anal cancer, although it seems likely based on the analogy to cervical disease, and a clinical trial to examine this question is well under way, with an estimated completion date of 2026 (ClinicalTrials.gov Indentifier: NCT02135419).

Screening for HPV-associated OPC risk is not recommended, even though the cancers typically present at a late stage with lymph node involvement, and the rate of HPV-associated OPC is starting to exceed the rate of cervical cancer in the U.S. and some Western European countries.[194] There are multiple reasons for this situation. First, long-term survival of HPV-associated OPCs remains high, so the measurable outcome of early detection would more likely be a reduction in morbidity associated with treatment rather than reduced mortality. In addition, the precursor lesions of OPC have not been identified, although oral HPV DNA is more frequently detected in OPC patients than in controls. In one study, oral HPV-16 prevalence was detected in approximately 20% of OPC cases an average of 6 years prior to diagnosis versus 1% in controls.[4] However, the relative low rate of OPC in the general population would mean that most positive results would be false positive for OPC. In addition, there are few prospective studies that relate detection of oral HPV and subsequent risk of OPC, that is, establish the positive predictive value. Surprisingly, antibody responses to HPV-16 E6 appear to be a sensitive and specific marker for HPV-16–associated OPC. In several studies, 25% to 50% of OPC patients were seropositive HPV-16 E6 (vs. 0.4%-0.7% in controls), which is similar to the fraction of cases attributable to HPV-16 in these study cohorts. There was 100% concordance between positivity for HPV-16 antibodies and oral HPV-16 DNA in the limited number of cases that could be evaluated, and the antibodies were detected in sera many years prior to cancer

diagnosis.[190,194] However, as with HPV DNA testing, this level of specificity would result in many more false positive than true positive tests. More acceptable false positive rates might be obtained if testing were limited to higher risk individuals, for example males, populations with a high HPV-16–attributable fraction, smokers, or those with high-risk sexual behavior profiles. In addition, an effective triage test to further risk stratify HPV-16 antibody or DNA-positive individuals might need to be developed and validated before general screening for HPV-associated OPCC would be practical.

Treatment

In cervical HPV infection, treatment of low-grade dysplasia is not usually warranted, given that most of these lesions will clear spontaneously. High-grade dysplasias represent precancerous lesions that are unlikely to resolve spontaneously, and their treatment is recommended to prevent cervical cancer. Depending on the setting, treatment of cervical dysplasia can be surgical, with cryotherapy, via loop electrosurgical excision, or by laser. More recently, thermocoagulation has generated promising results in comparison to cryotherapy for treatment in see-and-treat trials in low-resource settings.[63] In most instances, these approaches prevent cervical cancer. HPV testing can be used to evaluate treatment effectiveness, because most successfully treated cases become negative for HPV DNA, whereas incompletely treated cases may remain positive,[400] although this follow-up testing is not routinely done. Cervical cancer is treated by surgery, radiotherapy, and chemotherapy, with early-stage tumors having a better prognosis than more advanced tumors.[226]

Treatments of anal HSIL include imiquimod, fluorouracil, infrared photocoagulation, thermal ablation, and laser therapy. None are considered optimal, and they are associated with a high recurrence rate and with more morbidity than treatment of cervical HSIL.[129]

Therapeutic vaccines have been under active development for decades, yet none have proven effective enough to warrant commercialization.[66,112] Most have targeted HPV-16 and HPV-18 E6 and/or E7 with the aim of generating cell-mediated immune responses that would induce regression of CIN2+ lesions, or in some cases high-grade vulvar lesions. Various vaccine strategies have been tested, including those based on peptides, whole proteins, naked DNA, and viral or bacterial vectors.[391] While many have induced detectable T-cell responses, they have mostly been directed at generation of systemic T cells, although the targeted lesions are intraepithelial, raising the question of whether the circulating T cells efficiently traffic across the basement membrane into the tissue where the lesion resides.[71]

CIN2+ may represent a relatively high bar for a therapeutic vaccine, both commercially and immunologically. Current ablative therapies for it are generally well tolerated and effective, making it difficult to improve on standard of care. In addition, CIN2+ are persistent lesions that have likely already undergone considerable immune selection, so they might be resistant to vaccine-induced cell-mediated immune responses. By contrast, persistent high-risk HPV infection/CIN1 may prove to be a more attractive target. With the transition to HPV-based screening, increasing large numbers of women are being informed that that they have a sexually transmitted infection by an oncovirus, but there is no treatment available. These infections are also less likely to have undergone immune selection and might therefore be more likely to respond to the vaccine. However, the vaccine would have to be very well tolerated and effective, since 90% of low-grade infections will spontaneously resolve, and so trials would have to be

large and the primary end points probably based on time to clearance rather than ultimate rate of clearance.[72]

Given what is now known about key molecular events in HPV infection, considerable potential exists for developing antiviral therapies against HPV in addition to immunotherapy.[111,262] An antiviral that targeted a molecular activity common to all HPV types, or at least to a large number of them, such as the interaction between high-risk E6 and E6AP, might have the theoretical advantage of being active against multiple types, in contrast to the predominantly type-specificity of most viral antigens. However, development of antivirals targeting the viral oncoproteins has proven difficult, in part because they lack, with the exception of E1, enzymatic activities.

Antisense and ribozyme approaches may also have some potential, but their activity is likely to be type specific. Alternatively, the use of genome-editing technologies to inactivate E6/E7 genes can be envisioned. Both transcription activator-like effector nuclease (TALEN) and clustered regulatory interspaced short palindromic repeats (CRISPR)–Cas9 based systems were shown to induce cell death *in vitro* and reduce tumor growth *in vivo* of HPV-16– and HPV-18–derived cervical cancer cell lines.[176,323,394] However, efficient delivery to infected cells within the lesions remains a substantial hurdle to clinical application.

Two immunomodulatory agents, interferon and imiquimod, are approved for use against genital warts, although destructive therapy is often used to treat these lesions.[395] In placebo-controlled trials, intralesional and parenteral interferon therapy was active against refractory genital warts,[378] and topical imiquimod, which activates TLR7 and induces interferons and other cytokines, was also effective.[377] Neither agent, however, cures more than two-thirds of treated patients.

Surgery remains the principal therapeutic modality for RRP, although it is seldom curative.[195] Intralesional cidofovir, an antiviral that inhibits DNA polymerases, has been used as an adjuvant therapy to surgery, but it showed no significant efficacy in a randomized control trial.[230] Interferon therapy of RRP has been less successful than that of genital warts, and treatment is associated with serious side effects, including leukopenia and thrombocytopenia.[146] More recently, intralesional or systemic Bevacizumab, an anti-VEGF monoclonal antibody, and intramuscular injection of Gardasil, the prophylactic HPV vaccine, have been evaluated as RRP treatments.[195] While both have yielded some promising results, the findings are derived from individual cases or small case series. Larger randomized control studies will be needed to critically evaluate their effectiveness.

As with other HPV infections, no specific antiviral therapy is available for nongenital warts. Most treatments are aimed at destroying the lesional tissue while causing as little long-term damage to the surrounding normal tissue. No single therapeutic modality will cure all warts, which has led to the wide range of therapies. At least partial regression can be obtained with many therapies, but even complete clearance that is then followed by recurrence is usually of limited clinical value. Treatment of cutaneous warts is based on destruction and/or immunostimulation. The most common destructive treatments are cryotherapy, laser therapy, and salicylic acid. Cryotherapy and salicylic acids have similar cure rates, about 50% compared to 25% for placebo control.[38,298] Immunostimulatory treatments include imiquimod (a TLR 7 agonist), 5-fluorouracil, and intralesional injection of tuberculin protein, Candida antigen or the measles/mumps/rubella vaccine. They generate clearance rates of 25% to 95%.[108] However, it is

likely that destructive treatments also function, at least in part, by immunostimulatory mechanisms, via induction of local inflammation and promoting exposure of viral antigens to the immune system.

PREVENTION

Interruption of Transmission

As noted above, the epidemiology of various forms of HPV infection can differ drastically. Therefore, approaches to control genital HPV infection would be distinct from those to control nongenital infections. Optimal Pap smear and/or HPV-based screening programs can prevent most cervical cancers, which represent the most serious public health consequence of HPV infection, but screening is complex and expensive and presumably does not have appreciable impact on transmission.

Public health efforts that can prevent other sexually transmitted infections should, in principle, also be effective in preventing genital HPV infection. Indeed, decreased sexual promiscuity on the part of both sexual partners should reduce the likelihood of exposure to genital HPV.[362] In the absence of specific treatment that would eradicate genital infections, investigation of sexual partners of infected individuals would not be expected to have much impact on HPV transmission, although it may help identify infected individuals who otherwise might not realize that they are infected.

Although HPV can infect genital areas that are not covered by condoms, condom use may reduce the incidence of genital HPV infection. Consistent with this possibility, several studies in men have reported that condom use is associated with fewer genital HPV infections and a shorter duration of infection in those men who were infected.[250] For women, a meta-analysis found no consistent evidence that condom use in their sexual partners reduced the risk of acquisition of cervical HPV infection, but it was associated with some protection against genital warts, CIN2, CIN3, and cervical cancer.[221] However, in a well-conducted prospective study, consistent condom use by their partners reduced cervicovaginal HPV infection in young women by two-thirds.[385]

As another possible intervention measure, circumcision of adult men was shown to reduce their acquisition of high-risk HPV infection by almost one-half after 2 years.[130,351] A recent meta-analysis reported that male circumcision reduces the odds of penile HPV infection in HIV-positive MSMs (OR 0.71, 95% CI 0.51 to 0.99) but was not significantly protective in HIV-negative MSMs (OR 0.86, 95%CI 0.53 to 1.41). Circumcision was not found to protect against anal infection in MSMs, regardless of HIV status.[396]

HPV topical microbicides are under active evaluation. Carrageenan, a complex polysaccharide derived from red algae, is a potent and broadly active inhibitor of cultured cell infection by alpha HPV types.[39] *In vivo*, it mitigates the potentiating effects on cervicovaginal HPV pseudovirus infection induced by nonoxonol 9 containing over-the-counter spermicides in mouse and macaque models.[290,291] Carrageenans are widely used in food and cosmetic products and are the main gelling agent in some over-the-counter sexual lubricants. In a trial designed to

test the efficacy of a carrageenan gel in the prevention of HIV infection, some protection against HPV infection at the exit visit was observed, but only in the subgroup that was most compliant with use instructions.[222] Clinical trials designed to formally evaluate carrageenan gels as HPV microbicides in women and MSMs are under way.[202,274]

Epidemiologic findings, discussed earlier, suggest that most cases of juvenile-onset RRP that arise in infants and young children have been transmitted from exposure to the mother's HPV during vaginal delivery. This hypothesis raises the possibility that the use of cesarean section for the delivery of infants of mothers with known genital HPV infection would reduce the risk of HPV exposure. The incidence of genital HPV infection is high, however, whereas that of RRP is low, which means that many cesarean sections would be needed to prevent each case of RRP. These considerations suggest that the morbidity and mortality risk to the mother associated with cesarean section may, in most situations, be greater than the risk of RRP to the baby, which has led some investigators to argue against the widespread use of this procedure to prevent RRP. However, because the risk of RRP is greater for younger women and for first pregnancies, a subset of HPV-positive women may exist for whom the cost-to-benefit analysis might favor cesarean section.[321] HPV vaccination in Australia with Gardasil (or Gardasil 9), which prevents genital HPV-6 and HPV-11 infections (discussed below), has been reported to result in a more than fivefold reduction in RRP compared with historic controls.[253]

Prophylactic Vaccination

The important public health consequences of genital HPV infection made it highly desirable to develop effective vaccines against those HPV infections associated with cancer, especially cervical cancer. Vaccines to prevent oncogenic HPV infections could potentially prevent the full spectrum of HPV-associated cancers, in contrast to current screening programs, which are mainly effective in preventing squamous carcinoma of the cervix. Although it would be ideal if a vaccine could both treat established infection and induce long-term protection against incident infection, therapeutic and prophylactic vaccines generally have distinct effector mechanisms, cell-mediated immunity and antibodies, respectively, so they have largely been pursued separately. As noted above, efforts to develop therapeutic vaccines have thus far had limited success in human clinical trials, and there are no commercial therapeutic HPV vaccines. By contrast, initiatives to develop HPV prophylactic vaccines have followed the success of preventive vaccines against other viral diseases[280] and have led to the commercial licensing of four distinct vaccines.

Early studies with CRPV indicated that systemic injection with papilloma suspensions that did not produce detectable infection could induce serum-neutralizing antibodies and protect rabbits against high-dose cutaneous viral challenge.[326] Intradermal injection of a vaccine composed of formalin-inactivated COPV virions was shown to protect against COPV-induced oral lesions under field conditions.[24] This result demonstrated that systemic immunization can induce protective immunity against natural transmission of a mucosal PV infection. However, the viral determinants that conferred protection were not definitively identified in these studies.

The inability to produce preparative amounts of HPV virions, together with the presence of oncogenes in the viral genomes, suggested that a subunit vaccine would be a preferred approach. A key observation in the development of a prophylactic vaccine was finding that L1 can self-assemble into VLPs, which are empty capsids that closely resemble those of authentic virions

morphologically and immunologically.[139,181,297] As with authentic virions, L1 VLPs were highly immunogenic, inducing high titers of neutralizing antibodies that recognize conformation-dependent virion epitopes.[181] In several animal PV models, systemic immunization with L1 VLPs induced strong protection against high-dose experimental challenge by the homologous virus.[34,65,180,344] Protection was type specific, was of long duration, and could be passively transferred with immune IgG, implying that neutralizing antibodies were sufficient for protection. L2 also contains neutralization epitopes, but they are not exposed in the context of the mature virion.[316] Therefore, while co-expression of L1 and L2 in cells results in L1/L2 VLPs, these VLPs were neither more immunogenic nor more protective than L1 VLPs.[34] Human trials, therefore, went forward with L1 VLPs, with the main focus on HPV-16 and HPV-18, the two most oncogenic HPV types. Despite the excellent results with the preclinical models, none represented a genital infection, and it was unclear how relevant these models would be to genital infection under natural conditions. In addition, most vaccines protect against systemic infection that has a viremic phase, which exposes the virus in contact with antibodies in the blood, whereas HPV induces an infection that is confined to the epithelium.

Four commercial prophylactic HPV vaccines have been developed (Table 3.3). GlaxoSmithKline's Cervarix is a bivalent vaccine composed of L1 VLPs of HPV-16 and HPV-18; Merck's Gardasil is a quadrivalent vaccine composed of L1 VLPs of HPV-6, 11, 16, and 18; Merck's Gardasil 9 contains the four types in Gardasil plus VLPs of five additional high-risk types; and Cecolin is a bivalent vaccine composed of HPV-16 and HPV-18 VLPs. In addition to their valency, the vaccines differ in production system, adjuvant, and recommended injection schedule (Table 3.3). The vaccines were generally safe and able to consistently induce high titers of capsid-reactive antibodies in early-phase trials. In phase III clinical trials of young women in which three dose of the vaccine were administered by intramuscular injection over 6 months, all four vaccines were also highly effective at preventing acquisition of persistent cervical infection and high-grade CIN caused by the types targeted by the vaccine (Table 3.4).[10,285] These results have led to worldwide licensure of Cervarix, Gardasil, and Gardasil 9, while Cecolin is licensed exclusively in China. The vaccines have been licensed for prevention of CIN and cervical cancer caused by the vaccine-targeted types.

[a]Efficacy against vaccine-targeted types per protocol cohorts.

[b]Subjects were cervical HPV-16/18 DNA negative at entry but anal HPV not evaluated at entry.

95% CI, ninety-five percent confidence interval; PATRICIA, Papilloma TRial against Cancer In young Adults; FUTURE, Females United To Unilaterally Reduce Endo/Ecocervical Disease; CVT, Costa Rica Vaccine Trial; CIN2+, cervical intraepithelial neoplasia grade two or worse; VIN2+, vulvar intraepithelial neoplasia grade two or worse; VaIN2+, vaginal intraepithelial neoplasia grade two or worse.

Unexpectedly, both Cervarix and Gardasil appear to induce a high level of protection against persistent cervical infection up to a decade postvaccination even after administration of only one dose of the vaccine.[380] However, these findings are based on post hoc analyses that were not designed to evaluate one dose efficacy. Formal randomized trials comparing one versus two doses of Cervarix and Gardasil 9 are now underway.[303]

The vaccines also induced modest but durable protection against cervical infection caused by specific nonvaccine types closely related to HPV-16 or HPV-18.[220] For instance, both Cervarix and Gardasil induced partial protection against persistent infection by HPV-31. Cervarix, but not Gardasil, also induced substantial protection against HPV-45, and borderline protection against HPV-35 and HPV-58.[356]

Gardasil was also highly effective at preventing genital warts, and vulvar and vaginal intraepithelial neoplasia, and it has been licensed for these indications[92,183] (Table 3.4). Cervarix was not evaluated for these end points, apparently because it does not target HPV-6 and HPV-11, the types that cause most genital warts. Neither vaccine induced significant clearance of established infections or regression of established lesions, so they are not licensed for treatment of HPV infection or disease.[116,151]

Consistent with the observation of ongoing protection for more than a decade, neutralizing antibody titers induced by the vaccines have remained essentially stable, even after a single dose, and above the levels induced by natural infection, supporting optimistic projections for long-term, perhaps lifelong, protection without the need for booster immunizations (Fig. 3.13).[13,193] Cross-neutralizing antibodies against related types, when they are detected, appear to recognize subdominant epitopes, as their titers are much lower than the titers against the vaccine-targeted

types,[175] but they appear to be as durable as type-specific antibody responses.[128] The remarkably high, consistent, and durable antibody response to the vaccines may in large part be attributed to the strong signaling through the B-cell receptors after their engagement of the dense repetitive array of epitopes on the VLP surface. In addition, their repetitive and particular nature promotes their phagocytosis by antigen-presenting cells for generation of strong T helper responses and the binding of natural IgM and complement that promotes their acquisition by follicular dendritic cells for presentation to B cells in lymph nodes.[314]

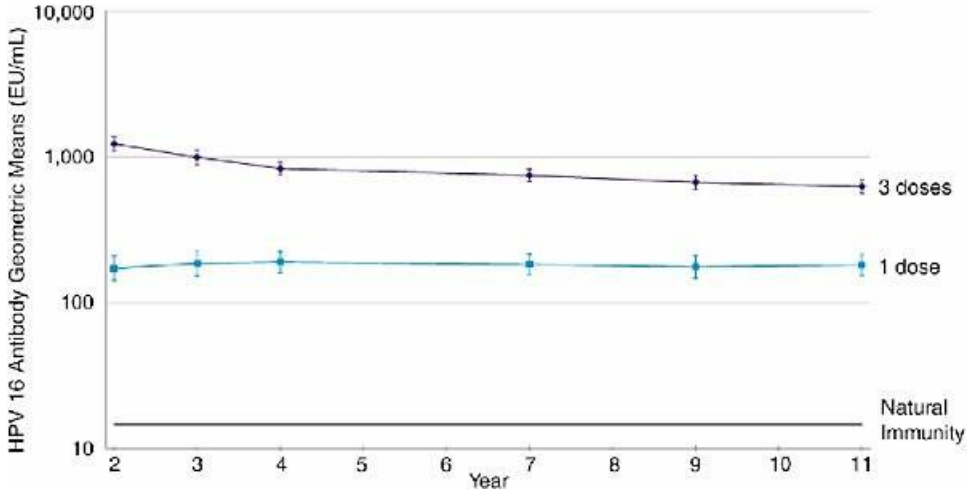

FIGURE 3.13 Durability of the serum antibody responses by doses of Cervarix received, as measured in an HPV-16 VLP ELISA. (Data derived from the long term follow up of the Costa Rican Vaccine Trial (CVT) Kreimer AR, Sampson JN, Porras C, et al. Evaluation of durability of a single-dose of the bivalent HPV vaccine: the CVT Trial. *J Natl Cancer Inst* 2020;112:1038–1046. The results were similar for HPV18.)

Gardasil was also tested for efficacy in men. Strong protection from genital warts was documented[127] (Table 3.4). Relatively few penile intraepithelial lesions were detected in the trials, so the trial was unable to critically evaluate this end point. The subset of the men who had sex with men was concurrently enrolled in a study of anal infection and anal intraepithelial neoplasia (AIN).[264] Excellent protection against vaccine type–related anal infection and AIN was observed (Table 3.4). The findings led to licensure for these indications and for prevention of AIN and anal cancer in the United States and elsewhere. Licensure was extended to anal neoplasia and anal cancer in women based on the argument that AIN and anal cancer are indistinguishable in the two sexes. Licensure of Gardasil 9 was based on immunological noninferiority for the four VLP types it shares with Gardasil, together with strong protection against CIN2+ caused by the five additional high-risk types in Gardasil 9. Although Cervarix has not been evaluated for prevention of AIN in either sex, it was shown to significantly reduce the prevalence of anal HPV infection at the end of a 4-year trial in young women.[191]

The above trials were conducted in young women and men ages 15 to 26 years, with the exception of Cecolin, where the women were 18 to 45. Immunobridging studies were used to extend licensure to 9- to 14-year-olds. Antibody responses to both Cervarix and Gardasil were

significantly higher (two- to threefold) in the younger vaccinees compared with the older age groups.[28,271] The higher responses in children led to a comparison of two- and three-dose vaccination protocols. For both vaccines, the antibody responses of children after two doses given 6 months apart were not inferior to the responses of young adults to three doses given according to the recommended schedules.[187,294] These findings have led most national programs to adopt a two-dose schedule for adolescents younger than 15 years of age.

Although highly immunogenic, both vaccines were well tolerated in both sexes. The primary side effects attributable to the vaccines were short-term pain, swelling, and erythema at injection site and low-grade fever and/or headache.[364,366] No pattern of serious adverse events was associated with vaccination in either the clinical trials or subsequently in immunization programs.[277,324,383]

Neutralizing antibodies are believed to be the primary, if not exclusive, immune effectors for the VLP vaccines, although a formal immune correlate of protection has not been determined.[314] In part, this shortcoming is due to the remarkably small number of vaccine failures to date and the inability to definitively distinguish incident infection from emergence or reactivation of infections present at the time of vaccination. Antibodies induced by systemic VLP vaccination could reach the anogenital sites of infection by two mechanisms. One mechanism is transudation of serum IgG, which is especially pronounced at the cervix.[247] Alternatively, systemic antibodies could be directly exudated at the site of trauma required for initiating infection.[290] The second mechanism appears to be fully able to prevent infection, since strong protection was observed against genital warts on external genitalia, sites not normally exposed to transudated antibodies in mucus. In a mouse cervicovaginal challenge model, VLP-induced antibodies were shown to protect from keratinocyte infection by two distinct mechanisms.[77] At high concentrations, the antibodies prevented binding of the capsids to the basement membrane of the cervicovaginal epithelium. At lower concentrations that were nonetheless effective at preventing infection, the capsids were able to bind the basement membrane and undergo the conformational change that exposes L2 N-terminal epitopes. However, they were subsequently unable to stably associate with the cervicovaginal keratinocytes. Two possible explanations for these observations are that lower antibody occupancy is needed to prevent capsid binding to the keratinocyte surface receptor than binding to the heparan sulfate proteoglycans of the basement membrane or that the capsids are efficiently phagocytosed by neutrophils and other phagocytic cells via interaction between their Fc receptors and the capsid/antibody complexes.

Since their initial approval in 2006, HPV vaccines have been introduced into the national programs of approximately 120 countries.[84] However, few countries have approached the WHO goal of 90% coverage rates, as stated in the WHO's call for cervical cancer elimination.[46] National programs are mostly centered on vaccination of preadolescent or adolescent girls, ages 9 to 15 years, since worldwide more than 90% of HPV-associated cancers occur in women,[81] genital HPV infections are often acquired soon after initiating sexual activity, and children responded better than adults to the vaccines. However, the evidence that Gardasil protects young men from genital warts and anal cancer precursors has provided additional support for considering male vaccination programs, and about 20 countries have adopted gender-neutral vaccination programs.

The HPV vaccines have now also shown impressive effectiveness in national immunization programs,[37,101] and this effectiveness is particularly evident in analysis of women from cohorts

vaccinated prior to sexual debut and in countries with high coverage rates, such as Scotland and Australia (Fig. 3.14).[101] In the Scottish program, which until recently employed Cervarix, an 89% (95% CI 81% to 94%) reduction in CIN3 diagnoses, independent of causal HPV type, was observed in young women vaccinated at age 12 to 13.[265] In 18- to 24-year-old Australian women, the prevalence of vaccine-targeted type infections before initiation of their Gardasil vaccination program in 2007 was 22.5% in contrast to 1.5% 9 years after its initiation.[218] Interestingly, the reduction in CIN2+ detection in Australia was comparable in women who received one, two, or three doses of vaccine at age 15 or younger.[36] Clear evidence of herd immunity has emerged in female vaccination programs, even in countries with modest coverage rates. For example, in the decade since the introduction of the vaccines in the U.S. in 2007, the prevalence of vaccine-targeted types in women age 20 to 24 at the time of screening decreased from 13.1% in 2007 to 1.3% in 2015–2016 in vaccinated women, but also decreased to 5.8% in unvaccinated women (Fig. 3.15).[225] The decrease in HPV prevalence was less dramatic in 25- to 29-year-olds, presumably because more of them were infected prior to vaccination. There is also clear evidence that the vaccines induce herd immunity in men. For example, there was a reduction of penile infections by the vaccine-targeted types in young men from 2004 to 2015 (prior to the initiation of a male vaccination program in Australia) from 22% (95% CI 14% to 33%) to 6% (3% to 10%).[64]

Because progression from incident infection to cancer generally takes at least a decade, there is limited evidence that the HPV vaccines prevent cervical or other HPV-induced cancers. However, a recent study based on the Swedish health registry reported that there has been a significant reduction in cervical cancer in women under 31 years[206] since the initiation of the Swedish vaccination program in 2006. The incident ratio was 0.47 (95% CI 0.27 to 0.75) in women vaccinated at age 17 to 30 and 0.12 (95% CI 0.00 to 0.34) for women vaccinated before the age of 17. In addition, modeling exercises indicate that there is great potential for cancer prevention worldwide if coverage rates could be improved.[331] There is an urgent need to expand vaccine coverages of girls, especially in low- and middle-income countries, because few will likely have the opportunity to participate in cervical cancer screening programs as adults. As an illustration of the unmet potential of the vaccines, it has been estimated that, in the absence of vaccination, there would be 19 million cases and 10 million deaths from cervical cancer worldwide in females who were age 14 to 29 in 2014. To date, only 365,000 cases and 150,000 deaths have been averted by vaccination, and almost all of these are in higher income countries (Fig. 3.16) with well-established vaccination programs.

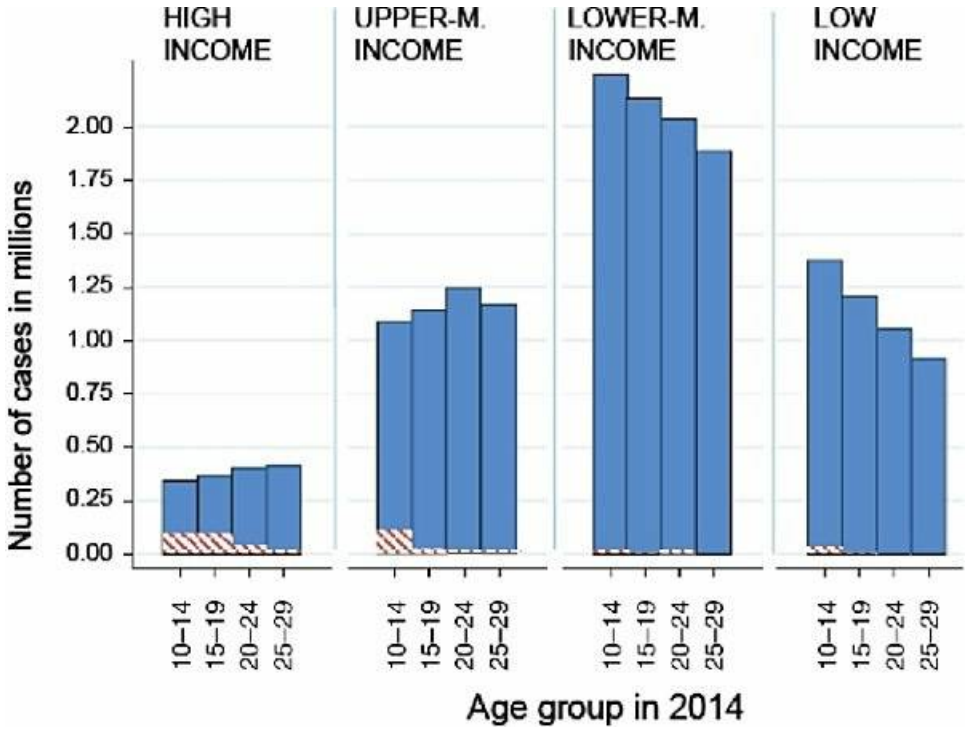

FIGURE 3.16 Estimated number of cumulative cases of cervical cancer over the next 65 years by age in 2014 and country income level in the absence of HPV vaccines (*blue bars*) and the number of cancers that have been averted by vaccination (*red stripe bars*). CHAPTER 4

Adenoviridae: The Viruses and Their Replication

Patrick Hearing

Classification
Virion structure
Genome structure and organization
Stages of replication
- Mechanisms of attachment
- Mechanisms of entry, uncoating, and intracellular trafficking
- Early gene transcription
- Functions of adenovirus early proteins
- Viral DNA replication
- Late gene transcription
- Regulation of RNA splicing during the late phase
- Regulation of translation
- VA RNAs
- Virion assembly
- Virus release

Perspectives
Acknowledgments

Adenoviruses were first isolated and characterized in the 1950s. In 1953, Rowe and colleagues observed spontaneous cytopathic effect in primary cultures of human adenoids.[254] In 1954, Hilleman and Werner isolated an agent from respiratory secretions of military recruits during an epidemic of respiratory disease.[120] The viruses discovered by the two groups were found to be related and named *adenoviruses*. Human adenoviruses cause acute respiratory disease among the military and in infants and the elderly, but they are responsible for a small portion of respiratory morbidity in the general population and for 5% to 10% of respiratory illnesses in children.[188] Due to significant morbidity caused by adenovirus infections among the military, a vaccine directed against Ad4 and Ad7 was redeveloped and currently is in use.[163]

Besides respiratory disease, adenoviruses cause epidemic conjunctivitis and infantile gastroenteritis, and less frequently pneumonia or myocarditis.[188] With immunocompetent individuals, adenovirus infection is clinically inapparent or generally associated with mild and self-limiting disease. With immunosuppressed patients, however, adenovirus infections can lead to severe, life-threatening disease including fulminant pneumonia, hepatitis, encephalitis, and/or systemic infection.[175] Patients undergoing immunosuppressive therapy, including organ transplant patients and hematopoietic stem cell transplant recipients, and AIDS patients are

included in this category. Adenoviruses have been identified that infect all vertebrates. With humans, over 100 types (serotypes/genotypes) have been identified, with many recent isolates corresponding to intra- and intertypic recombinants.[175] Adenoviruses contain a linear, double-stranded DNA (dsDNA) genome packaged within an icosahedral capsid.

In 1962, Trentin and colleagues made the seminal discovery that human adenovirus type 12 induces malignant tumors after inoculation into newborn hamsters.[303] This was the first time that a human virus was discovered to be oncogenic. No compelling epidemiologic evidence was reported linking adenoviruses with cancers in humans despite extensive studies.[201] Nevertheless, the ability of adenovirus to induce tumors in animals and to transform primary cells in culture established an important model system for studying oncogenesis.

Adenoviruses provide a highly tractable model system for studying virus–host interactions. In general, human adenoviruses may be propagated to high titer and used to establish synchronous infections in cultured cells. With the advent of recombineering, the viral genome may be readily manipulated to generate highly specific viral mutants, facilitating the study of adenovirus gene functions.[283] Studies of adenovirus have provided fundamental insights into the identification and our understanding of numerous cellular processes including the regulation of viral and cellular gene expression and DNA replication, cell cycle control and oncogenic transformation, translational control, and the regulation of innate and adaptive immune responses to infection. Perhaps the most recognized contribution of the adenovirus system to modern biology was the discovery of messenger RNA (mRNA) splicing,[23] but seminal observations were made in many areas using adenovirus as a model system. Adenoviruses also are currently being utilized in a wide variety of gene therapy settings, including as oncolytic and vaccine vectors.[326] This chapter overviews the structure of the adenovirus particle, the adenovirus replication cycle in human cells, and adenovirus interactions with the host cell and organism.

CLASSIFICATION

Adenoviruses belong to the *Adenoviridae* family. *Adenoviridae* have been isolated from all vertebrates. Currently there are five genera: *Mastadenovirus* originate from mammals, including all human adenoviruses; *Aviadenovirus* originate from birds; *Atadenovirus* have a broader range of hosts including reptiles, birds, a marsupial, and mammals; *Siadenovirus* originate from reptiles and birds; and *Ichtadenovirus* originate from fish.[64] Over 100 human adenovirus types have been isolated that fall into one of seven species (A–G) based on serology, hemagglutination, oncogenicity in rodents, transformation of cultured primary cells, and genome sequencing[70] (http://hadvwg.gmu.edu/) (Table 4.1). Over half of human adenoviruses are species D, followed by species B; one to only a few human adenoviruses are species E, F, or G. Human adenoviruses are identified based on their species and type designation; for example, HAdV-C5 is human adenovirus species C type 5. Adenoviruses were previously categorized by antigenic serotypes, but the current nomenclature also includes definition based on genotype.[7] Serotypes are defined based on the antigenicity of the major capsid protein hexon, which contains the prominent neutralizing epitopes. Novel human adenoviruses may arise by intra- and interspecies recombination, resulting in chimeric viral genomes; this occurs most frequently with adenovirus

species D.[175] The tropism of human adenoviruses is diverse, with a variety of tissues and organs infected. Generally, adenoviruses within a species cause infections at particular sites in body, including ocular infections with species B and D; enteric infections with species A, F, and G; and respiratory infections with species B, C, and E.[175] Less common adenovirus infections include hemorrhagic cystitis and central nervous system infections with species B.

TABLE 4.1 Classification schemes for human adenoviruses (HAdVs, Genus *Mastadenovirus*)

		Oncogenic Potential			
Species	Representative Types	Tumors in Animals	Transformation In Culture	% GC	Hemagglutination Group
A	12	High	Positive	46–47	IV (little or none)
B	3, 7, 35	Moderate	Positive	49–51	I (complete for monkey erythrocytes)
C	2, 5	Low or none	Positive	55	II (partial for rat erythrocytes)
D	9, 17	Mammary tumors	Positive	55–57	III (complete for rat erythrocytes)
E	4	Low or none	Positive	58	III
F	40, 41	Unknown	Negative	51	III
G	52	Unknown	Unknown	55	Unknown

VIRION STRUCTURE

Adenoviruses are complex, nonenveloped, icosahedral particles approximately 95 nm in diameter, *pseudo* T = 25 triangulation number[258] (Fig. 4.1). The major capsid proteins include hexon (protein II) constituting the facets, penton base (protein III) constituting the vertices, and fiber (protein IV) projecting from each vertex (Fig. 4.2). Adenovirus particles have a mass of 150 MDa and contain DNA (13% of mass), protein (87% of mass), no membrane or lipid, and trace amounts of carbohydrate, because the virion fiber protein is modified by glucosamine.[132] Virions consist of a protein shell (capsid) surrounding a DNA-containing core. A single adenovirus particle contains 240 trimers of hexon, 12 pentamers of penton base, 12 trimers of fiber, and a number of other capsid proteins that serve to stabilize the virion and function as core proteins associated with the viral DNA[258] (Fig. 4.3, Table 4.2). The virion also contains a protease (AVP, adenovirus-associated protease), protein IVa2, and terminal protein covalently attached at each 5’ end of the genome.

TABLE 4.2 HAdV-C5 structural proteins

Polypeptide	Amino Acid Residues	Copies in Virion
II (Hexon)	952	240 trimers
III (Penton base)	571	12 pentamers
pIIIa	585	60 monomers
IV (Fiber)	581	12 trimers
IVa2	449	5
V	368	150–160
pVI	250	60 hexamers
pVII	174	500–800
pVIII	227	100–120
pIX	140	240
pμ (pX)	36	100–300

Adapted from Chen PH, Ornelles DA, Shenk T. The adenovirus L3 23-kilodalton proteinase cleaves the amino-terminal head domain from cytokeratin 18 and disrupts the cytokeratin network of HeLa cells. *J Virol* 1993;67:3507–3514.

The first high-resolution structures of an intact HAdV-C5 virion were reported in 2010 and included a 3.6Å resolution cryoelectron microscopic (cryoEM) structure[178] (Fig. 4.1) and a 3.5Å resolution x-ray crystallographic structure.[244] The cryoEM structure was reinterpreted several years later to include the structures and locations of the virion cement proteins IIIa, VI, VIII, and IX.[245] Additionally, a segment of core protein V was visualized in association with protein VI. The revised crystal structure of a pseudo-typed HAdV-C5/D17 virion was recently reported that is consistent with the models of minor capsid proteins determined by cryoEM.[162] In addition to these structures of intact virus particles, a number of high-resolution crystal structures have been reported for capsid proteins, including a hexon trimer (2.5Å resolution)[256] (Fig. 4.4), penton base (3.3Å resolution)[350] (Fig. 4.5), fiber shaft (2.4Å resolution),[243] and fiber knob (1.5Å resolution)[242] (Fig. 4.5). The structures of minor capsid proteins VI and VII were determined by cryoEM[61] (Fig. 4.6).

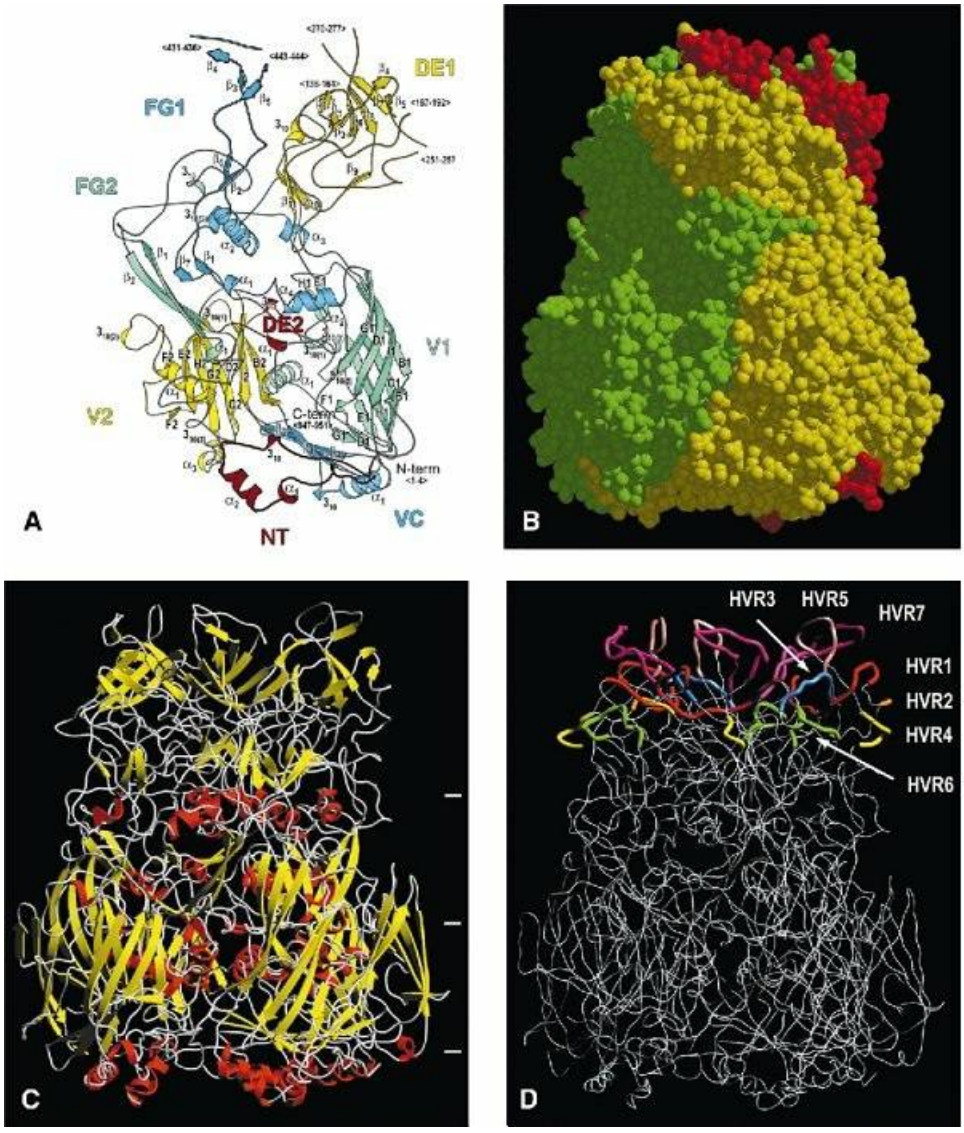

FIGURE 4.4 HAdV-C5 hexon structure. A: Ribbon diagram of a hexon monomer. View from the inside of the trimer. Loops DE1, FG1, and FG2 constitute the outer surface of hexon in the virion. DE2 is a small loop in the hexon monomer interface. **B:** Space-filling model of the hexon trimer. Subunits of the trimer are colored *red*, *green*, and *yellow*. **C:** Ribbon diagram of the hexon trimer. Structural elements are colored with β-strands in *yellow* and α-helices in *red*. **D:** The seven hypervariable regions (HVRs) that contain serotype-specific residues in HAdV-C5 hexon are shown on the trimeric hexon structure. The HVRs correspond to *red*, HVR1 (aa 137–181); *orange*, HVR2 (aa 187–193); *blue*, HVR3 (aa 211–218); *yellow*, HVR4 (aa 247–260); *tan*, HVR5 (aa 267–282); *green*, HVR6 (aa 304–315); and *magenta*, HVR7 (aa 421–449). FIGURE 4.6 Four different chemical environments of HAdV-C5 hexon trimers and locations of minor cement proteins. Models of one of the twenty facets of an Ad5 icosahedron viewed from outside (*Exterior*) and inside (*Interior*) the virion. Penton bases with the base of a fiber trimer are at the three corners of the triangular facet. Hexon trimers are in four distinct chemical environments, each shown in a different color shade: (H1) two hexon trimers neighboring each penton base; (H2) two hexon trimers on the edges of each facet between the penton base–associated hexon trimmers; (H3) three hexon trimers at the center of each facet; and (H4) three hexon trimers between the central hexon trimers and the penton-associated hexon trimers. These nonequivalent interactions are stabilized by protein IX (*purple*) between hexon trimers, visible from the exterior surface, and proteins IIIa (*red*) and VIII (*blue*) on the inner surface. (Courtesy of Z. Hong Zhou; from Liu H, Jin L, Koh SB, et al. Atomic structure of human adenovirus by cryo-EM reveals interactions among protein networks. *Science* 2010;329:1038–1043.)

Only the basal portions of the fibers were visualized in the cryoEM structure (Fig. 4.1).[178] However, full-length fiber proteins were evident in negatively stained transmission electron micrographs of single virions (Fig. 4.2) and in the x-ray crystal structure (Fig. 4.5). Most human adenoviruses encode a single fiber protein. However, HAdV-F40, HAdV-F41, and HAdV-G52 encode two fiber proteins, with one or the other bound to each penton base.[139,148] Because the fiber knob interacts with a cellular receptor, the incorporation of two different fiber proteins may extend the range of cell types to which these viruses bind. The fiber shaft of human adenoviruses is composed of repeats of an approximately 15-residue structural motif, and the length of the shaft varies among types from six repeating units in HAdV-B3 to 21 in HAdV-C2 and HAdV-C5.[243] A symmetry mismatch occurs in the interaction between the fivefold symmetric penton base and the threefold symmetric trimeric fiber. This interaction is mediated by a hydrophobic ring around a central pore on the top surface of the penton base, hydrophobic residues on the bottom of the fiber shaft, and flexible N-terminal tails of the fiber monomers (Fig. 4.5) that insert into three of five available grooves formed by neighboring subunits of the penton base.[182] The N-terminal residues of the fiber monomers extend to the bases of penton loops containing RGD sequences that bind to integrins on the target cell plasma membrane, triggering endocytosis of the virion (see Mechanisms of Entry, Uncoating, and Intracellular Trafficking).

Minor capsid proteins IIIa, VIII, and IX stabilize nonequivalent interactions between hexon trimers, allowing the same hexon trimer to be used in four different chemical environments on the surface of the capsid[178,244] (Figs. 4.6 and 4.7). Networks of interactions between the minor capsid proteins stabilize two groups of capsomeres and hold them together. On the outside surface of the virus particle, 240 copies of protein IX bind between adjacent hexons to stabilize the facets of the virion. On the inside surface of the virus particle at each of the vertices, five copies of protein IIIa bridge each penton base with adjacent hexons. Additionally, 120 copies of protein VIII per virion stabilize hexon–hexon interactions at the threefold and fivefold axes of symmetry[178,245] (Fig. 4.7).

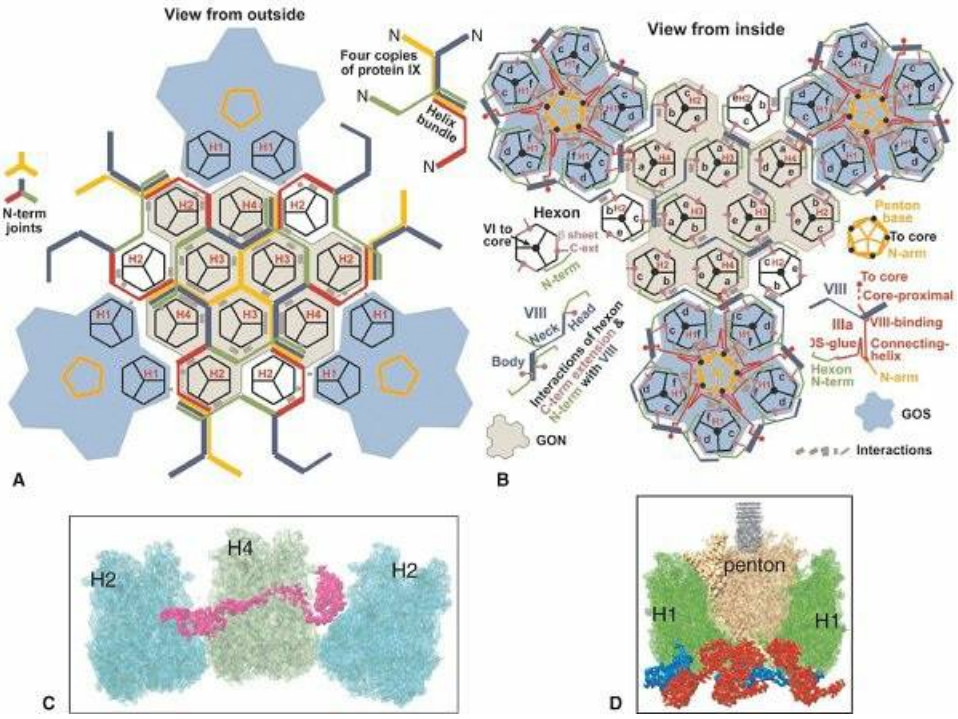

FIGURE 4.7 Diagram of the interactions of minor proteins IIIa, VIII, and IX that stabilize nonequivalent hexon trimer interactions. A: Hexon trimers are labeled H1 to H4 as described in Figure 4.6. The diagram at the upper right represents four different conformations of protein IX shown in different colors. N indicates their amino termini. These link hexon trimers in a group of nine (*gray*), and link groups of nine from neighboring facets. Groups-of-nine hexon trimers are released when virions are disrupted under mild conditions. **B:** Letters *a* through *f* indicate hexon monomers with distinct conformations of their extended N- and C-termini. As diagrammed at the lower left, three hexon C-termini and four hexon N-termini interact with one protein VIII. At each vertex of the icosahedron, five copies of protein IIIa link five hexon trimers to the central penton base, forming groups-of-six capsomeres (GOS, *shaded in blue*). Protein VIII links groups-of-nine hexon trimers (GON, *shaded in gray*) to groups-of-nine hexon trimers in neighboring facets and groups-of-nine hexon trimers to groups-of-six capsomeres at the vertices. Protein VI binds in a central cavity on the inner surface of hexon trimers, represented as a *black circle.* **C:** Side view of protein IX (*purple*) inlaid into the canyons between hexon trimers. **D:** Side view of proteins

IIIa (*red*) interacting with penton base and H1 hexons and protein VIII (*blue*) interacting with H1 hexons on the inner surface of the capsid shell. (Courtesy of Z. Hong Zhou. Adapted from Liu H, Jin L, Koh SB, et al. Atomic structure of human adenovirus by cryo-EM reveals interactions among protein networks. *Science* 2010;329:1038–1043.)

The core of the virion contains seven known viral proteins and the viral genome. Polypeptide VII (174 amino acids), the major core protein with 500 to 800 copies per virion, polypeptide V (368 amino acids; 150 copies/virion), and μ (36 amino acids; 100 to 300 copies/virion)[17,218] are basic, arginine-rich proteins that contact the viral DNA.[4,44] Adenovirus core protein VII condenses DNA in clusters and bundles within the capsid.[199] The adenovirus DNA–protein core lacks symmetry and precise order but exists in numerous, defined spheres (adenosomes) that may be visualized by cryoelectron tomography[234] (Fig. 4.8). Remarkably, Ad5 particles are efficiently assembled and visually appear normal in the complete absence of core protein VII.[226] Adenovirus particles that lack core protein VII exhibit increased internal pressure, indicating that VII reduces repulsive DNA–DNA interactions.[199]

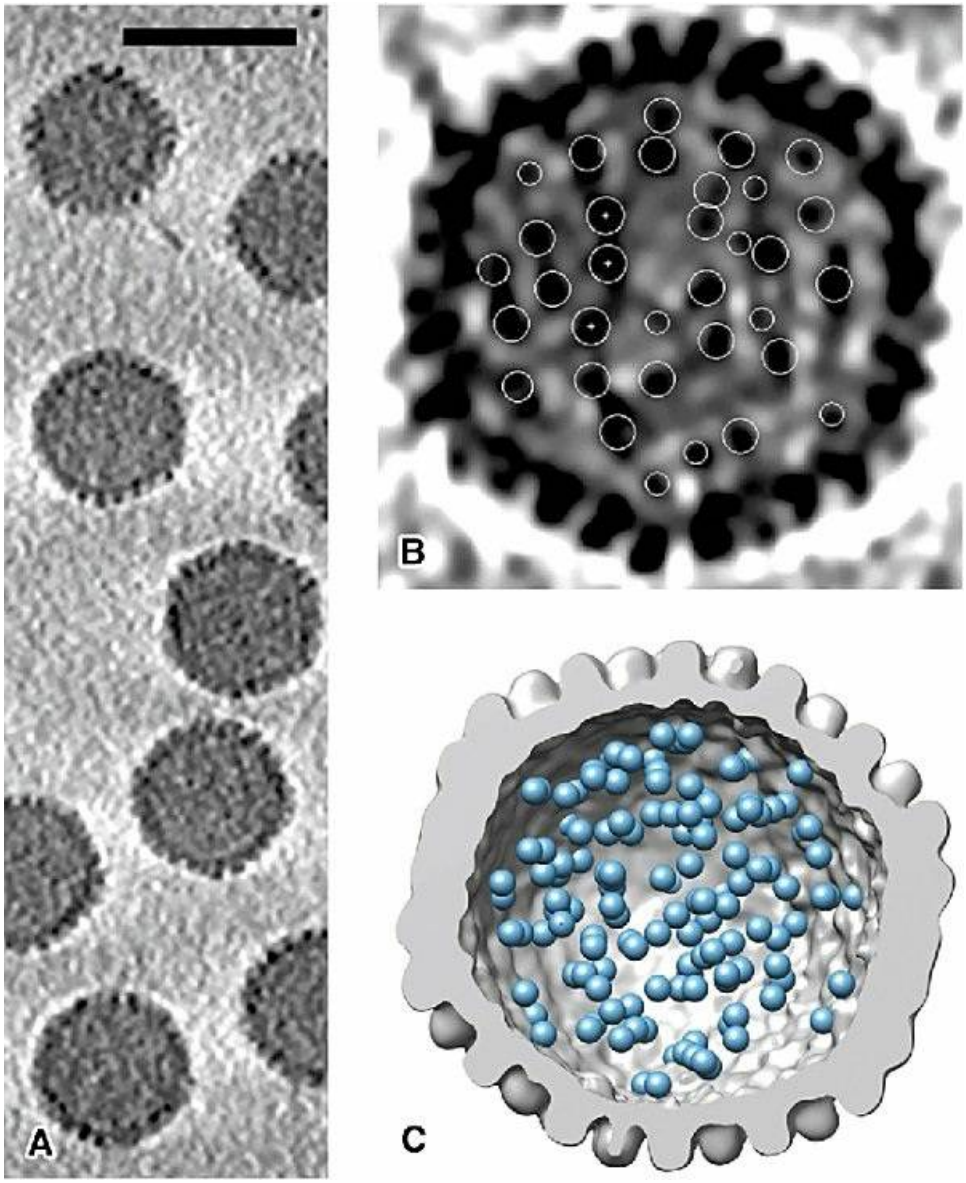

FIGURE 4.8 CryoEM modeling of HAdV-C5 adenosomes within a virion particle. **A:** CryoEM tomogram of adenovirus particles. The bar = 100 nm. **B:** A single virus particle is shown with the highest density regions in *black*. Adenosomes are circled in *white*. **C:** Surface rendering showing an HAdV-C5 capsid cross section; adenosomes are indicated in blue. (From Pérez-Berná AJ, Marion S, Chichón FJ, et al. Distribution of DNA-condensing protein complexes in the adenovirus core. *Nucl Acids Res* 2015;43:4274–4283. Reproduced by permission of Oxford University Press.)

Protein VI associates with a cavity on the inner surface of hexon trimers[61,178,245] (Fig. 4.7) and with protein V,[200] tethering the highly ordered capsid to the less ordered DNA–protein core. A basic 115-residue disordered region in the middle of each polypeptide VI is proposed to contribute to an interaction with the core.[257] The N terminus of each penton base monomer also interacts with the core, and the C terminus of protein IIIa may as well,[178] consistent with reports

that these proteins also interact with protein V[272] and that IIIa is responsible for type-specific packaging of viral DNA into virions.[190] Protein IVa2 is present in only a few copies at one vertex of the icosahedron,[52] binds to the packaging domain at the left end of the viral genome, and is required for packaging viral DNA into the capsid (see Virion Assembly). The sixth protein in the core is terminal protein, which is covalently attached to the 5′ ends of the viral DNA and therefore present in only two copies per virion. The core also contains approximately 10 molecules of the viral cysteine protease AVP that functions to cleave precursors of a number of virion proteins during maturation of the virion and in virus escape from endosomes during the infection process[194] (see Virion Assembly and Mechanisms of Entry, Uncoating, and Intracellular Trafficking).

GENOME STRUCTURE AND ORGANIZATION

Adenovirus genomes are linear dsDNAs ranging in size from 26,000 to 45,000 base pairs (bp).[64] Adenovirus terminal protein is covalently attached to the 5′ end of each strand and serves as a protein primer of DNA replication (see Viral DNA Replication). Homologous genes shared by all adenoviruses encode the three viral proteins required for viral DNA replication, the preterminal protein (pTP), viral DNA polymerase (Ad-Pol), the viral single-stranded DNA-binding protein (DBP), and the major structural components of the virion described above (see Virion Structure), except that core protein V is found only with *Mastadenoviruses* isolated from mammals.[64] These conserved genes are encoded in the central portion of the genome. Additional genes specific to adenoviruses from different vertebrates are encoded primarily near the ends of the genome. The genomes of all adenoviruses have inverted terminal repeat (ITR) sequences ranging in size from 36 to over 200 bp.[64] The ITRs function as DNA replication origins (see Viral DNA Replication). Most human adenovirus genomes encode homologous genes represented by the extensively studied and closely related HAdV-C2 and HAdV-C5. HAdV-C2 DNA was the first adenovirus genome to be completely sequenced[249] with a length of 35,937 base pairs bp. This chapter will concentrate on the human adenoviruses, all having the same general genome organization.

The human adenovirus genome contains a *cis*-acting packaging domain at the left end that is required for encapsidation of the viral genome into the virion at late times after infection.[224] The packaging domain is located just upstream of the E1A coding region and within the E1A transcriptional enhancer region. The human adenovirus genome contains five early transcription units (E1A, E1B, E2, E3, and E4), four intermediate transcription units transcribed around the time of onset of viral DNA replication (pIX, IVa2, L4 intermediate, and E2-late), and one major late transcription unit that is processed to generate five families of late mRNAs (L1–L5) (Fig. 4.9). These transcription units are all transcribed by host RNA polymerase II. The major late promoter (MLP) is transcribed at a low level during the early phase of infection, generating only the L1 family of mRNAs encoding the L1-52/55-kD protein. After the onset of viral DNA replication, transcripts are generated from all five late regions (L1–L5). In addition, the E2 transcription unit is transcribed from an alternative promoter, the E2-late promoter, as well as

from the E2-early promoter. The adenovirus genome encodes one or two (depending on the type) virus-associated (VA) RNAs transcribed by host RNA polymerase III. By convention, the adenovirus genome map is drawn with the E1A gene at the left end (Fig. 4.9). Both strands of the viral DNA are transcribed, with the rightward reading strand as the template for the E1A, E1B, pIX, major late, VA RNA, and E3 transcription units, and the leftward reading strand as the template for the E4, E2, and IVa2 transcription units.

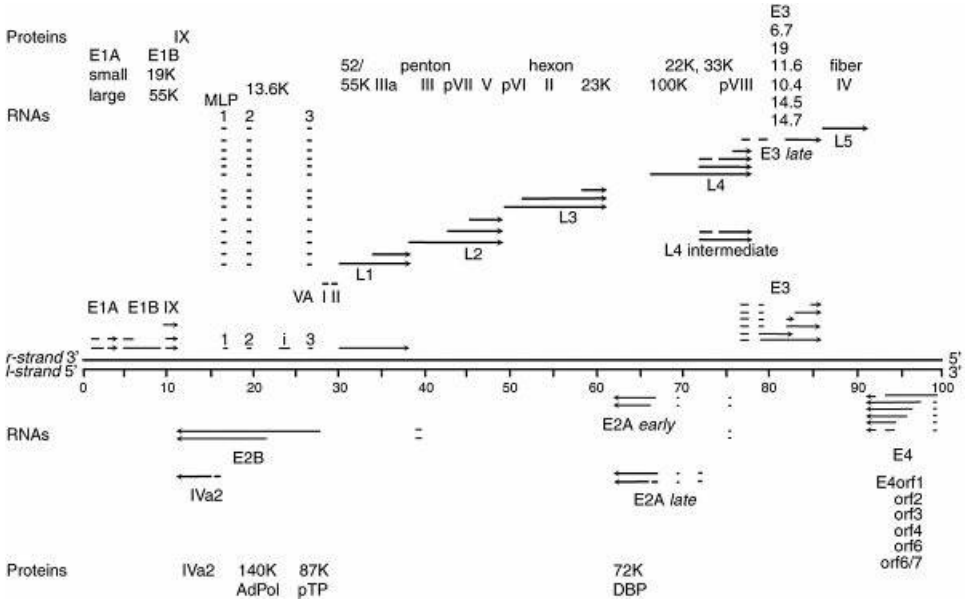

FIGURE 4.9 HAdV-C2 and HAdV-C5 genomes. The 35,937 bp genome of HAdV-C2 is divided into 100 map units. Early mRNAs are E1A, E1B, E2A-*early*, E2B, E3, and E4. Late mRNAs are L1, L2, L3, L4, and L5. Intermediate RNAs are IX, IVa2, L4 intermediate, and E2A-*late*. *Arrowheads* represent polyadenylated 3′ ends. Most late mRNAs originate at the major late promoter (MLP) at 16.8 map units and contain the tripartite leader (TPL) whose exons are labeled 1, 2, and 3. Proteins translated from the mRNAs transcribed to the right and left are named along the top and along the bottom of the diagram, respectively. Penton base is also designated virion protein III. Hexon is also designated virion protein II. Fiber is also designated virion protein IV. pVI, pVII, and pVIII refer to precursor polypeptides that are cleaved during virion maturation.

Except for the IVa2 and pIX transcription units, each of the adenovirus genes transcribed by RNA polymerase II gives rise to multiple mRNAs generated by alternative pre-mRNA splicing, and in the case of the major late, E2, and E3 transcription units, by the use of alternative polyadenylation sites as well. The L4 intermediate mRNAs shown in Figure 4.9 encode proteins L4-22K and L4-33K expressed from an intermediate phase promoter.[207]

Some of the proteins generated from the same transcription unit share amino acid sequences, such as the two major polypeptides encoded by the E1A region (Fig. 4.10) and the L4-22K and L4-33K proteins of the L4 region (Fig. 4.11). Other proteins encoded by a specific transcription unit have no sequences in common, such as the two major E1B-encoded proteins (Fig. 4.10) and the L4-100K, L4-22K, and L4-pVIII proteins (Fig. 4.11). Unfortunately, no consistent

terminology has been adopted for naming adenovirus proteins: the E1A proteins are named large and small E1A and are often referred to by the sedimentation coefficient of the mRNAs that encode them (13S and 12S) or their amino acid composition (289aa and 243aa). The E1B and E3 proteins are designated by their apparent molecular mass estimated from SDS gel electrophoresis (although specific acronyms now have been assigned to certain E3 gene products). The E2 proteins are named for their functions, and the E4 proteins are named by their reading frames. Proteins encoded by the major late transcription unit are named for the virion proteins discussed above (see Virion Structure) and based on their relative mobilities by SDS-PAGE. Various historical names of viral polypeptides are used in this chapter, generally preceded by the name of the transcription unit or family of late mRNAs that encodes them (e.g., E4 ORF6, L4-100K).

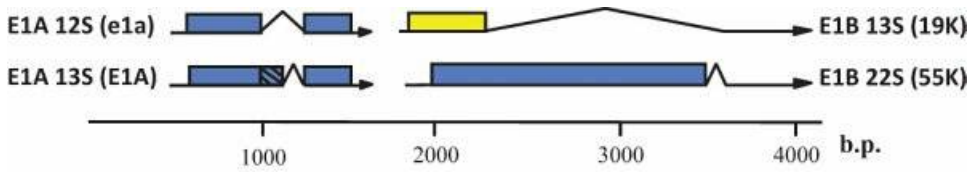

FIGURE 4.10 HAdV-C2 and HAdV-C5 major E1A and E1B mRNAs and proteins expressed during the early phase of infection and in transformed cells. The small e1a and large E1A proteins, 243R and 289R, respectively, are translated from spliced mRNAs with single introns having alternative 5′ donor splice sites and the same 3′ acceptor splice site (12S and 13S E1A mRNAs). Translation starts at the first AUG of both mRNAs, and the second exon of both mRNAs is translated in the same reading frame. Consequently, the E1A 243R and 289R proteins are identical with the exception of the unique 43 aa central region in 289R (hatched). E1B proteins of 19K and 55K proteins are translated from the first and second AUG in alternative reading frames of the 22S E1B mRNA. E1B 19K also is expressed from the first AUG of the smaller 13S E1B mRNA.

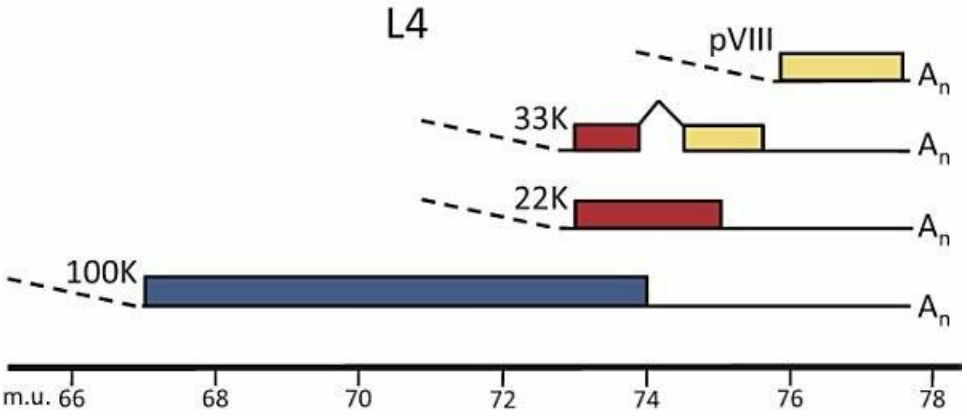

FIGURE 4.11 HAdV-C5 mRNAs and proteins from the L4 region. The coding sequences of the L4-100K, L4-22K, L4-33K, and L4-pVIII proteins shown. *Dashed lines* at the left represent splicing to the third exon of the tripartite leader.

Many of the individual adenovirus transcription units encode a series of polypeptides with

related functions. As will be discussed, the E1A unit encodes two principal proteins that activate transcription and induce the host cell to enter S phase of the cell cycle. E1B encodes two proteins that block apoptosis. E2 encodes three proteins that function in viral DNA replication. E3 encodes products that modulate the innate and adaptive immune responses to infection. The late family of mRNAs encodes proteins primarily involved in the production and assembly of viral capsids. Only the E4 unit encodes proteins with a disparate set of functions. E4 products mediate transcriptional, RNA splicing, and translational regulation, mediate mRNA nuclear export, modulate DNA replication and apoptosis, and counteract innate responses to infection.

STAGES OF REPLICATION

The replication cycle is divided by convention into two phases, early and late, that are separated by the onset of viral DNA replication (Fig. 4.12). Early events commence as soon as the infecting virus interacts with the host cell. These include adsorption, penetration, movement of partially uncoated virus particles to a nuclear pore complex (NPC), transport of viral DNA through the NPC into the nucleus, and the expression of early genes. Early viral gene products promote further viral gene expression and viral DNA replication, induce cell cycle progression, block apoptosis, and antagonize a variety of host antiviral measures. The length of the early phase of infection varies depending on the cell type and multiplicity of infection but generally lasts 6 to 12 hours. Concomitant with the onset of viral DNA replication, the late phase begins with the expression of late viral genes and the assembly of progeny virions. The infectious cycle generally is completed 30 to 72 hours after infection, depending on parameters listed above. By the end of the lytic replication cycle, approximately 10^5 progeny virus particles per cell are produced, along with the synthesis of a substantial excess of viral proteins and DNA that are not assembled into virions.

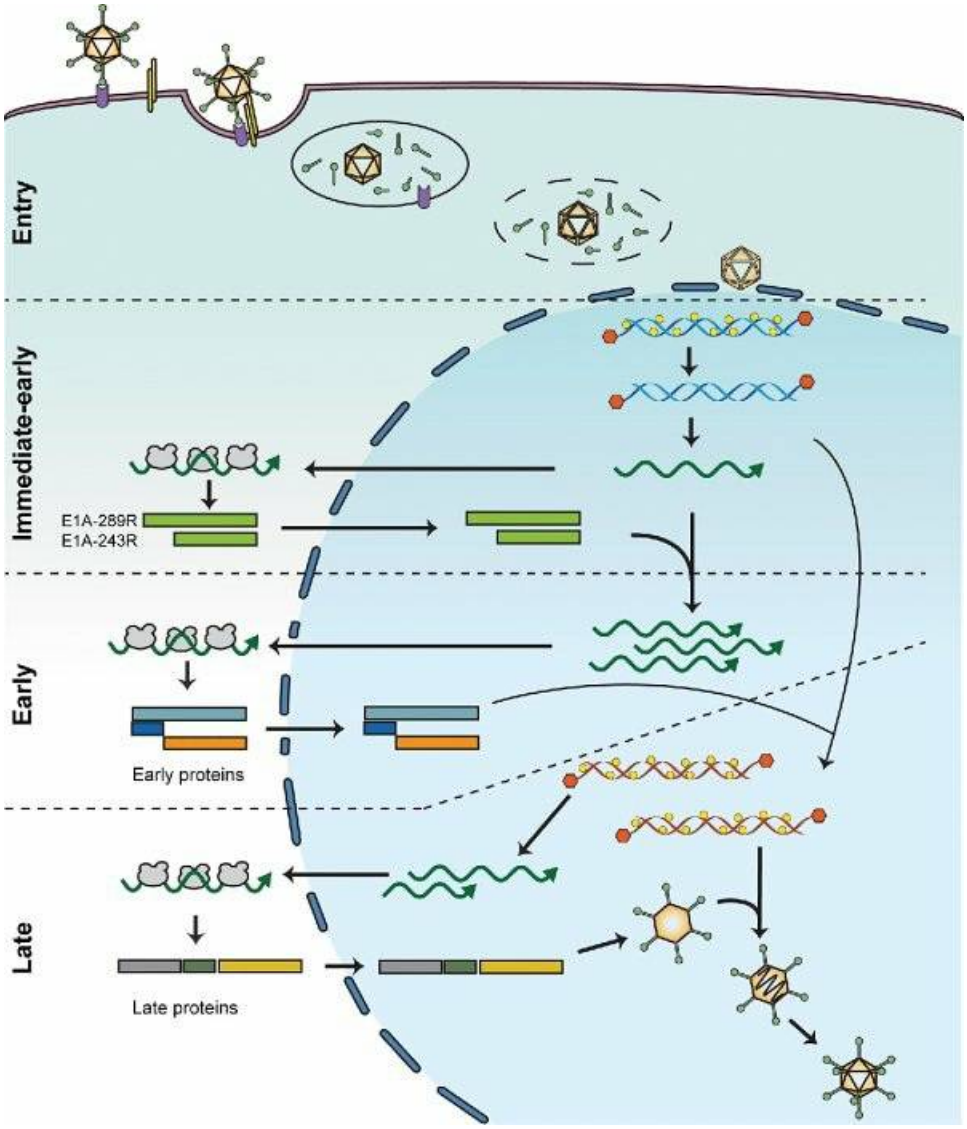

FIGURE 4.12 The HAdV-C5 life cycle. HAdV-C5 attachment to the cell is initiated by the fiber protein interacting with the cellular CAR receptor (*purple shape*), followed by interaction between the Ad penton base and cellular integrins (*yellow shapes*). Ad enters the cell through the endocytic pathway, where the viral particle is partially degraded inside the endosome, before being released into the cytosol. At the nuclear pore complex, the viral particle is disassembled. The Ad DNA–terminal protein (*orange hexagons*)–core protein VII (*yellow circles*) complex is transported through the nuclear pore; VII is released from viral genome during the early phase on infection. Immediate early E1A proteins are expressed first during infection and induce the expression of other early genes that facilitate viral replication and counteract cellular antiviral responses. Viral DNA replication proceeds, which triggers activation of the major late promoter and late gene expression. Progeny viruses are then assembled. Following encapsidation of the viral genome, the viral protease proteolyzes multiple viral proteins inside the virus particle to generate a mature virion that is released from the infected cell.

Studies of the human adenovirus replication cycle have focused primarily on the closely related HAdV-C2 and HAdV-C5 (Ad2, Ad5) viruses. These closely related types have been favored because they are easily grown in the laboratory and an extensive collection of mutant viruses have been developed. When other human adenovirus types have been studied, their growth strategies generally have proved similar to the paradigm established for these prototypes, although unique aspects are evident.

Mechanisms of Attachment

Adenoviruses use distinct cellular receptors for attachment and internalization. Initial attachment of HAdVs in species A and C–F (but not species B) is mediated by high-affinity binding of the fiber knob domain to the host–cell transmembrane CAR protein (coxsackie B, adenovirus receptor)[20,250,300] (Fig. 4.13). Human CAR (345 amino acids) is a transmembrane protein of epithelial cell tight junctions with extracellular domains in the immunoglobulin (Ig) superfamily.[53] CAR is abundantly expressed in a number of tissues (brain, heart, lung, intestine, pancreas, liver, and kidney), but little or no CAR is expressed on hematopoietic cells or adult muscle.[165] Infection does not require the CAR cytoplasmic domain, implying that CAR function in infection is primarily as an anchor for high-affinity virus binding.[313] The finding that most CAR is localized below the apical surface of polarized epithelial cells, on the basolateral surface, raises the question of how adenoviruses that utilize CAR infect from the lumen of the airway since the apical and basolateral surfaces are excluded from each other by tight junctions. The resolution of this question lies in the expression of an alternatively spliced isoform of CAR, CAR(Ex8), that localizes to the apical membrane of epithelia.[78] Interestingly, CAR(Ex8) apical expression is stimulated by the host innate immune response to infection suggesting that adenoviruses may utilize innate signaling pathways to promote epithelial cell infection.[158]

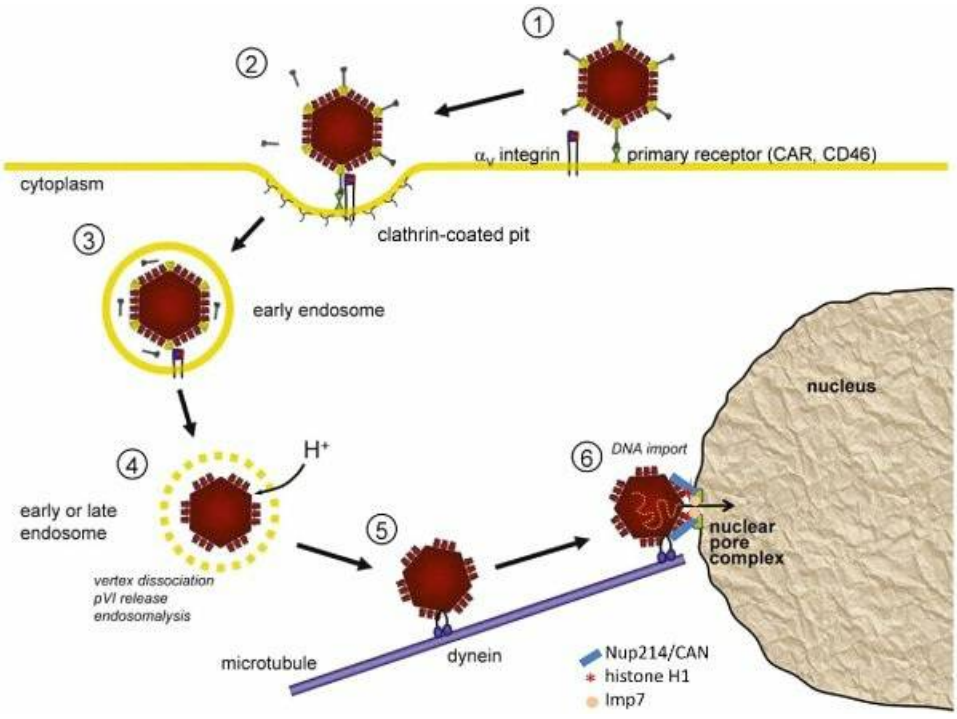

FIGURE 4.13 HAdV attachment, internalization, uncoating, intracellular transport. (1) The fiber knob binds to the primary cellular receptor, CAR (HAdV species A, C, D, E, F) or CD46 (HAdV species B); (2) The RGD loops of penton monomers (Fig. 4.5A) bind α_v integrins and stimulate endocytosis in clathrin-coated vesicles for species C; (3) Fibers begin to dissociate from pentons at the plasma membrane and completely dissociate in early endosomes; (4) The vertices of the particle composed of penton base and peripentoneal hexon trimers dissociate in endosomes, and the internal capsid proteins IIIa, VI, and VIII are released. Protein VI lyses the endosome, releasing the partially uncoated particle into the cytosol; (5) where it is transported on microtubules by dynein motor proteins to the microtubule organizing center and then associates with the cytoplasmic filament nucleoporin NUP214/CAN (6). The viral DNA bound by protein VII is then imported through the nuclear pore complex. (Reprinted from Nemerow GR, Pache L, Reddy V, et al. Insights into adenovirus host cell interactions from structural studies. *Virol* 2009;384:380–388. Copyright © 2008 Elsevier. With permission.)

The x-ray crystal structure of a complex between the HAdV-A12 fiber knob and the extracellular N-terminal Ig-like domain (D1) of CAR showed that three CAR molecules bind to the three interfaces between fiber knob monomers through the same surface used by CAR for homotypic interactions.[24] The avidity generated from the three independent interactions generates a high-affinity binding with a $K_D \approx 1$ nM.[185] Free fiber proteins produced during the late phase of infection in excess over fiber proteins incorporated into virions are released with progeny virions from the basolateral surfaces of infected airway epithelial cells and interfere with CAR oligomerization at tight junctions. This promotes release of progeny virions to the airway lumen.[311] In this way, the fiber protein serves two functions: initial attachment of virions to CAR on host cells during infection and disruption of CAR-mediated intercellular binding to promote virus escape.

Species B adenoviruses and species D HAdV-D37 bind CD46, a regulator of the complement cascade present on the plasma membrane of most cell types, including hematopoietic cells.[90,268] As with CAR binding, three extracellular domains of CD46 are bound by three fiber monomer interfaces in the fiber knob.[237] HAdV-F40 and HAdV-F41 incorporate one of two different fibers at each vertex of the virion. The longer of these binds to CAR. The receptor for the shorter fiber protein of HAdV-F40 and HAdV-F41 is not known, but it is postulated to contribute to the tropism of these viruses for intestinal epithelium.[56] In addition to CAR and CD46, a number of other cell surface molecules serve as receptors for different human adenoviruses, including desmoglein 2 (DSG2, species B), scavenger receptor A-II (species C), heparan sulfate proteoglycans (species A–D), and sialylated glycoproteins (species D).[165]

Infection by adenoviruses elicits a potent, long-term humoral immune response. While most neutralizing antibodies bind to the major virion protein hexon and are primarily responsible for the classification of HAdVs into serotypes,[92,301] neutralizing antibodies to fiber are also generated[79] and neutralize synergistically with antibodies to penton base,[91] which interacts with the secondary HAdV receptor.

Mechanisms of Entry, Uncoating, and Intracellular Trafficking

Following high-affinity binding of the HAdV-C5 fiber knob to CAR, the RGD loop domains of penton base subunits associate with αvβ3 and αvβ5 integrins on the host cell surface with 50-fold lower affinity than the interaction of fiber with CAR[319] (Fig. 4.13). Integrins are abundant heterodimeric transmembrane proteins involved in cell adhesion to the extracellular matrix and neighboring cells via RGD peptide motifs in the bound extracellular protein and are exploited by many viruses for cell entry.[287] At saturation, approximately 4 integrins are bound to the pentameric penton base.[50] Neutralizing antibodies that bind loops on the outer surface of penton block association with integrins.[122] Interaction of the penton base with integrins is presumably facilitated by their high local concentration resulting from high-affinity binding of the fiber knob to transmembrane CAR. Clustering of integrins through binding to the subunits of a pentameric penton base triggers integrin transmembrane signaling, leading to activation of phosphoinositide-3-OH kinase (PI3K), p130CAS, and Rho family GTPases.[172] This results in the localized actin polymerization required for endocytosis of the virion via clathrin-coated pits in classic receptor-mediated endocytosis that involves clathrin adapters and the large GTPase dynamin[101] (Fig. 4.13). Dynamin multimerizes into a spiral-shaped structure that promotes the membrane fusion required for separating an endosome from the plasma membrane.[93,314]

By contrast, species B adenoviruses, with CD46 as the primary receptor, enter cells through a penton base interaction with αv integrins that stimulates an alternative, clathrin-independent mechanism of endocytosis termed macropinocytosis.[3,141] Macropinocytosis requires integrins, F-actin, protein kinase C, and small G proteins of the Rho family, but not dynamin.[203] Species C HAdVs also stimulate macropinocytosis but do not use this process as a primary route of infection.[3]

Uncoating of the virion begins at the cell surface (Fig. 4.13). The interaction of penton base with integrins at the cell surface and during endocytosis leads to detachment of fibers, and fiberless virions are endocytosed.[212] Following endocytosis of clathrin-coated vesicles containing HAdV-C2, the vesicles mature into early endosomes. Release of penton base, peripentoneal hexon trimers, and the internal capsid proteins IIIa, VI, and VIII occurs in the endosome.[104] Lysis of the endosome and release of partially uncoated virions into the cytosol is mediated by an N-terminal amphipathic helical, membrane lytic domain of protein VI.[321] Protein VI binds the internal side of the endosomal membrane and induces positive curvature strain that leads to membrane fragmentation.[192]

For adenovirus species A, B, C, and D, release of penton base and protein VI and lysis of endosomes are blocked by α-defensins, antimicrobial cysteine-rich peptides released from host neutrophils.[214,274] CryoEM and other studies indicate that thousands of defensin molecules bind to HAdV species A, B, C, and D (but not E or F) virions. Defensins bound at the interface between fiber and penton base are particularly important for inhibiting infection, by preventing the loss of the vertex region and therefore preventing escape of protein VI and endosome lysis.[274] As a consequence, virion-containing endosomes mature into late endosomes and fuse with lysosomes where virion proteins and DNA are degraded.[274]

In the absence of these host defenses, endosomal lysis occurs. The subvirion particles released into the cytosol are transported to the nucleus on microtubules[170,191] (Fig. 4.13). Fluorescently labeled virion particles were observed with live cell imaging to switch rapidly

between minus-ended microtubule motility toward the juxtanuclear microtubule organizing center (MTOC) and plus-ended motility away from the nucleus. But transient activation of protein kinase A (PKA) by integrin signaling and activation of the p38 MAP kinase and its target MAPKAP kinase 2 (MK2) increased the frequency and velocity of minus-end directed movement of subviral particles by the dynein motor protein complex[293] until they reach the MTOC.[13] A neutralizing monoclonal antibody to hexon does not interfere with endosome lysis but rather blocks infection by inhibiting the association of virions with microtubules, suggesting that it is hexon that binds to microtubule motors.[273]

From the juxtanuclear MTOC, subvirion particles associate with NPCs[102] via an interaction between hexon trimers and the Phe-Gly repeat–containing domain of NPC cytoplasmic filament protein CAN/Nup214.[304] Surprisingly, the activity of exportin 1 (CRM1), a nuclear export factor, is required for this association with the cytoplasmic side of NPCs, since association of subvirion particles with NPCs is blocked by leptomycin B and ratjadone A, highly specific inhibitors of exportin 1, and by small interfering RNA (siRNA) to exportin 1.[291] How exportin 1 functions in this process is unclear.

The diameter of subviral particles bound to the NPC (~90 nm) is too large to pass through diffusional channels in the pore, approximately 5 to 9 nm.[2] Viral uncoating occurs at the nuclear pore as shown by exposure of core polypeptide VII and hexon epitopes that are hidden in intact virions.[102] FRET experiments with fluorescently labeled virions indicate that the half-time for disassembly of the icosahedral capsid, probably coincident with unpackaging at the NPC, is approximately 60 minutes.[198] Blocking NPC binding by microinjection of wheat germ agglutinin or specific antibodies that bind to central domains of the NPC blocks exposure of the VII and hexon epitopes, indicating that an interaction with the NPC is required to trigger final capsid disassembly.[102] This mechanism assures that viral DNA is released only at the NPC in preparation for transport into the nucleus. Nuclear import of the viral DNA core requires histone H1 and H1 import factors.[304]

Viral DNA bound by the major basic core protein VII enters the nucleus, while most hexon and protein IX remain associated with NPCs, indicating that the viral DNA– protein VII complex separates from the partially dissociated capsid during the nuclear import process.[43,102,281,333] The protein VII–viral DNA complex is imported into the nucleus in a Ran-dependent mechanism involving protein VII binding to the importin transportin.[121,324] Experiments with HAdV-C2 containing a green fluorescent protein V fusion protein indicate that core protein V remains on the cytoplasmic side of the NPC and does not enter the nucleus with the protein VII–viral DNA complex.[239] Protein VII remains associated with viral DNA during the early phase of infection and may be dissociated by transcription of the viral genome,[45] although this idea and how viral DNA is converted from a VII-bound state to a cellular histone–associated chromatin state are controversial.[97]

Adenovirus infection activates components of the innate immune response that recognize pathogen-associated molecular patterns (PAMPs), specifically endosomal and cytoplasmic viral DNA. Binding of purified recombinant HAdV-C5 fiber knob to the CAR receptor of human A549 lung carcinoma cells causes an increase in MAP kinases ERK1/2 and JNK activities minutes after addition to cells and NF-κB translocation to nuclei thereafter.[294] This is associated with the induction of proinflammatory chemokine gene expression. Toll-like receptor 9 (TLR9) is activated by viral DNA within endosomes in plasmacytoid dendritic cells (pDCs), resulting in

the secretion of interferon alpha (IFNα).[15,39,130,348] Adenovirus DNA recognition in non-pDCs is TLR independent, via cytoplasmic sensing of viral DNA.[348] In some human cell lines, cytoplasmic viral DNA induces the activation of cGAS/STING, resulting in the phosphorylation and activation of TBK1 and IRF3 and the subsequent induction of IFNβ gene expression.[164] In human THP1 monocyte cells, infection with species B or C adenoviruses triggers the activation of the NLRP3 inflammasome to promote an innate response and IL-1β secretion.[210] Many studies have used murine models of human adenovirus infection. In mice, adenovirus infection induces the production of high levels of type I IFNs by pDCs, conventional DCs, and macrophages.[348] Additionally, adenovirus infection of murine antigen-presenting cells (APCs) and primary lung fibroblasts stimulates IRF3-mediated IFN and proinflammatory responses through a TLR-independent DNA-sensing mechanism[215] dependent on the cGAS-STING pathway.[164,348] These data demonstrate that in a cell type–specific manner, adenovirus uncoating stimulates innate antiviral cellular responses that induce IFN and inflammatory signaling pathways.

Early Gene Transcription

Core protein VII serves the crucial role of suppressing activation of the cellular DNA damage response (DDR) when the viral DNA first enters the nucleus.[146] In the absence of such protection, the cellular Mre11-Rad50-Nbs1 complex is activated by the termini of the viral DNA; if unabated, a DDR significantly inhibits viral DNA replication[317] (discussed below). Protein VII interacts with the cellular chromatin remodeling factor, template activating factor-I (TAF-I/SET), during the early phase of infection.[110,111,333] TAF-I/SET is a histone-binding chromatin remodeling factor. TAF-I/SET knockdown in adenovirus-infected cells results in a delay in transcription of early genes.[111] It is proposed that TAF-I/SET promotes the remodeling of the adenovirus protein VII–DNA complex into cellular histone–containing chromatin. Chromatin immunoprecipitation assays indicate that cellular histones replace much of protein VII early in infection, generating viral genomes bound by both VII and acetylated nucleosomes.[154] The DNA of an HAdV-C5 gene therapy vector is assembled into physiologically spaced nucleosomes containing histone H3.3, the isotype associated with transcribed cellular genes, dependent on the activity of the histone chaperone HIRA.[251] Protein VII-SET interaction also contributes to the ability of protein VII to inhibit DDR signaling pathways.[9] Protein VII interacts with cellular nucleosomes and alters chromatin composition and accessibility.[10] This includes proteins of the high-mobility group protein B (HMGB) family. HMGB1 is released in response to inflammatory stimuli and serves as a danger signal to trigger immune responses. Protein VII binds directly to HMGB1, sequesters HMGB1 in cellular chromatin, and inhibits its activity to block extracellular immune signaling.[10] Thus, core protein VII plays multiple important roles at early and late times after adenovirus infection.

The E1A region is the first region to be transcribed following infection[213] due to a constitutive transcriptional enhancer region located upstream of the E1A promoter.[117] The major cellular transcription factor that activates E1A expression via the enhancer is GABP, but a number of other transcription factors interact with this and flanking sequences including members of the ATF family, SP1, and E2F transcription factors to stimulate E1A expression.[35,114,176] Two major E1A mRNAs and encoded proteins are expressed early after infection by alternative splicing of a primary transcript, using either one of two 5′ donor splice

sites and the same 3′ acceptor splice site[236] (Fig. 4.10, 13S and 12S E1A mRNAs). The protein encoded by the longer E1A mRNA has been termed large E1A, E1A 13S protein, and E1A 289R (289 amino acid residues). The protein encoded by the shorter E1A mRNA has been termed small e1a, E1A 12S protein, and E1A 243R. E1A 289R and E1A 243R will be used henceforth.

The E1A 289R protein transactivates the early region E1B, E2-early, E3, and E4 promoter regions (discussed below). The E1B transcription unit is located immediately to the right of the E1A region (Fig. 4.9). The E1B promoter is composed primarily of an SP1 transcription factor–binding site closely juxtaposed to a TATA box.[328] Additional transcription factor–binding sites in the 3′-end of the E1A transcription unit stimulate E1B transcription further.[230] Transcription of the E2 region peaks after the other early regions,[213] and while the other early regions continue to be transcribed throughout the late phase of infection, E2 transcription reaches much higher levels than the other early regions, in part because of the activation of a second E2 promoter, the E2-late promoter (Fig. 4.9). The E2-early promoter is composed of two binding sites for the E2F family of transcription factors in inverted orientation upstream of a TATA box and a binding site for the ATF family of transcription factors located upstream of the E2F sites.[159,169] The E2-late promoter extends upstream from the transcription start site and includes a TATA box, binding sites for two SP1 transcription factors, and two sites that bind CAAT box–binding factors.[25] The E3 promoter consists of a TATA box and upstream binding sites for transcription factors NF1, AP1, and ATFs.[129] In lymphoid cells, an upstream NF-κB site is critical for E3 expression.[322] The E3 region expresses a number of alternatively spliced mRNAs encoding proteins that inhibit innate and acquired immune responses to viral infection (discussed below). Consequently, activation of E3 by NF-κB, which activates multiple cellular genes involved in innate and acquired immune responses, likely functions in a regulatory feedback loop that protects virus-infected cells from host antiviral mechanisms. The E4 promoter region contains a TATA box and binding sites for multiple transcription factors including E4F, E4TF1, ATFs, and GABP.[35,169,315] The E1A enhancer region also activates all of the adenovirus early promoter regions *in cis*.[118]

Although early and late are conventional terms for events that occur during the replication cycle, the functional distinction between early and late genes is often blurred. Early genes continue to be expressed at late times after infection, and the promoter controlling expression of the major late transcription unit directs a low level of transcription early after infection. Also, the viral genes encoding proteins IVa2, pIX, L4-22K, and L4-33K are expressed at an intermediate time, thus forming a delayed-early or intermediate expression category.

Functions of Adenovirus Early Proteins

E1A

There are three main outcomes of adenovirus early gene expression. First, the host cell is induced to enter S phase of the cell cycle, providing an optimal environment for viral replication. E1A and E4 gene products play roles in this process. Second, various antiviral defenses of the host cell and organism are inhibited. The E1A, E1B, E3, and VA RNA genes contribute to these defenses. Third, viral gene products required for viral DNA replication are synthesized. E2 encodes the viral replication proteins.

Both E1A 289R and 243R proteins share regions that are conserved across adenovirus

species and include conserved region 1 (CR1) and CR2 in the 5′ exon and CR4 in the 3′ exon (Fig. 4.14). In addition, E1A 289R contains CR3 corresponding to the unique sequences in this protein. Three additional, alternatively spliced E1A mRNA species designated 9S, 10S, and 11S accumulate at later times in the infectious cycle that contains the same 3′ exon but have additional sequences spliced out of the 5′ exons.[285] However, no functions have been described for products of these mRNAs.

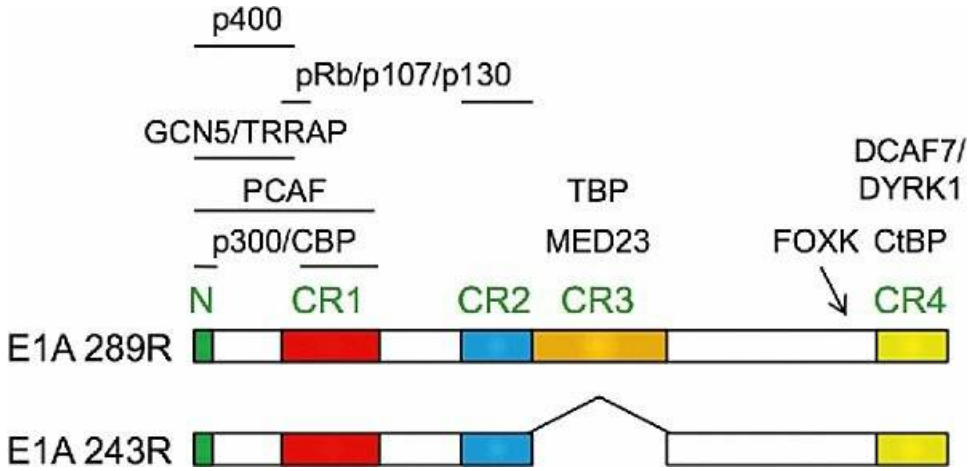

FIGURE 4.14 Protein–protein interaction domains of the E1A protein. Extensively conserved amino acid sequences in the primate adenoviruses are designated CR1 (*red*), CR2 (*blue*), CR3 (*orange*), and CR4 (*yellow*) and the conserved N-terminal region is indicated (*green*). N-terminal, CR1, and CR2 sequences that mediate interactions with cellular binding proteins are indicated by horizontal lines with the proteins listed above. MED23 and TBP bind to CR3. CtBP and DYRK1/DCAF7 bind to CR4 and FOXK protein interacts with sequences just N-terminal of CR4.

The E1A 289R and E1A 243R proteins can each stimulate G_0- and G_1-arrested cells to enter S phase in the absence of other mitogenic signals via the conserved sequences that they share.[211,241,282] Presumably, this reflects the situation when HAdV-C2 and HAdV-C5 infect differentiated, G_0-arrested upper respiratory tract epithelial cells. Induction of cellular DNA synthesis requires E1A protein interactions with the abundant, closely related nuclear lysine acetyl transferases p300 and CBP (KAT3B, KAT3A) and the retinoblastoma family proteins pRb (RB1), p107 (RBL1), and p130 (RBL2).[151] E1A proteins interact with p300/CBP via sequences at the N terminus and CR1 and bind RB family proteins via CR1 and CR2 (Fig. 4.13). E1A binds to Rb family members using sequences in CR1 and a conserved LXCXE motif in CR2 that interacts with the pocket domain of Rb family proteins (Fig. 4.15).[73] The transforming proteins of other DNA tumor viruses, polyomavirus large T antigen and papillomavirus E7 proteins, use the same conserved sequence for interactions with Rb family proteins.[151] The E2F family of transcription factors control genes required for entry into S phase.[147] Rb family proteins interact with E2F transactivators via the central Rb pocket domain and the C-terminal regions of E2Fs, which contain the transactivation domain. Rb proteins mask the E2F transactivation domain and

recruit transcriptional repressors (e.g., HDACs) to promoter regions.[66] E1A binds to the Rb pocket region with high affinity and displaces Rb family proteins from E2Fs by competitive interaction with the same Rb pocket sequences that bind to the E2F transactivation domain[12] (Fig. 4.15). The interactions of E1A with p300/CBP and Rb family members induce cell proliferation and are required for transformation of primary cells,[74,124,318] and these E1A protein interactions induce global changes in the localization of these transcriptional regulators throughout the host cell genome to alter cellular gene expression patterns.[81]

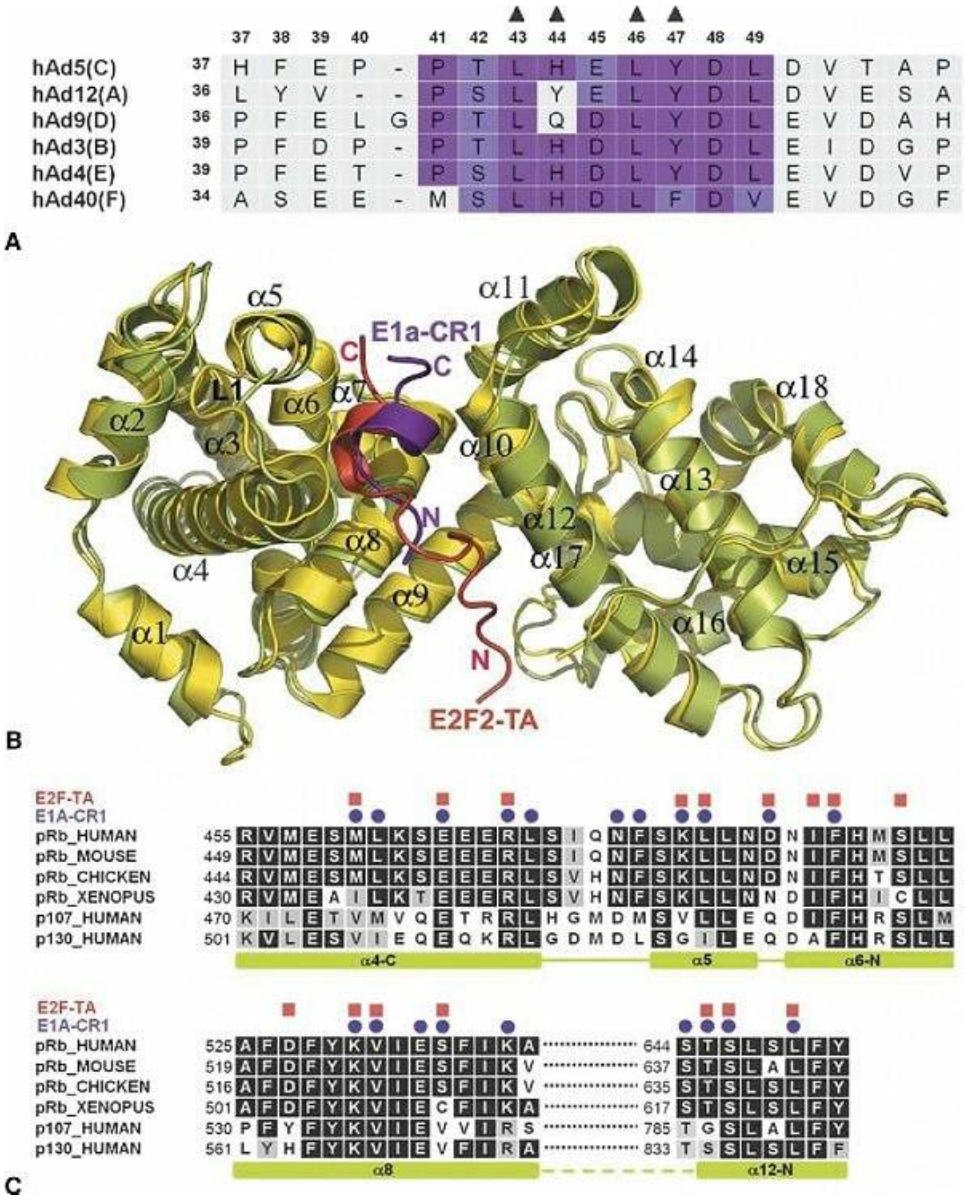

FIGURE 4.15 Structure of the E1A–Rb complex. A: Sequence alignment of E1A CR1 from different adenovirus types/species. Invariant and conserved CR1 residues are highlighted in *dark* and *light purple*, respectively. Residues indicated by *solid triangles* are involved in pRb interaction. **B:** Ribbon diagram of the E1A CR1–Rb and E2F2-TA–Rb structures with E1A CR1 and E2F2-TA are shown in *purple* and *red*,

respectively. **C:** Sequence alignment of human pRb paralogs and pRb orthologs from selected species. Residues that mediate interaction with E1A CR1 and E2F2-TA are marked with *purple* circles and *red* squares, respectively. (Reprinted with permission from Liu X, Marmorstein R. Structure of the retinoblastoma protein bound to adenovirus E1A reveals the molecular basis for viral oncoprotein inactivation of a tumor suppressor. *Genes Devel* 2007:21:2711–2716, with permission. A series of reports have defined how the adenovirus E1A proteins positively and negatively regulate cellular gene expression. In quiescent mouse cells, the promoter regions of the cell cycle–regulated genes Cdc6 and cyclin A are bound by E2F4 associated with p130 and the histone deacetylation complex HDAC1/2–mSin3B to repress gene expression.[96] These promoter regions also are associated with the Suv39H1 histone methylase transferase, which methylates histone H3 lysine 9 (H3K9), generating binding sites for the repressive heterochromatin protein 1 (HP1).[96,269] E1A expression leads to the loss of repressive E2F4–p130 complexes and replacement with activating E2Fs 1, 2, and 3 and the acetylation of H3K9.[96,269] This was not observed with an E1A CR2 mutant that does not bind Rb family proteins.[96] An N-terminal E1A mutant that does not bind the histone acetyl transferase/chromatin remodeling complex containing TRRAP–PCAF–p400[89] displaces the E2F4–p130 corepressor complex but does not induce acetylation of H3K9, transcription of the Cdc6 and cyclin A genes, and entry into S phase.[269] These results demonstrate that E1A induces cells to enter S phase by reconfiguring chromatin structure on specific cellular promoter regions both by displacing repressive E2F4 complexes via interaction with Rb family proteins and by inducing H3 acetylation using the TRRAP–PCAF–p400 complex.[96,269]

Genomic studies with an HAdV-C5 mutant virus that expresses the E1A 243R but not the E1A 289R protein revealed that, remarkably, E1A 243R associated with the promoters of most cellular genes in a specific temporal order, either activating or inhibiting their expression.[81] In quiescent primary human fibroblasts, the E1A 243R protein was associated with the promoter regions of genes involved in cell cycle, and DNA, RNA, and protein synthesis, amounting to approximately 30% of all cellular genes. The E1A 243R protein directed the enrichment of p300/CBP and PCAF, the depletion of Rb family proteins, and the acetylation of histone H3K18 at these genes, resulting in their transcriptional activation.[81] Induction of many of these genes also was observed in quiescent human fibroblasts infected with HAdV-C5.[204] The E1A 243R protein was also associated with the promoters of genes involved in inflammation and other defenses against pathogens (~20% of cellular genes) causing the enrichment for pRb, p130, the acetylation of histone H4K16, and transcriptional repression.[81] Repression of genes involved in innate immune responses, inhibition of cell cycle progression, and induction of genes involved in metabolic pathways contributing to cell growth also were observed after infection of HeLa cells with HAdV-C2.[99,345] At later times after infection of growth-arrested primary human fibroblasts, E1A 243R and p107 associated with the remaining approximately 50% of genes involved in differentiated cell functions and repressed their transcription.[81] The E1A 243R protein represses the expression of a specific set of cellular genes (e.g., cytokine signaling pathway genes such as TGFβ and TNF) via an E1A–p300–pRb complex that specifically interacts within the transcribed sequences of these genes.[80] The E1A–p300–pRb complex condenses cellular chromatin

dependent on the lysine acetyl transferase activity of p300 associated with E1A and pRb acetylation.[80] These novel and important results revealed specific epigenetic reprogramming of cellular gene expression by the E1A 243R protein dependent on interactions with p300/CBP and Rb family proteins. Further, the results suggested that after E1A dissociates Rb family proteins from E2F4 and other transcription factors to induce cell proliferation, it also exploits the same Rb family proteins to repress antiviral response genes and differentiated cell functions that may otherwise inhibit virus replication.

The E1A 289R protein autoactivates transcription of the E1A region approximately fivefold and stimulates transcription from the E1B, E2 early, E3, and E4 regions from tenfold (E1B) to hundredfold (E2-early, E3, and E4).[206] Activation requires a stable, highly specific interaction of E1A CR3 with the MED23 subunit of the human mediator transcription complex.[31,286] E1A CR3 transcriptional activation domain interaction with MED23 both increases the assembly of preinitiation complexes on promoters and stimulates transcriptional elongation.[36,312] The zinc finger in E1A CR3 binds to the TATA-binding protein, TBP, and other components of the TFII-D general transcription factor complex, stimulating the formation of an RNA polymerase II preinitiation complex.[94,95] The E1A 289R protein does not bind to DNA directly but may be recruited to promoter regions via interaction with several cellular transcription factors, including members of the ATF family, AP1, USF, and SP1.[176,177,290] E1A may recruit positive (e.g., p300/CBP) or negative (e.g., Rb family members) regulators of transcription in conjunction with these cellular factors, activating or repressing gene expression, respectively. In addition, a glutamic acid–proline repeat, AR1, immediately C terminal to CR3 in HAdV-C2 and HAdV-C5 E1A, is essential for E1A 289R activation of the early adenovirus promoters.[290]

E1A CR4 (Fig. 4.14) contains a nuclear localization signal (NLS) at the very C terminus.[189] The E1A 243R protein is sufficient to immortalize primary rodent cells *in vitro* and promote oncogenic transformation in conjunction with another oncogene such as Ad E1B 55K or activated H-Ras.[255] Sequences in the C-terminal exon of the E1A 243R protein reduce transformation in these assays, since specific CR4 mutant proteins displayed augmented transformation properties.[49] The C-terminal region of the E1A proteins binds to a number of cellular proteins including forkhead transcription factors FOXK1/K2, protein kinase DYRK1A and cofactor DCAF7, and the transcriptional repressor C-terminal–binding protein (CtBP). DYRK1A/DCAF7 and CtBP bind to sequences within CR4, while FOXK1/K2 interacts with sequences just N terminal of CR4. The C-terminal transformation repression function was originally attributed to interaction with CtBP, which binds to the highly conserved sequence PXDLS present in all primate adenoviruses.[49] CtBP is a transcriptional corepressor. A complex picture has emerged concerning the regulation of E1A immortalization and transformation functions by these C-terminal–binding proteins. Initially, the interaction of E1A CR4 with CtBP was found to be important for transformation of primary rodent cells by HAdV-C2 E1A and E1B, whereas CtBP binding negatively regulated E1A-mediated tumorigenesis and metastasis in cooperation with oncogenic H-Ras.[49] More recent studies have presented somewhat divergent views of these processes, with one report suggesting that E1A–CtBP interaction suppresses both immortalization and oncogenic H-Ras transformation of primary rodent cells without significantly affecting tumorigenicity,[292] whereas another study concluded that the interaction of E1A with DYRK1A/DCAF7 plays an important role in E1A 243R suppression of transformation by activated H-Ras while CtBP was not involved.[54] A third study concluded that E1A interaction

with either FOXK1/K2 or DYRK1A/DCAF7 decreases oncogenic transformation.[155] These discrepancies may reflect differences in the types of transformation and oncogenicity assays used as well as differences in specific E1A C-terminal mutants. The results may indicate functional redundancy in the interaction of E1A with the three different cellular protein complexes FOXK1/K2, DYRK1A/DCAD7, and CtBP. Finally, the interaction of E1A with CtBP was shown to enhance replication during HAdV-C5 infection of normal human bronchial epithelial cells, and consistent with this result, CtBP knockdown in human U2OS osteosarcoma cancer cells also augmented the virus replication cycle.[292]

In a separate study, the role of E1A CR4–binding partners in the regulation of cellular gene expression was examined.[339] Growth-arrested primary human epithelial cells were infected with HAdV-C5 E1A CR4 mutant viruses containing specific amino acid substitutions individually within the FOXK1/K2, DYRK1A/DCAF7, or CtBP-binding sites and RNA-seq was conducted to analyze changes in cellular gene expression compared to wild-type HAdV-C5. Comparing E1A CR4 mutant viruses to wild-type HAdV-C5, only a small number of genes showed altered expression, but of those genes, a large overlap was observed with genes that were overexpressed with all three individual CR4 mutants.[339] Some of these genes encode proteins that have antiviral functions, and their promoter regions are enriched for IFN-stimulated response elements. Further analyses showed that the E1A CR4 mutant viruses activate transcription of a subset of IFN-stimulated genes (ISGs). Expression of these ISGs was mediated by an increase in protein levels of the transcription factor IRF3 and IRF3 bound to the promoters of the activated ISGs.[339] CR4 mutant viruses with combinations of these mutations displayed the same phenotype as did the individual mutants, indicating that all three CR4 cellular proteins function as a complex. This idea was supported by protein biochemical experiments.[339] These results demonstrate that wild-type E1A suppresses the expression of ISGs and that the CR4 mutants are not able to do so. Further, the results suggest that FOXK1/K2, DYRK1A/DCAF7, and CtBP bind coordinately to the C-terminal region of E1A and that disruption of any one interaction relieves E1A repression of all three activities.

The adenovirus E1A proteins are well characterized for their ability to block IFN signaling pathways and the induction of ISG expression. Early studies in cancer cell lines demonstrated that HAdV-C5 infection, or HAdV-C5 E1A expression alone, blocked the induction of ISG expression by IFNα.[246] This was the result of reduced formation of the ISGF3 complex due to decreased levels of its constituent proteins.[108,142] Inhibition of ISG expression also correlated with E1A binding to p300/CBP.[252] Different results were found in primary human airway epithelial cells, in which E1A blocked IFN-induced ISG expression by direct interaction with STAT1 via E1A N-terminal sequences.[184] E1A expression also resulted in down-regulation of STAT1 phosphorylation.[184] Cancer cell lines have altered signal transduction pathways and likely respond to viral infection in different ways compared to primary cells. Recently, E1A was found to inhibit ISG expression via the cellular DNA-dependent ATPase RuvBL1.[217] The RVB complex is required for efficient activation of ISG expression during type I IFN signaling.[98] The C-terminal region of E1A binds RuvBL1, and E1A–RuvBL1 complexes bind to the promoter regions of ISGs to repress their activation.[217]

Modification of histones by ubiquitin marks transcriptionally active chromatin.[332] In a study to analyze if HAdV-C5 regulates histone modification, global ubiquitylated histone 2B levels were compared for wild-type HAdV-C5 and an E1A-null mutant virus.[84] The HAdV-C5 E1A

mutant virus strongly induced H2B ubiquitylation at lysine 120 (H2B-K120) in primary and transformed human cells, but wild-type HAdV-C5 did not. A similar induction of H2B ubiquitin levels was observed following type I IFN treatment; E1A expression alone reversed this effect.[84] Human Bre1/RNF20 is an E3 ubiquitin ligase that monoubiquitylates H2B-K120. The N-terminal region of E1A binds to hBre1/RNF20 and blocks the interaction between hBre1 and the ubiquitin conjugase catalytic subunit Ube2b.[84] This results in the inhibition of histone 2B monoubiquitylation at ISG promoter regions and an inhibition of ISG induction following type I IFN treatment. Subsequent studies showed that E1A also utilizes hBre1 to recruit the RNA polymerase II transcription elongation factor hPaf1 to adenovirus early promoter regions, stimulating viral gene expression.[83] These studies demonstrated how the E1A proteins co-opt cellular transcriptional regulators to promote viral gene expression and inhibit the expression of cellular genes involved during innate responses to infection, in this case specifically during type I IFN signaling.

While the E1A proteins were originally described as activators of viral early gene expression, it is clear that an important effect of the E1A proteins is the down-regulation of innate cellular responses to infection, particularly with respect to different aspects of IFN signaling. E1A proteins block cytoplasmic IFN signaling pathways, inhibiting the cellular response to infection, and they down-regulate mechanisms that are used by the cell to promote ISG expression in the nucleus. In addition, a recent study suggests that IFN inhibition of viral gene expression may promote persistent adenoviral infection.[347]

E1B

The E1B region encodes two abundant spliced mRNAs (13S and 22S), encoding proteins commonly referred to as E1B 19K and E1B 55K (Fig. 4.10). The level and activity of the tumor suppressor p53 are induced by the abnormal stimulation of the cell cycle induced by the E1A proteins.[65,186] The E1B 19K and E1B 55K proteins inhibit p53-dependent induction of apoptosis by different mechanisms. E1B 19K is homologous to cellular BCL-2 family of proteins and functions as a viral mimic of MCL-1, an antiapoptotic member of the BCL-2 family.[58] MCL-1 binds to the proapoptotic BCL-2 family members BAK and BAX, preventing them from co-oligomerizing and forming pores in the outer mitochondrial membrane. Apoptosis is induced following infection with an E1B 19K mutant virus because the critical cellular antiapoptotic BCL-2 family member MCL-1 is degraded by the proteasome.[57] In the absence of E1B 19K, formation of such BAK–BAX pores in the outer mitochondrial membranes of infected cells releases apoptogenic proteins such as cytochrome c and Smac/DIABOLO, leading to the activation of caspase-9 and caspase-3 and the ensuing apoptotic program.[58] This pathway is blocked in wild-type virus-infected cells by the sequestration of activated BAK and BAX by E1B 19K.

p53 function is directly inhibited by the E1B 55K protein through multiple mechanisms. Like SV40 large T antigen, the E1B 55K protein binds the tumor suppressor p53.[22] E1B 55K binds to the amino terminus of p53, which also contains the p53 activation domain and the region bound by MDM2, the major ubiquitin ligase controlling p53 proteasomal degradation.[145,174] As a result, p53 is stabilized and transcriptional activation by p53 is inhibited.[334,335] The E1B 55K protein functions as an E3 SUMO1 (small ubiquitin-like modifier) ligase for p53,[232] resulting in the sumoylation of approximately 1% of p53 and association of the complex with promyelocytic

leukemia protein (PML) nuclear bodies.[208,232] Sumoylation of a small fraction of a nuclear protein can result in the association of nearly all of the nuclear protein with PML nuclear bodies, based on higher-order protein–protein interactions.[115] In the case of the E1B 55K–p53 complex, this can be explained by the formation of a large network of p53 tetramers cross-linked by the binding of E1B 55K dimers[197] and the binding of sumoylated E1B 55K[75,323] to SUMO-interaction motifs in the PML protein within PML nuclear bodies. Association of E1B 55K–SUMO1 complexes with PML nuclear bodies promotes E1B 55K nuclear export by exportin 1 (CRM1).[149,160,232] In cells transformed by E1A and E1B, or when E1B 55K is expressed in the absence of other viral proteins, E1B 55K–p53 complexes exported to the cytoplasm are transported on microtubules by dynein motor proteins to the microtubule organizing center (MTOC) where they accumulate, forming large cytoplasmic inclusion bodies,[338] termed aggresomes, and are targeted for degradation.[180,232]

The HAdV-C5 E1B 55K protein also forms a complex with the E4 ORF6 protein. This complex associates with cellular proteins elongins B and C, cullin 5, and Rbx1 to form an E3 ubiquitin ligase that polyubiquitinates p53, leading to its proteasomal degradation[109,240] (Fig. 4.16). E1B 55K also binds the host cell Mre11-Rad50-Nbs1 (MRN) complex through a distinct region from the E1B 55K region that binds p53.[267] The MRN complex functions as a sensor of DNA damage, activating a DDR and cell cycle checkpoint signaling.[317] If activated, a cellular DDR significantly inhibits adenovirus DNA replication and results in an abortive viral infection. The E1B 55K–E4 ORF6 ubiquitin ligase complex plays a pivotal role among all species of adenoviruses to prevent a DDR from occurring.[317] E1B 55K–MRN complexes also associate with PML nuclear bodies and subsequently are exported to aggresomes at the MTOC.[180] The HAdV-C5 E1B 55K–E4 ORF6–elongin B/C–cullin 5–Rbx1 ubiquitin ligase also polyubiquitinates subunits of the MRN complex, inducing their proteasomal degradation.[288] During infection, MRN complex components and p53 are first inhibited by being sequestered into PML nuclear bodies and then by their nuclear export and proteasomal degradation. This prevents them from interacting with nuclear substrates, and transport to the MTOC accelerates the rate of their degradation; proteasomes and components of the ubiquitination pathway are concentrated at the MTOC.[180] The E1B 55K–E4 ORF6 ubiquitin ligase complex also targets other proteins involved in the DNA damage response, including DNA ligase IV[14] and the Bloom helicase.[219] The interaction of these two proteins with the termini of adenovirus genomes would be expected to interfere with viral DNA replication. Integrin α3 was identified as another substrate of this viral ubiquitin ligase.[63] Additional substrates targeted for degradation by the E1B 55K–E4 ORF6 ubiquitin ligase complex include Tankyrase 1–binding protein 1, Tip60, SPOC1, ATRX, SMARCAL1, ALCAM, EPHA2, and PTPRF.[279] Interestingly, the E1B 55K–E4 ORF6 proteins of other Ad serotypes form ubiquitin ligase complexes with either Cul2 or Cul5, which directs their substrate specificity; all of the E1B 55K–E4 ORF6 complexes target components of the DNA damage response, ensuring efficient viral DNA replication.[47,48,86] In an E4 ORF6–independent manner, HAdV-C5 E1B 55K targets the chromatin remodeling factor Daxx for proteasomal degradation.[266] While it is not clear why all of these substrates are targeted for degradation, several of them (Tip60, SPOC1, and Daxx/ATRX) function as intrinsic cellular activities that limit viral early gene expression and virus replication.

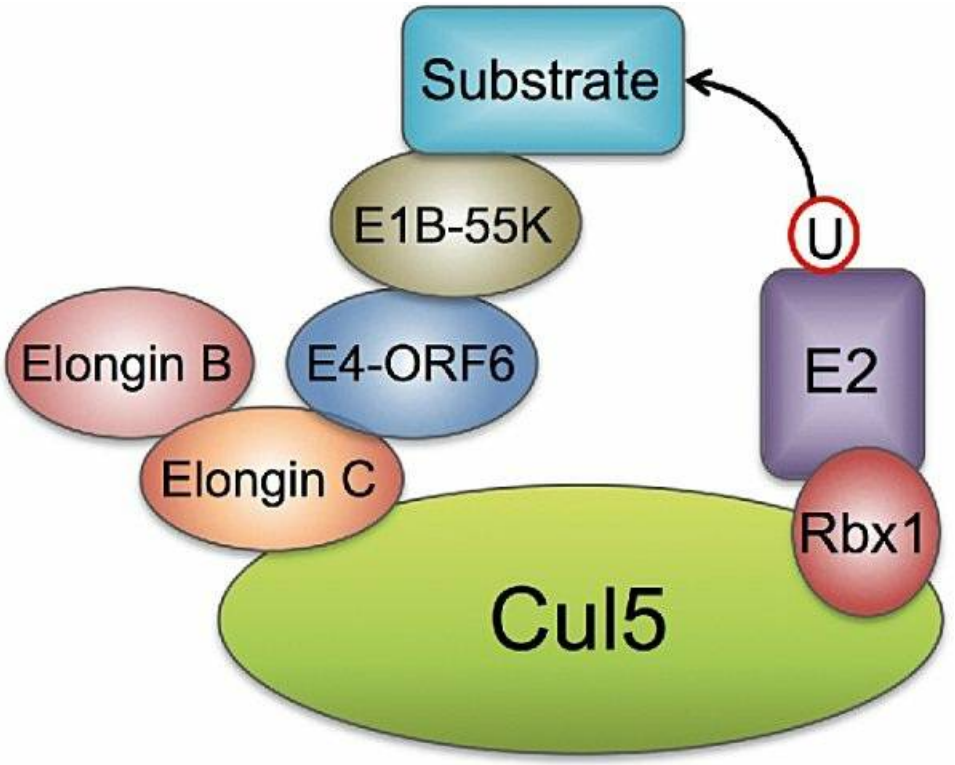

FIGURE 4.16 The HAdV-C5 E1B 55K–E4 ORF6 ubiquitin ligase complex. The E1B 55K–E4 ORF6 ubiquitin ligase complex is depicted with Cul5, elongins B and C, Rbx1, E4 ORF6, E1B 55K, ubiquitin (U), and substrate shown. The model of the E1B 55K–E4 ORF6 ubiquitin ligase complex is hypothetical and based on the crystal structure of the Cul1-Rbx1-Skp1-F boxSkp2 SCF[346] ubiquitin ligase complex.

The E1B 55K–E4 ORF6 ubiquitin ligase complex is required for the inhibition of host mRNA nuclear export and the nuclear export of viral late mRNAs during the late phase of infection,[29,327] but the relevant substrate involved in nuclear export of cellular and viral mRNAs remains to be identified. Finally, E1B 55K counteracts the inhibition of Ad replication by type I IFNs in normal human cells by inhibiting ISG induction.[41] This function requires the transcriptional repression domain of E1B 55K[40] but is independent of the formation of the E1B 55K–E4 ORF6 ubiquitin ligase complex.[41] In the absence of E1B 55K, type I IFNs inhibit viral DNA replication, although viral replication protein expression is similar compared to that of the wild-type virus.[41]

E2

E2 encodes the three viral proteins required for adenovirus DNA replication, pTP, Ad-Pol, and DBP. DBP, encoded in the E2A region, is required in much larger amounts than the Ad-Pol or the pTP encoded in the E2B region (Fig. 4.9). Greater levels of E2A mRNAs, which encode DBP, are expressed than the E2B mRNAs as the result of alternative polyadenylation of the E2 primary transcript, most frequently at the E2A polyadenylation site near 62 map units. Some E2 primary transcripts are spliced to exons at 39 and then 29 map units to generate pTP mRNAs or

to exons at 39 and then 23 map units to generate Ad-Pol mRNAs (Fig. 4.9). The E2B mRNAs utilize the same polyadenylation site as the IVa2 mRNA expressed at intermediate times postinfection. The mechanism of Ad DNA replication is discussed below.

E3

The proteins encoded by the E3 region provide protection of infected cells from innate and adaptive host immune responses[173] (Fig. 4.17). The HAdV-C2 and HAdV-C5 E3-gp19K protein is a type I glycoprotein localized in the endoplasmic reticulum (ER). E3-gp19K binds to major histocompatibility complex class I (MHC-I) heavy chain in the ER, prevents transport of MHC-I to the cell surface by virtue of an ER-retrieval signal on E3-gp19K, and prevents killing of Ad-infected cells by cytotoxic T lymphocytes.[173] E3-gp19K and its function are conserved among all human adenovirus species, except species A,[88] in which the E1A proteins cause down-regulation of MHC-I expression.[138] E3-gp19K binds with higher affinity to HLA-A than it does to HLA-B, and it binds poorly if at all to HLA-C.[88] E3-gp19K binds via a domain conserved among adenovirus serotypes to the outer surface of the peptide-binding groove on MHC-I molecules.[181] E3-gp19K also binds to TAP (transporter associated with processing), prevents formation of the TAP–tapasin complex, and limits the inclusion of TAP into the peptide-loading complex of antigenic peptide, MHC-I, and chaperones.[19] This property of E3-gp19K could retard cell surface expression of MHC-I in individuals with HLA-B and HLA-C MHC-I molecules. Reduced expression of MHC-I could render infected cells susceptible to killing by natural killer (NK) cells. Further, the E1A proteins up-regulate ligands recognized by the NKG2D receptor on NK cells and sensitize the E1A-expressing cells to NK cell–mediated cell lysis.[202,253] Multiple ligands for NKG2D are known, including the MHC-I chain–related A (MICA) and B (MICB) proteins. As is the case with MHC-I, E3-gp19K causes retention of MICA and MICB in the ER, prevents their transport to the cell surface, and reduces killing of E3-gp19K–expressing cells by NK cells.[202]

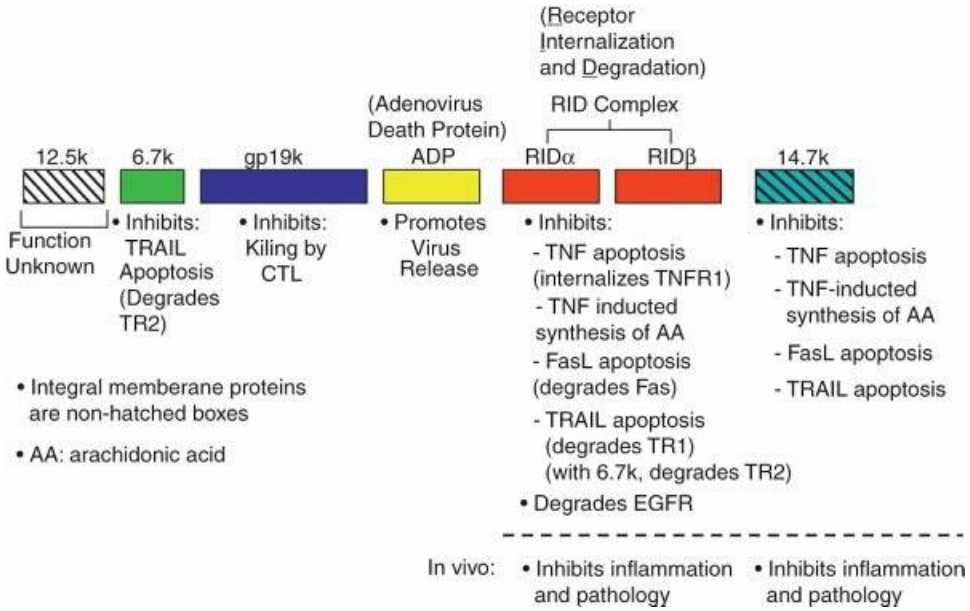

FIGURE 4.17 Schematic illustrating the E3 proteins and their functions. Each colored bar represents a protein with the name of the protein given above. Colored bars without hatches designate integral membrane proteins.

The E3-14.7K protein inhibits TNF-induced cytolysis of adenovirus-infected cells.[173] E3-14.7K binds to cellular IKKγ/NEMO, modulating NF-κB activity and inhibiting TNF-induced apoptosis, and it also binds to caspase 8 (FLICE) and inhibits Fas ligand–induced apoptosis.[173] In addition, E3-14.7K inhibits internalization of TNF receptor 1 and the formation of the death-signaling complex (DISC) that is required for TNF-induced apoptosis.[265] E3-14.7K also inhibits the activity of cytoplasmic phospholipase A2 blocking TNF-induced cell lysis and TNF-induced release of arachidonic acid,[173] a property that might be important in reducing inflammation.

The E3-10.4K protein and the E3-10.4K/E3-14.5K complex clear the epidermal growth factor receptor (EGFR) from the cell surface.[173] The E3-10.4K and E3-14.5K proteins were later renamed RIDα and RIDβ (receptor internalization and degradation), respectively, when it was shown that these proteins also cause the internalization and lysosomal degradation of not only EGFR but also cell surface Fas, TRAIL receptor 1, and TNF receptor 1.[173] RID inhibits cytolysis induced by Fas ligand and TNF. RID, functioning in concert with the E3-6.7K protein, also down-regulates TRAIL receptor 2 from the cell surface.[173] RID inhibits TNF-induced translocation of cytosolic phospholipase A_2 to membranes from where arachidonic acid is generated,[173] and it inhibits lipopolysaccharide- and interleukin-1β–mediated signaling responses.[68] Thus, both RID and E3-14.7K might function *in vivo* to inhibit inflammatory responses associated with infection. RIDα has been reported to function independently of RIDβ to down-regulate EGFR.[173]

The E3-6.7K protein alone inhibits apoptosis induced through Fas, TNF receptor, and TRAIL receptors and prevents TNF-induced release of arachidonic acid.[205] Further, E3-6.7K interacts with calcium modulator and cyclophilin ligand (CAML), a calcium-modulating protein, preventing calcium efflux from the ER, maintaining calcium homeostasis and inhibiting apoptosis induced by thapsigargin, which inhibits calcium uptake by the ER.[205]

The E3 adenovirus death protein (ADP) is an 11.6-kD integral membrane, palmitoylated glycoprotein that is expressed most abundantly at late times after infection from the major late promoter; ADP promotes the efficient lysis of cells late after infection, allowing virus release and dissemination.[173]

E4

The HAdV-5 E4 region encodes six identified proteins named based on their open reading frame numbers (E4 ORF1, E4 ORF2, E4 ORF3, E4 ORF4, E4 ORF6, and E4 ORF6/7) (Fig. 4.18). The E4 proteins have a variety of functions. HAdV-D9 induces mammary fibroadenoma tumors in female rats[135] and the E4 region is required.[136] The HAdV-D9 E4 ORF1 protein is an oncogene and transforms cells in culture and promotes mammary tumors in rats.[134] The oncogenic properties of E4 ORF1 map in part, to a C-terminal PDZ-binding domain that interacts with cellular PDZ-containing proteins such as DLG, MUPP1, MAGI1, and ZO2.[137] E4 ORF1 proteins from adenoviruses of species A–D were found to activate PI3K, but only HAdV-D9 E4 ORF1

both transforms cells in culture and promotes tumors in animals; E4 ORF1 proteins from species A–C have limited transformation potential.[87] The E4 ORF1 PDZ-binding domain is required for PI3K activation, which stimulates activation of downstream effector protein kinases PKB and S6K.[87] HAdV-D9 E4 ORF1, DLG1, and PI3K form a ternary protein complex that localizes to the plasma membrane to activate PI3K, and the ability of E4 ORF1 to transform human epithelial cells in culture is ablated by a PDZ-domain mutation that blocks DLG1 and PI3K binding and by inhibitors of PI3K activity.[156] Interestingly, the ability of E4 ORF1 to activate PI3K via DLG1 binding and membrane localization is a conserved function with adenoviruses of species A–D, although the oncogenic potential for mammary tumor formation is unique to the HAdV-D9 E4 ORF1 protein.[161] The lack of oncogenic potential of the E4 ORF1 protein of nonspecies D adenoviruses may be due to poor protein expression in rat cells with species A–C E4 ORF1 proteins.[316]

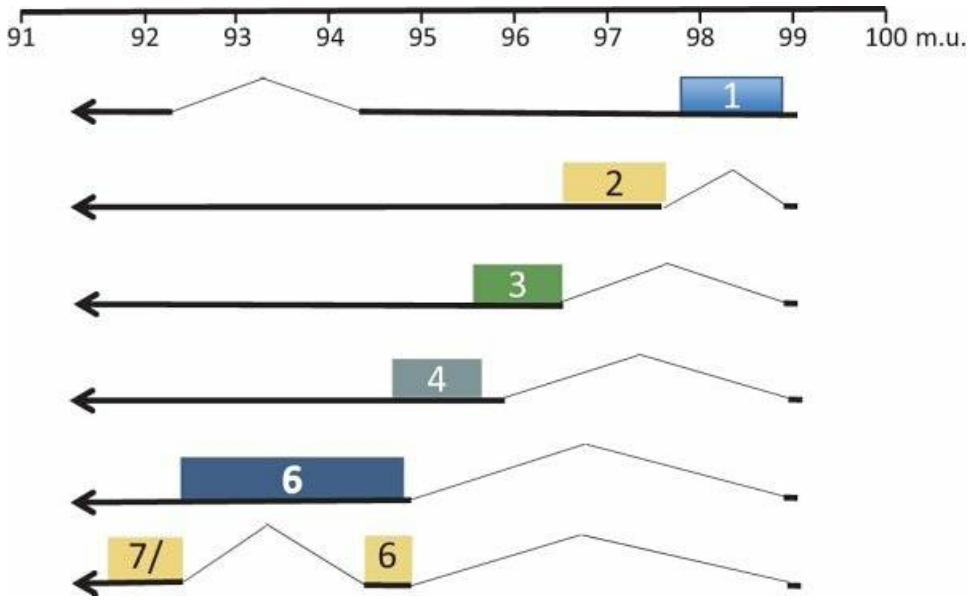

FIGURE 4.18 HAdV-C2 E4 mRNAs and proteins. The E4 open reading frames are designated above the ORFs. Alternative pre-mRNA splicing locates the first AUG of each E4 open reading frame near the 5′ end of the respective mRNA. E4 ORF7 is translated as a fusion with the N-terminal part of ORF6 fused in-frame with ORF7. Additional mRNAs not shown encoding E4 ORF1, −ORF3, and -ORF4 additionally are spliced to remove the intron that fuses ORFs 6 and 7.

The HAdV-C5 E4 ORF1 and E4 ORF4 proteins activate the protein kinase mTOR in the absence of nutrient and mitogenic signaling.[221] Activated mTOR stimulates protein synthesis by phosphorylating and inhibiting 4EBP1, an inhibitor of the eIF4E cap-binding translation initiation factor.[259] Activated mTOR also phosphorylates and activates S6K, which stimulates translation by phosphorylating ribosomal protein S6 and additional targets, leading to increased synthesis of ribosomes and translation factors.[259] Mitogens activate mTOR by activating PI3K through a pathway involving AKT and PKB, the tumor suppressor complex TSC1–TSC2, and the Ras-family GTPase Rheb that ultimately leads to mTOR activation.[259] E4 ORF1 stimulates

PI3K, resulting in Rheb-GTP loading and mTOR activation.[221] Human epithelial cells infected with wild-type HAdV-C5, but not a complete E4-null virus, have increased glycolytic metabolism with elevated glucose consumption and lactate production, and decreased oxygen consumption.[296] The E4 ORF1 protein is sufficient to induce this glycolytic flux. Surprisingly, this effect does not require the PDZ-binding domain of E4 ORF1, indicating that this effect is independent of PI3K activation.[296] E4 ORF1 binds to the transcription factor MYC in the nucleus and augments MYC binding to promoters of glycolytic genes resulting in their elevated expression.[296] An HAdV-C5 E4 ORF1 mutant (D68A) was identified that did not enhance glycolytic metabolism. By comparing cells infected with the E4 ORF1 D68A mutant virus to wild-type HAdV-C5 infection, increased glycolytic metabolism was found to significantly enhance viral DNA replication, possibly due to increased nucleotide pools.[296] Subsequently, HAdV-C5 infection was found to alter host cell glutamine utilization and increase expression of glutamine transporters and glutamine catabolism enzymes.[297] Consequently, there were increased intracellular levels of both essential and nonessential amino acids in HAdV-C5–infected cells compared to those in uninfected cells or cells infected with the E4 ORF1 D68A mutant virus.[297] This effect required E4 ORF1, MYC activation, and it promoted optimal adenovirus replication.[297] The ability of E4 ORF1 to activate constitutive epidermal growth factor and insulin receptor signaling contributes to MYC activation, a function that is conserved among different adenovirus species.[157] Collectively, these results show how adenovirus infection subverts cellular metabolism, similar to that which occurs in cancer cells, to optimize conditions for viral replication.

There is no functional activity to date linked with E4 ORF2.

The E4 ORF3 protein is multifunctional. It functions by forming a multimeric protein scaffold in the nucleus of infected cells and sequestering cellular proteins into these structures to block their activities. These E4 ORF3 filamentous structures have often been referred to as nuclear tracks. This was first described with the reorganization of PML nuclear bodies (PML-NB), also known as PML oncogenic domains (PODs), or ND10,[37,72] where E4 ORF3 is both necessary and sufficient for this to occur (Fig. 4.19). The reorganization of PML-NB requires higher-order multimerization by E4 ORF3.[228,231] E4 ORF3 interacts with PML isoform II, mediating PML-NB disruption and inhibiting the activity of PML-II as part of an innate response to infection.[8,123] PML-NB have antiviral properties, particularly with DNA viruses, both intrinsically and following induction by IFNs.[262] E4 ORF3 inhibits PML-NB antiviral activity.[307,308]

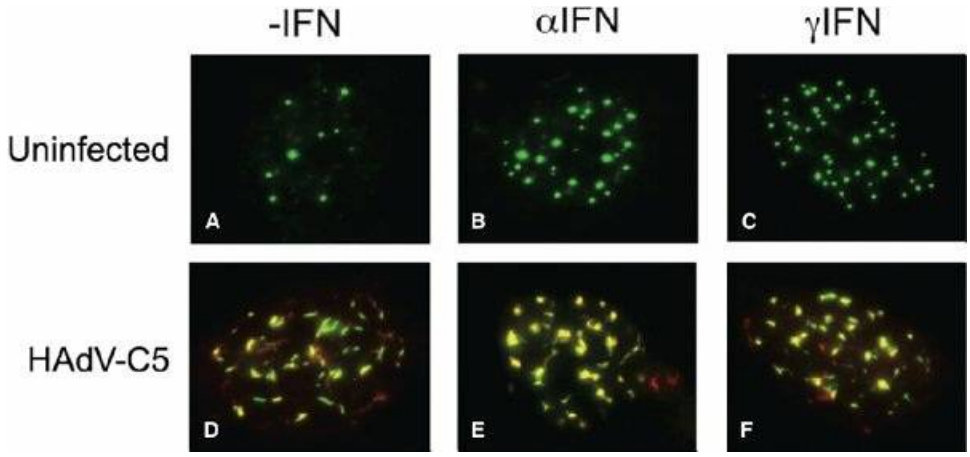

FIGURE 4.19 HAdV-C5 E4 ORF3 rearranges PML-NB during an IFN response. Vero cells seeded onto coverslips and were untreated **(A, D)**, or pretreated with IFNα **(B, E)** or IFNγ **(C, F)** for 24 h. Subsequently, the cells were left uninfected **(A–C)** or infected with HAdV-C5 **(D–F)**. At 18 h after infection, the cells were immunostained for PML (FITC, *green*) and E4 ORF3 (TRITC, *red*). The images represent a merge of compressed, deconvolved Z stacks. (Adapted from Ullman AJ, Reich NR, Hearing P. The adenovirus E4 ORF3 protein inhibits the interferon-mediated antiviral response. *J Virol* 2007;81:4744–4752.)

The E4 ORF3 protein of species C adenoviruses inhibits a DDR. In this way, E4 ORF3 and E4 ORF6 display redundant activities, since inhibition of a DDR is the most critical aspect of E4 function *in vitro*.[33,126] E4 ORF3 directs the relocalization of MRN complex proteins into PML-containing nuclear tracks to sequester and block their activity.[77,288,289] It is curious that this function is only conserved among species C E4 ORF3 proteins, since inhibition of a DDR is so crucial for viral replication, although this activity is redundant with MRN degradation by the E1B 55K–E4 ORF6 ubiquitin ligase complex that is more widely conserved. The E4 ORF3 protein inhibits p53 signaling by inducing the formation of heterochromatin at p53-induced promoter regions, thereby blocking p53 DNA binding and transactivation.[280] Once again, this E4 ORF3 activity parallels, and perhaps complements, the inhibition of p53 by E1B 55K alone and the E1B 55K–E4 ORF6 complex.

E4 ORF3 induces SUMO modification of Mre11 and Nbs1 in virus-infected cells.[277] Protein sumoylation regulates diverse processes including protein–protein interaction, subcellular localization, protein stability, and enzymatic activity.[343] Ad infection, or E4 ORF3 expression alone, causes a dramatic reorganization of endogenous SUMO1 and SUMO2/SUMO3 into nuclear tracks.[277] A proteomic study identified multiple cellular proteins whose sumoylation is increased upon Ad5 E4 ORF3 expression.[276] Many of the E4 ORF3 SUMO substrates are involved in a DDR. Like ubiquitylation, sumoylation is carried out by a cascade of enzymatic steps.[343] Biochemical studies using an *in vitro* SUMO conjugation assay demonstrated that E4 ORF3 functions as a SUMO E3 ligase.[278] Several substrates whose sumoylation is increased by E4 ORF3 (e.g., TFII-I and TIF-1γ) are subsequently degraded by the ubiquitin–proteasome pathway in the absence of any other viral proteins.[34,85] E4 ORF3 SUMO ligase activity is conserved across the human adenovirus species.[275] The E4 ORF3 protein does not possess any of

the typical domains of SUMO E3 ligases, but E4 ORF3 interacts with the SUMO E2 conjugation enzyme UBC9 along with noncovalently bound SUMO. E4 ORF3 oligomerization is critical for this ternary binding to occur, and this interaction correlates directly with E4 ORF3 E3 SUMO ligase activity.[275] These results are consistent with a model whereby E4 ORF3 serves as a platform for SUMO modification by mediating colocalization of components of the SUMO conjugation machinery with target substrate proteins.

The E4 ORF4 protein regulates multiple different aspects of the adenovirus replication cycle including viral and cellular gene expression,[18,30] alternative pre-mRNA splicing[76,144] (see Regulation of RNA Splicing During the Late Phase), protein translation,[209,221] and cell death.[171,271] The E4 ORF4 protein binds to the substrate-binding β subunits of the trimeric protein phosphatase PP2A family,[153] and all E4 ORF4 activities are attributed to this interaction. PP2A is a highly abundant serine/threonine protein phosphatase with broad-based activity affecting metabolism, RNA splicing, translation, development, and cell cycle progression. E4 ORF4 induces death in transformed cells that is independent of p53 and involves non-canonical programmed cell death.[167,195,270] E4 ORF4 is redundant with E4 ORF1 in stimulating mTOR activity, and this requires PP2A binding, although E4 ORF4 does not affect Rheb-GTP levels, and mTOR activation is independent of PI3K and AKT.[221] How this interaction leads to mTOR activation is not understood, but it seems likely that alterations in the substrate specificity or activity of PP2A are involved.[342] Finally, the E4 ORF4 reduces the phosphorylation of the DDR effector protein kinases ATM and ATR, inhibiting a DDR in adenovirus-infected cells, and consequently sensitizes cells to DNA-damaging agents.[32]

The E4 ORF6 protein was discussed earlier in the context of E1B 55K and the E1B 55K–E4 ORF6 ubiquitin ligase complex (Fig. 4.16). E4 ORF6 also has unique functions. E4 ORF6 interacts with and inhibits p53 independently of E1B 55K.[71] E4 ORF6, but not E1B 55K, also can bind to p73 and inhibit p73 function.[119,196,284,320] The p73 protein is a member of the p53 family that is able to activate transcription through p53 response elements. p73 is transcriptionally induced by the E1A 243R protein, probably through E2F-binding sites associated with one of its two alternative promoters.[82] Thus, E4 ORF6 antagonizes the function of both p53 and p73, blocking their potential inhibitory effects on viral replication. Finally, HAdV-A12 E4 ORF6 targets DNA topoisomerase II–binding protein 1 (TOPBP1), a DDR protein, for CUL2-based degradation independent of E1B 55K.[27]

E4 ORF7 is expressed as a fusion with the N-terminal region of E4 ORF6 by alternative pre-mRNA splicing and results in the translation of a protein called E4 ORF6/7 (Fig. 4.18). E4 ORF6/7 forms a dimer that binds to E2F transcription factors, greatly increasing their affinity for the E2-early promoter by cooperative binding to inverted E2F-binding sites.[127] This serves as an important transcriptional activator of the E2-early promoter.[131] E4 ORF6/7 also can displace Rb family proteins from E2Fs by competitive binding with the E2F–pRb interface and functionally substitute for this E1A activity, stimulating viral replication.[216] Finally, E4 ORF6/7 also can activate the cellular E2F-1 promoter by the same mechanism.[261]

Viral DNA Replication

Adenovirus DNA replication occurs by a mechanism requiring a minimal set of viral replication proteins: pTP, Ad-Pol, and DBP. The ITRs serve as the replication origins. Viral DNA

replication takes place in two stages[168] (Fig. 4.20). First, synthesis is initiated at either terminus of the linear DNA and proceeds in a continuous fashion to the other end of the genome. The products of this stage of replication are a duplex consisting of a parental and daughter strand plus a displaced single strand of parental DNA. In the second stage, a complement to the displaced single strand is synthesized. The single-stranded template circularizes through annealing of its self-complementary ITRs. The resulting duplex "panhandle," in the otherwise single-stranded circle, has the same structure as the termini of the duplex viral genome. This structure is recognized by the same initiation machinery that operates in the first stage of replication, and complementary strand synthesis generates a second completed duplex consisting of one parental and one daughter strand.

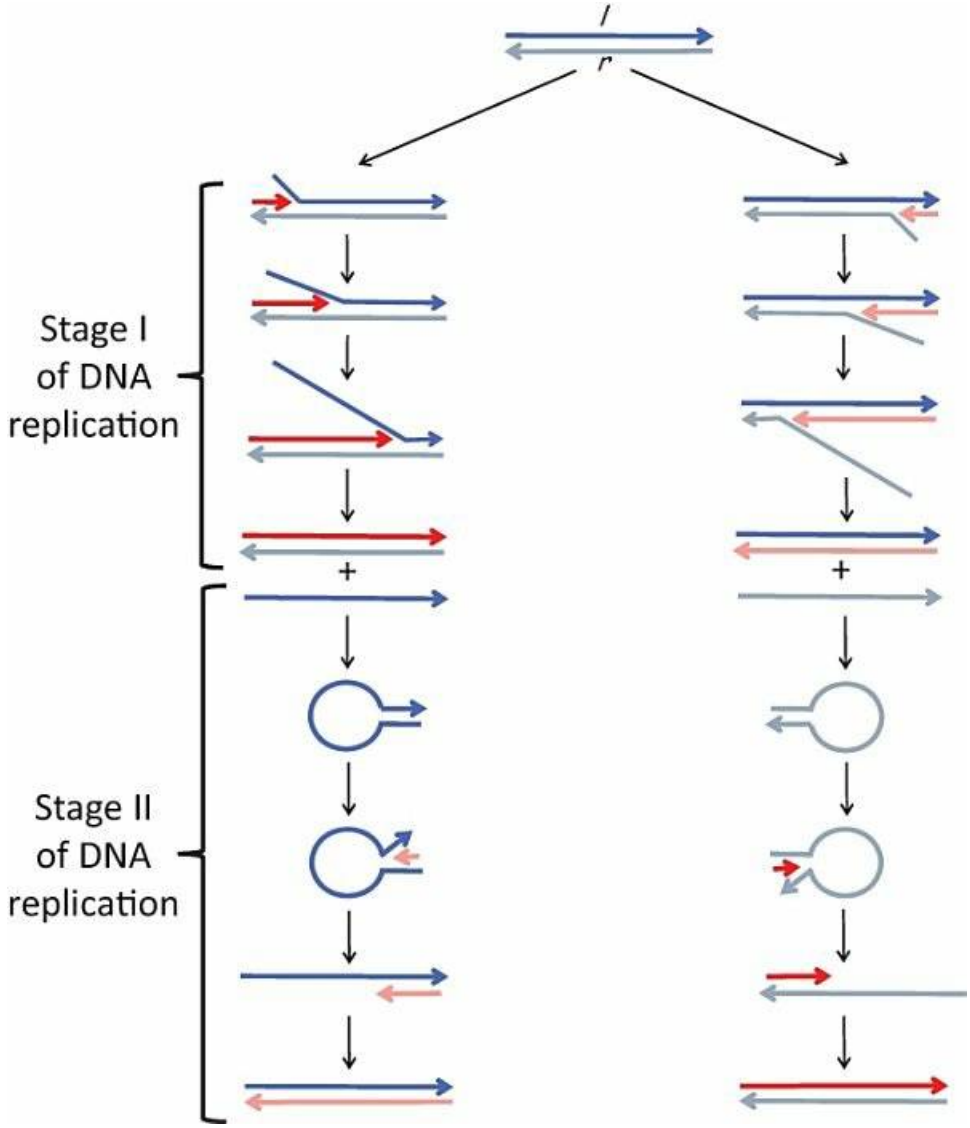

FIGURE 4.20 Mechanism of adenovirus DNA replication. With molecules where replication is initiated at the right end, the *l* parental strand is replicated displacing the *r* parental strand; with molecules where replication is initiated at the left end, the *r* parental strand is replicated displacing the *I* parental strand. Replication beginning at

the left end is shown on the left column and beginning at the right end is shown on the right column. Replication occurs in two stages: synthesis of the entire length of one strand (Stage 1), followed by synthesis of the entire length of the complementary strand (Stage 2). Replication is primed by the pTP protein (not shown) covalently attached to dCMP whose 3′-OH group is extended by Ad-Pol. One entire strand is displaced as ssDNA. A "panhandle" structure is formed when the left end and right end ITRs of this molecule base pair generating a double-stranded ITR identical to that contained in the parental genome. Note that unlike the mechanism for replication of most other DNA molecules, lagging-strand synthesis does not occur as short Okazaki fragments that are ligated together. (Adapted from Lechner RL, Kelly TJ Jr. The structure of replicating adenovirus 2 DNA molecules. *Cell* 1977;12:1007–1020. Copyright © 1977 Elsevier. With permission.)

Three functional domains have been defined within the terminal 51 bp of species C adenovirus ITRs.[42] Nucleotides 1 to 18 contain the minimal core sequences sufficient for origin function, although at low levels of activity. The sequence between base pairs 9 to 18 (5′-ATAATATACC-3′) is conserved among different human adenovirus species, and a complex of pTP and Ad-Pol binds to this region.[295] Nucleotides 19 to 40 and 41 to 51 contain binding sites for cellular proteins NFI (CTF, CCAAT box transcription factor) and NFIII (Oct-1, octamer-binding protein 1), respectively. These cellular transcription factors significantly stimulate core origin activity. The DNA-binding domain of NFI interacts with Ad-Pol, and the DNA-binding domain of Oct-1 binds to pTP.[140] The binding of NFI is stimulated by DBP.[140] The resulting protein–DNA and protein–protein interactions stabilize binding and properly position the pTP–Ad-Pol complex at the genome termini. pTP is synthesized as an 80-kD polypeptide that is active in the initiation of DNA replication. It is subsequently processed by AVP proteolysis at three sites during assembly of virions to generate a 55-kD fragment (TP) that is covalently attached to the genome within the viral capsid. Ad-Pol is a 140-kD protein in the eukaryotic Polα family.[179] Like other Polαs, Ad-Pol contains both 5′ to 3′ DNA polymerase activity and 3′ to 5′ exonuclease activity; the latter serves a proofreading function during DNA replication.[150] The error rate of Ad-Pol is estimated at 1.3×10^{-7} per bp per infection cycle.[248]

As a protein primer, pTP preserves the integrity of the viral genome termini during multiple rounds of DNA replication. The priming reaction begins with the formation of an ester bond catalyzed by the Ad-Pol between the β-OH of serine residue 580 in pTP and the α-phosphoryl group of deoxycytidine monophosphate (dCMP), the first residue at the 5′ end of the DNA chain.[42] pTP melts the end of the DNA duplex, allowing the template strand to enter the active site of the polymerase. The 3′-OH group of the pTP–dCMP complex then serves to prime synthesis of the nascent strand by Ad-Pol.[42] Replication and late transcription take place in large nuclear domains called replication compartments or replication centers.[238] pTP association with the insoluble nuclear matrix fraction[260] may help to localize the viral replication centers. In addition, pTP binds to the multiprotein pyrimidine biosynthesis enzyme CAD (carbamyl phosphate synthetase, aspartate transcarbamylase, and dihydroorotase).[6] CAD colocalizes with pTP and viral replication compartments on the nuclear matrix.[6] pTP–CAD interaction may anchor viral genomes at the nuclear matrix and in proximity to nucleotides and other factors required for replication.

Chain elongation requires viral Ad-Pol, DBP, and cellular topoisomerase I.[42] DBP binds tightly and cooperatively in a sequence-independent fashion to single-stranded DNA. The three-dimensional structure of the C-terminal DBP DNA-binding domain sufficient for *in vitro* replication was determined by x-ray crystallography.[305] The DBP C-terminal domain has a flexible hinge that hooks onto an adjacent DNA-binding protein monomer. This drives the formation of long, multimeric DBP chains bound to single-stranded DNA. Polymerization of the DNA-binding protein on single-stranded DNA drives strand separation, consistent with the lack of a requirement for a DNA helicase to unwind the double-stranded template at the growing fork in reconstituted DNA replication reactions.[67] In the presence of DBP, Ad-Pol is highly processive and can travel the entire length of the chromosome after it has separated from pTP.[42] Topoisomerase I enhances the synthesis of nascent chains greater than 9 kbp long; hence, it must be needed to overcome a DNA structural problem that arises only after extensive replication.

Late Gene Transcription

Adenovirus late genes begin to be actively expressed at the onset of viral DNA replication. The adenovirus late coding regions are organized into a single large transcription unit with the major late promoter (MLP) directing the initiation of an approximately 28 kb pre-mRNA.[349] The MLP exhibits low activity early after infection but becomes several hundredfold more active on a per DNA molecule basis at late times. This primary transcript is processed by differential use of five polyadenylation sites to generate late mRNA families L1–L5 and extensive alternative splicing to generate multiple distinct mRNA sites[349] (Fig. 4.9). The mechanism that prevents RNA polymerase II elongation past the L1 region during the early phase is poorly understood, as is the mechanism that relieves this inhibition during the late phase. The processed L1–L5 mRNAs all contain a 201-nucleotide (nt) untranslated tripartite leader (TPL) sequence generated from the splicing of three short exons[21,51] (Fig. 4.9). Different open reading frames in each late mRNA family are accessed by alternative RNA splicing of donor splice sites at the 3′ end of the third tripartite leader exon to different splice acceptor sites within L1–L5 that define the 5′ end of the protein-coding exon(s) (Fig. 4.9). There appear to be at least two distinct components that contribute to the delayed activation of the major late promoter during infection: a *cis*-acting change in the viral chromosome dependent on viral DNA replication[299] and transactivation by two viral proteins, IVa2 and L4-22K, synthesized at intermediate times postinfection.[336] The IVa2 and L4-22K proteins stimulate transcription from the MLP by binding to sites in the first intron between TPL exons 1 and 2.[336] These two proteins also bind cooperatively to repeated sequences at the left end of the genome to promote packaging of viral DNA into capsids (see Virion Assembly).

Regulation of RNA Splicing During the Late Phase

Three viral proteins, E4 ORF4[76,144] and the L4-33K and L4-22K proteins,[26] remodel the host cell splicing machinery, regulating the splicing of viral pre-mRNAs, and likely cellular pre-mRNAs, during the late phase of infection. During the late phase, alternative splicing of the L1 pre-mRNA is regulated by L4-33K, shifting expression from the L1-52/55K protein to L1-IIIa.[302] The L4-33K protein regulates this splicing via the sequence immediately upstream of the L1-IIIa 3′ acceptor splice site, functioning as a splicing enhancer that induces splicing to this site.[302] Early during infection, host cell SR proteins bind to a sequence just upstream from the

IIIa splicing branch point, blocking binding of the U2 snRNP to the L1-IIIa 3′ acceptor splice site.[143] Dephosphorylation of host SR proteins dependent on E4 ORF4 relieves this inhibition of L1-IIIa splicing.[144] Since the phosphorylation of serine–arginine–rich (SR) proteins is required for their association with consensus splicing signals, the dephosphorylation and inactivation of SR proteins may contribute to the inhibition of host cell gene expression during the late phase.[144] Several other 3′ acceptor splice sites in the MLP pre-mRNA with short polypyrimidine tracts also are activated during the late phase of infection, probably through similar mechanisms to the control of the L1-IIIa splice site.[1] Finally, during the intermediate stage of infection, the L4-22K protein (Fig. 4.11) is translated from an mRNA expressed from the L4P promoter, termed L4P, that is embedded in the upstream coding region of L4-100K[207] (Fig. 4.9). The L4-22K protein directs splicing of the L4-33K pre-mRNA.[105] As described above, the L4-33K protein in turn regulates splicing of other adenovirus late transcripts. Analysis of an HAdV-C5 L4-22K mutant virus demonstrated that only L4-33K transcripts, and transcripts for the adjacent L4-pVIII protein, are regulated by L4-22K.[105] Thus, while both L4 proteins are splicing regulators, they clearly have different targets. There is an exquisite level of regulation that takes place during the late phase of adenovirus infection that precisely coordinates the cascade of late viral gene expression. This represents an elegant feedback loop that finely tunes the temporal switch of gene expression patterns during the late phase of infection.

Regulation of Translation

During the early phase of infection, viral early mRNAs are translated along with the continued translation of host cell mRNAs. During the late phase of infection, however, translation of host cell mRNAs is significantly inhibited, and virtually all translation is dedicated to late viral mRNAs, especially mRNAs containing the TPL sequence.[60] In addition to their facilitated transport from the nucleus to the cytoplasm, viral late mRNAs are preferentially translated when they reach the cytoplasm.[16] During this period, when viral mRNAs constitute about 20% of the total cytoplasmic mRNA pool, they are translated to the exclusion of host mRNAs.[11] The inhibition of host mRNA translation results from the inhibition of cap-dependent translation. eIF4E, the translation initiation factor that binds the 5′-^{m7}GpppN cap structure on most cellular mRNAs, is dephosphorylated at late times after adenovirus infection.[128] eIF4E is a subunit of eIF4F multiprotein complex, which functions as a cap-dependent RNA helicase to unwind secondary structures at the 5′ ends of mRNAs and promote recruitment of the 40S ribosomal subunit and scanning to the translation initiation codon.[133] Dephosphorylation of eIF4E inhibits the interaction of the eIF4F complex with capped mRNAs, thus inhibiting all cap-dependent translation.[128]

In uninfected cells, eIF4E is phosphorylated by the protein kinase Mnk1, which is thought to allow tighter binding to cap structures.[133] During the late phase of adenovirus infection, the L4-100K protein binds to eIF4G, displacing Mnk1 kinase and resulting in reduced eIF4E phosphorylation.[59] Late viral mRNAs transcribed from the major late promoter continue to be translated because of the 5′ TPL.[183] The TPL promotes cap-independent translation by two mechanisms. First, the TPL promotes an alternative form of translation initiation referred to as ribosome shunting.[337] Rather than scanning from the 5′ cap to the initiation codon, the 40S ribosomal subunit binds the TPL and is translocated to the translation initiation codon without scanning the 5′ untranslated region. Ribosome shunting is largely dependent on three regions of

the TPL that are complementary to the 3′ end of 18S rRNA, evoking a mechanism of translation initiation similar to that in bacteria.[337] Similar complementarity between the 5′ untranslated region of the IVa2 mRNA and 18S ribosomal RNA also promotes ribosome shunting and maintains IVa2 translation during the late phase.[337] In addition to the structure of the TPL, L4-100K is required for the stimulation of translation by the TPL during the late phase of infection.[116] L4-100K binds both the TPL and the eIF4G scaffolding subunit of eIF4F, thereby directly stimulating ribosome shunting.[331] The TPL also stimulates late mRNA export from the nucleus during the late phase, possibly through an interaction with L4-100K.[125]

VA RNAs

The small, abundant VA RNAs were named when their viral origin was still uncertain. Different adenovirus species encode one or two VA RNAs; HAdV-C2 and HAdV-C5 encode two VA RNAs termed VAI and VAII. The VA RNAs are each about 160 nt in length, are GC rich, adopt stable secondary structures that are important for their function, and are transcribed by host cell RNA polymerase III.[309] VA RNA synthesis begins during the early phase of infection and dramatically accelerates during the late phase as the viral DNA template is amplified. VAI accumulates to about 10^8 molecules per infected HeLa cell, roughly the abundance of ribosomes, and VAII reaches about 10^7 molecules per cell.[309]

The function of VA RNAs was first discovered by analysis of a mutant HAdV-C5 virus in which the VAI gene was deleted.[298] The VAI mutant virus grew poorly and displayed greatly reduced levels of viral late proteins. Further studies identified a defect in protein initiation[264] resulting from phosphorylation of the eukaryotic initiation factor-2 (eIF-2) α subunit.[247,263] eIF-2 binds to guanosine triphosphate (GTP) and the initiator tRNA to form a ternary complex, which then interacts with the 40S ribosomal subunit. When the 40S ribosomal subunit binds the initiation codon, eIF-2 hydrolyzes the GTP to GDP and leaves the 40S subunit with the initiator tRNA in the ribosomal P site. Subsequent steps in the initiation process involving additional factors result in the binding of the 60S ribosomal subunit and chain elongation.[133] For eIF-2 to participate in another round of translation initiation, GDP must be replaced with GTP in a reaction catalyzed by eIF-2B, a guanosine nucleotide exchange factor. This exchange reaction is inhibited by phosphorylation of the eIF-2 α subunit. Phosphorylated eIF-2-α forms a tight complex with eIF-2B, preventing it from cycling and catalyzing the exchange reaction.[133] As a result, global translation initiation is inhibited when about one-third to one-half of eIF-2 is phosphorylated, trapping all available eIF-2B.

Phosphorylation of eIF-2 is mediated by the cellular protein kinase PKR. Synthesis of an inactive form of PKR is induced by IFN and the latent PKR enzyme phosphorylates eIF-2α when activated by dsRNA.[309] It is presumed that the symmetrical transcription of the adenovirus genome gives rise to dsRNA. PKR is activated by transautophosphorylation when two molecules of PKR interact with one molecule of dsRNA.[309] The highly abundant VAI RNA adopts a tertiary structure with extensive base pairing (Fig. 4.21) that binds PKR in monomeric form and blocks PKR activation by preventing PKR dimerization.[152] VAI RNA thereby blocks the antiviral effect of dsRNA and the antiviral effect of IFN. In contrast to VAI, an HAdV-C5 VAII mutant virus grows normally.[298]

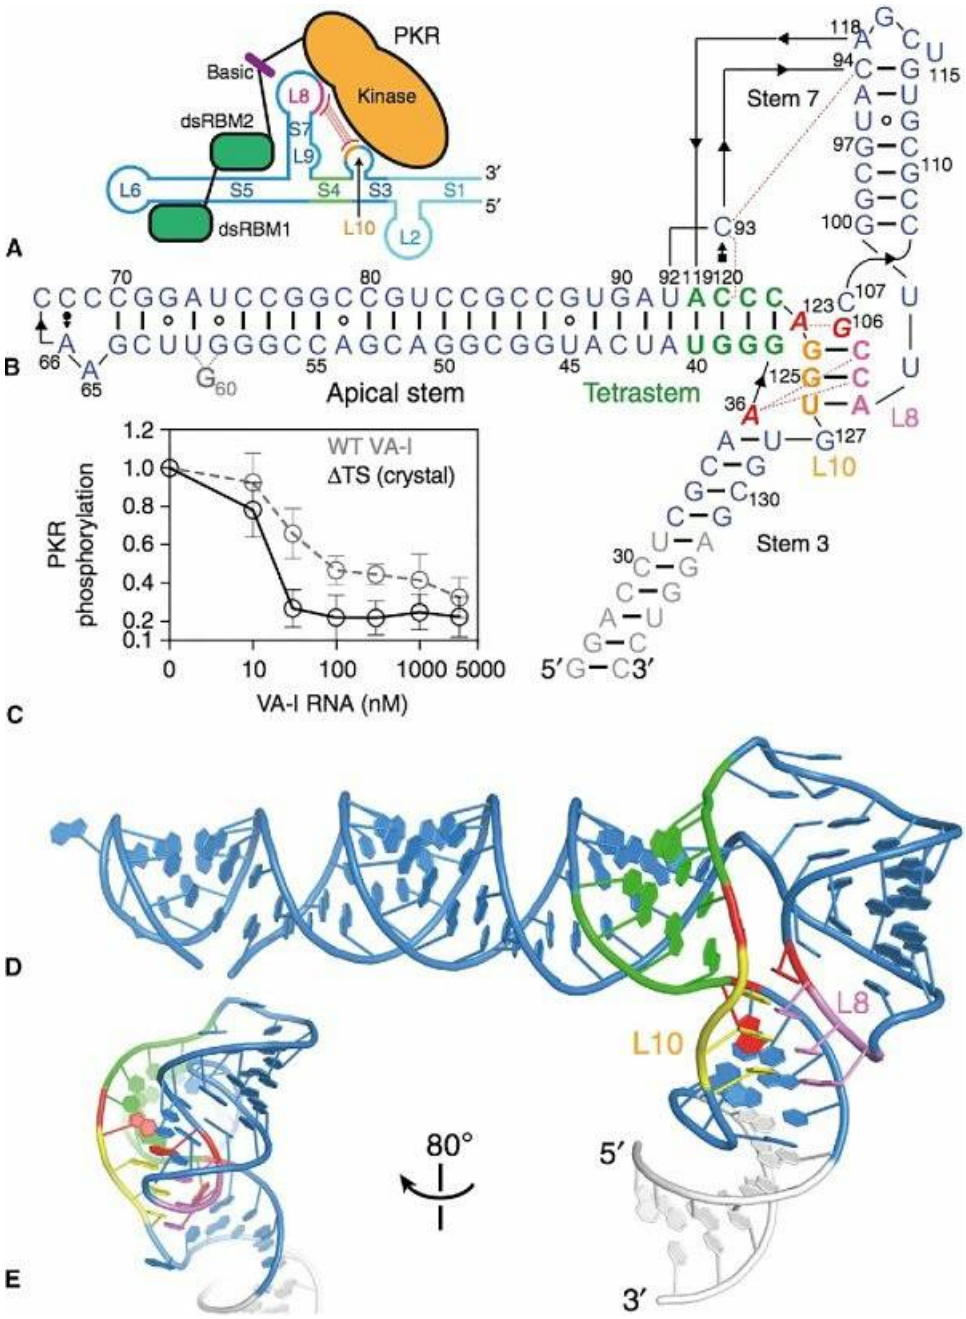

FIGURE 4.21 HAdV-C2 VA RNA. A: Schematic diagram of HAdV-C2 VA RNAI and binding to PKR. Stem structures are indicated by S designations and loops are indicated by L designations. S1 and L2 are absent from the VAI crystal structure. Double-stranded RNA-binding motifs are labeled dsRBM1 and dsRBM2. Base pairing between loops 8 and 10 is indicated by *triple red lines*. **B:** VAI RNA secondary structure derived from the crystal structure. Base pairing is indicated by lines and open circles between individual bases. Arrows designate adjacent residues. Base pairing between residues in loop 8 (*violet*) and loop 10 (*orange*) are shown with helix capping residues indicated in *red*. Wild type VAI residues are shown in blue; synthetic sequences used for the replacement of S1 and L2 are shown in *gray*. **C:** Inhibition of

PKR phosphorylation by wild-type VAI and the truncated VAI used for crystallography. **D and E:** Ribbon diagram of the three-dimensional structure of HAdV-C2 VAI RNA. Both VAI and VAII RNAs inhibit the processing of cellular microRNAs (miRNAs).[5,187] miRNAs are approximately 22 nucleotide RNAs incorporated into RNA silencing complexes (RISC) that inhibit translation of mRNAs to which they base pair with a small number of base-pair mismatches.[310] They are transcribed as long precursors called pri-miRNAs and processed by the nuclear enzyme Drosha into approximately 65 nucleotide stem-loop RNAs called pre-miRNAs. pre-miRNAs are exported from the nucleus to the cytoplasm where they are further processed by the ribonuclease Dicer into the approximately 22 nucleotide miRNAs incorporated into RISC complexes.[310] RISC complexes can also be programmed by siRNAs that have the characteristics of products of Dicer digestion: approximately 22 bp dsRNAs with two base 3′ single-stranded regions. When the siRNA in an RISC complex hybridizes to perfectly complementary regions of an mRNA in vertebrate cells, the RISC complex cleaves the mRNA, initiating its rapid degradation by exonucleases.[310]

VA RNAs are synthesized in the nucleus and transported into the cytoplasm by the same exportin that transports pre-miRNAs. During the late phase of adenovirus infection, the abundantly expressed VA RNAs interfere with the nuclear export of pre-miRNAs by competing with them for binding to exportin-5.[187] VA RNAs in the cytoplasm also bind to Dicer and competitively inhibit pre-miRNA processing.[5,187] The competitive inhibition of pre-miRNA nuclear export and cytoplasmic processing by VA RNAs interferes with the expression of cellular miRNAs. Since Dicer is a critical enzyme in processing dsRNA into miRNAs and siRNAs, the VA RNAs are expected to interfere with endogenous miRNA activities and siRNA interference that might result from adenovirus-specific dsRNAs. Deep RNA sequencing during the course of HAdV-C2 infection of normal, quiescent human lung fibroblasts demonstrated the deregulation of cellular miRNA expression during different phases of infection with both up-regulation and down-regulation of specific cellular miRNAs.[344] A number of these miRNAs are associated with the control of cell growth, but the functional consequences of these changes remain to be determined.

Virion Assembly

The replication of viral DNA, coupled with the production of large quantities of the adenovirus structural and assembly proteins, sets the stage for virion production. The multifunctional L4-100K protein functions as a chaperone in the folding of the trimeric hexon protein.[38] Penton capsomeres consisting of a pentameric penton base and trimeric fiber assemble in the cytoplasm, subsequently joining to form a complete penton capsomere. Hexon and penton capsomeres are imported into the nucleus, where assembly of the virion occurs.

The adenovirus genome is packaged into capsids in a polarized manner starting at the left end of the genome.[224] Extensive mutational analysis of the HAdV-C5 genome showed that seven AT-rich sequences, termed A repeats, with the consensus sequence 5′-TTTG-N_8-CG-3′ and

located between nt 200 and 400 function as *cis*-acting packaging sequences.[224] This approximately 200 nt packaging domain functions in virion assembly when placed at the right end of the genome and in an inverted orientation at the left end but must be located within approximately 500 bp of an end.[224] Results from mutational studies of the packaging sequences, *in vitro* protein–DNA binding studies, and chromatin immunoprecipitation assays of infected cells demonstrate that the viral IVa2, L1-52/55K, and L4-22K proteins bind the packaging domain and promote viral DNA packaging into capsids.[223,227,235,306,330,340] Viral mutants in the IVa2, L1-52/55K, and L4-22K proteins are defective for genome packaging and produce empty virion particles.[106,113,222,330,341] Mutation of the L4-33K and L1-IIIa proteins also results in the formation of empty capsids,[69,329] but the L4-33K protein does not interact directly with the packaging sequences,[329] and L1-IIIa binds weakly to this region.[190] The L1-IIIa protein binds directly to the L1-52/55K and this interaction mediates, at least in part, serotype specificity that is observed with adenovirus packaging.[190,325] The IVa2 and L4-22K proteins mediate the sequence specificity by binding to the conserved packaging motifs, specifically the GC motif with IVa2 and the TTTG motif with L4-22K, and bind to these sites in a cooperative manner.[223,227,235,306,340] The L1-52/55K protein is brought into this complex by interaction with IVa2, and L1-IIIa is recruited by L1-52/55K binding.[107,190]

Analysis of the IVa2 sequence from human and nonhuman adenoviruses showed that they contain conserved Walker A box and B box consensus sequences found in ATPases. Consistent with this, HAdV-C5 IVa2 binds ATP,[225] and mutation of the conserved lysine in the Walker A box required for activity of ATPases resulted in loss of viability.[229] The IVa2 protein is associated with one vertex of the mature virion particle,[52] consistent with a potential role in a portal complex for viral DNA encapsidation. A long-standing model for adenovirus assembly hypothesizes that viral DNA is inserted into an empty capsid using a unique portal vertex and a packaging motor, as found with DNA-containing bacteriophages.[224] DNA-containing bacteriophages package naked DNA by the direct contact between the DNA phosphate backbone of the viral genome and the portal motor complex.[224] As described above, the Ad genome within the mature capsid is associated with viral core proteins raising the question if naked adenovirus DNA, or a preformed DNA–protein complex, is the packaging substrate. If an adenovirus DNA–core protein complex is encapsidated via a portal vertex, then a new type of packaging motor would have to be invoked compared to those used by bacteriophages. Recent results suggest that adenovirus assembly occurs by an alternative mechanism using a concerted process whereby virus particles assemble around the DNA in the nucleus at the periphery of replication compartments.[55] Such a model requires verification but more easily accommodates the assembly of virions containing a preformed DNA–core protein complex.

The final step in virion maturation involves numerous proteolytic cleavages of internal capsid proteins by the adenovirus protease, AVP. AVP is a cysteine protease that requires viral DNA and a C-terminal peptide of pVI (pVIc) as cofactors for cleavage of the precursor proteins.[193] pVIc forms a disulfide bond with AVP.[100] The AVP–pVIc complex binds to and slides along DNA, with pVIc serving as a molecular sled.[28] It is hypothesized that as AVP–pVIc complexes slide on DNA, they encounter and process the virion precursor proteins in proximity to the DNA.[28] AVP cleaves seven internal capsid proteins, including pIIIa, pVI, pVII, pVIII, pμ (pX), pTP, and L1-52/55K.[194] These cleavages are absolutely essential for the formation of fully infectious particles. AVP cleavage of internal capsid proteins increases the internal pressure

within the virion, which has been proposed to promote virus disassembly following infection.[220] AVP cleavage of pVI also exposes the N-terminal amphipathic helix region that is required for virus escape from the endosome (see Mechanisms of Entry, Uncoating, and Intracellular Trafficking). Finally, AVP activity is required for the exit of the L1-52/55K protein from maturing capsids.[112,233] A mutant virus with a temperature-conditional AVP accumulates noninfectious virion particles that fail to escape the endosome because they contain unprocessed polypeptides.[103] The requirement of DNA and a pVI fragment for activation of AVP prevents AVP from processing precursors until the protease, DNA, and precursor proteins are incorporated into maturing virion particles.

Virus Release

There are several processes that facilitate the release of progeny virions from infected cells and the spread of progeny virus in infected tissues. Late in the infectious cycle, AVP cleaves the cellular cytokeratin K18.[46] This cleavage occurs at amino acid 74 of the cytokeratin, creating a "headless" protein that is not able to polymerize and form filaments; rather, it accumulates in cytoplasmic clumps. A normal intermediate filament system helps to maintain the mechanical integrity of cells, and perturbations to the network would be expected to make the infected cell more susceptible to lysis. The E3-ADP protein facilitates the release of progeny virions by the induction of cell death (see Functions of E3 Proteins). The E1B 55K–E4 ORF6 ubiquitin ligase complex induces the degradation of integrin α3, which appears to decrease attachment of infected cells to their substratum.[62] This likely increases virus spread in the respiratory tract. The interaction of E4 ORF1 protein with PDZ-domain–containing members of the membrane-associated guanylate kinase protein family disrupts tight junctions between epithelial cells and likely aids in progeny virus dissemination.[137,166] Finally, tight junctions are also disrupted by free fiber trimers released from infected cells that interfere with CAR oligomerization.[311] This likely promotes the release of progeny virions into the airway lumen in the respiratory tract.

PERSPECTIVES

Since their discovery nearly seven decades ago, adenoviruses have maintained their status as a fertile ground for revealing fundamental insights into multiple aspects of animal cell biology and human antiviral defenses. Successively deeper understanding of the structure and assembly of the virion provides exquisite examples of macromolecular interactions and assembly. It also allows the design of novel adenovirus gene therapy vectors with engineered receptor-binding domains to direct cell type–specific viral infection and with genetic alterations to promote replication in specific cell types such as cancer cells. Adenovirus evolution has led to the expression of multiple proteins that interact with a variety of cellular effectors, each of which has a profound effect on the biology of the cell. Through these interactions, adenoviruses help to identify cellular proteins and protein complexes that are nodes in the regulation of cellular processes. Adenoviral proteins provide us with molecular tools for exploring cell biology. The large number of recent references in this chapter demonstrates that research on adenoviruses continues to provide fundamental advances in all aspects of biology and that adenovirus research

continues to be a productive and rewarding area of discovery.

ACKNOWLEDGMENTS

I am very grateful to Dr. Arnold J. Berk who provided the *Adenoviridae* chapter from the previous edition of this book as a reference for the current chapter and to Dr. William S.M. Wold who provided the section on E3 proteins from the previous edition of this book. I thank Dr. Yueting Zheng who created Figure 4.12.

CHAPTER 5

Adenoviruses

Thomas Lion • William S. M. Wold

Introduction
History
Infectious agent
- Propagation and assay in cell culture
- Biological characteristics
- Key antigens
- Infection of experimental animals

Pathogenesis and pathology
- Entry into the host
- Sites of primary replication and spread of the virus
- Tissue tropism in the host
- Chemical defense and immune response
- Virulence
- Persistence and latency
- Persistence and reactivation in the gastrointestinal tract

Epidemiology
- Transmission
- Prevalence of HAdV species and types
- Stability and inactivation of adenovirus

Clinical features
- Respiratory diseases
- Ocular infections
- Hemorrhagic cystitis
- Meningoencephalitis
- Gastrointestinal diseases
- Myocarditis
- Hepatitis
- Adenovirus infections during pregnancy
- Obesity

Diseases associated with immunocompromised patients
- Risk factors
- Incidence of HAdV infections in immunocompromised adult and pediatric patients
- De novo infection and viral reactivation in transplant recipients
- Definitions of adenoviral infection and disease
- Clinical presentation and outcome of HAdV infections in solid organ and allogeneic stem cell transplantation

Evidence linking adenoviruses to human cancer
Diagnosis
Diagnosis in the immunocompromised setting
Predictive value of viremia and HAdV replication in the gastrointestinal tract
Diagnostic screening
Relevance of HAdV detection and quantification at specific sites
Adenovirus typing
Molecular HAdV detection and monitoring of viral load
Prevention and treatment
Approaches to antiadenoviral treatment in immunocompromised patients
Current treatment modalities
Adenoviruses as vectors for vaccination, gene therapy, and cancer treatment
Perspectives

INTRODUCTION

Since the first isolation from adenoidal tissue over 60 years ago,[571] human adenoviruses (HAdVs; *adén, gen.adénos = gland*) have provided continuous challenges in a variety of clinical settings. In addition to their well-established role as infectious agents, adenoviral genomes were also shown to contain potent oncogenes, and the ability of certain types of the virus to induce tumor growth has been demonstrated in different mammalian animal models in the early 1960s.[250,297,677] Despite a number of studies addressing the possible role of HAdVs in human malignant disease, their putative oncogenicity in man has remained enigmatic.[367,368,583] The investigation of adenovirus (AdV) biology has led to Nobel Prize–winning discoveries in mRNA splicing and to important progress in the understanding of antigen presentation to T cells.[208] Moreover, the ability of adenoviruses to infect many cell types facilitated their exploitation as vectors for gene delivery to generate new tools for innovative treatments of important diseases such as cancer and cardiovascular disorders.[136,137,473,610,738] Hence, adenoviruses are highly versatile organisms with a broad spectrum of clinical roles and applications. They are an important cause of infections in both immunocompetent and immunocompromised individuals, and continue to provide clinical challenges pertaining to diagnostics and treatment. The growing number of HAdV types identified by genomic analysis, as well as the improved understanding of the sites of viral persistence and reactivation, require continuous adaptations of diagnostic approaches to facilitate timely detection and monitoring of HAdV infections. In view of the clinical relevance of life-threatening HAdV diseases in the immunocompromised setting, there is an urgent need for highly effective treatment modalities lacking major side effects. A major focus of this chapter will therefore be the recent progress in the understanding and management of HAdV infections, including pertinent recent literature. Some of the earlier literature can be found in previous Editions of Fields Virology.[724,725]

HISTORY

During attempts to establish tissue culture lines from tonsils and adenoidal tissue surgically removed from children, Rowe and colleagues recognized that a transmissible agent was causing degeneration of the epithelial-like cells, and adenoviruses were first cultured and reported as distinct viral agents in 1953.[571] A nomenclature for HAdVs was adopted in 1956, and reclassification was performed in 1999.[686] The family of *Adenoviridae* included four genera, each corresponding to an independent evolutionary lineage that supposedly coevolved with the respective vertebrate hosts: *Mastadenovirus* (mastós = breast) from mammals, *Aviadenovirus* (avis = bird) from birds, *Atadenovirus* (the prefix stands for adenine and thymine, acknowledging the high AT content in the genomes of the first recognized members of this genus) and *Siadenovirus* (the prefix stands for sialidase, reflecting the presence of a putative sialidase homolog in members of this genus) from a broad range of hosts.[39,117,686] A fish adenovirus falls into a fifth clade, the more recently established genus *Ichtadenovirus* (ichthýs = fish).[226] In turtles, members of a sixth AdV lineage have been discovered, pending official recognition as an independent genus.[226] Human AdVs are divided into seven species termed A, B, C, D, E, F, and G, based on serum neutralizing and hemagglutination epitopes, genome sequence and function, oncogenic properties in newborn hamsters, and pathology in humans. These species were previously referred to as groups or subgroups.

Historically, human AdV isolates were designated as serotypes, based on neutralization of productive infection by homologous sera.[39] More recently, with the advent of high-throughput AdV genome sequencing and bioinformatic analysis, new insights into AdV genome structure and taxonomy have been obtained.[117,224] Evolution of AdVs seems to have been driven not only by sequence divergence but also by frequent recombination between different (sero)types.[436,441,557,559,560,607,707_709] Researchers have taken the view that AdV isolates should be designated as "types" rather than "serotypes," as per definitions of the International Committee on Taxonomy of Viruses. Two similar but not exact proposals have been advanced to characterize AdVs.[18,605] With one proposal, for example, human AdV serotype 1 will be designated "type HuAdV-1," with the "1" referring to hexon (the major capsid protein) identity. The rationale is that hexon should remain the major identifier "because it contains the major neutralizing epitope, which is targeted in molecular diagnosis".[18] With the other proposal, human AdV serotype 1 will become "type HAdV-C1," with the "C" referring to species C.[605] In the current article, "type" rather than "serotype" will be used to reflect the important impact of genomic analysis on the identification of novel variants during the last decade.[605] According to current standard nomenclature, "H" (for Human) should precede the species and type number, for example, HAdV-C5.

The first 51 HAdV types belonging to the species A-F were identified by serotyping, and were therefore originally referred to as serotypes (Table 5.1). Species B was further divided based on their genome similarities and restriction enzyme analysis into subspecies B1 (HAdV B3, B7, B16, B21, B50) and B2 (HAdV B11, B14, B34, B35, B55).[759] The first HAdV type identified by genomic analysis, which had been isolated from a patient with gastroenteritis, was assigned to the newly established species G in 2007, and was termed HAdV-G52.[307] All subsequent HAdV types, generally representing intraspecies recombinants, were identified by whole genome sequencing (WGS) and computational analysis[133,219,220,284,325,422,423] (Table 5.1). Furthermore, the genome sequence of the HAdV-C5 reference material (ARM) was published as a reference strain for vectors based on this HAdV type.[643] The genomes of different types within

a species are usually highly related, but the divergence between different species can be considerable, and may therefore also affect the specificity of molecular detection.[422,423]

TABLE 5.1 Current spectrum of known human adenoviruses

Species	Types (Serotypes/Genotypes)
A	12, 18, 31, 61
B	3, 7, 11, 14, 16, 21, 34, 35, 50, 55, 66, 68, 76–79
C	1, 2, 5, 6, 57, 89, 104
D	8-10, 13, 15, 17, 19, 20, 22-30, 32, 33, 36–39, 42-49, 51, 53, 54, 56, 58, 59, 60, 63, 64, 65, 67, 69–75, 80–88, 90–103
E	4
F	40, 41
G	52

The HAdV species (A–G) and types (1–104) belonging to individual species are indicated. While the types 1–51 were identified by serotyping, all subsequently identified types (52–104) were identified by genomic sequencing and computational analysis.

INFECTIOUS AGENT

Propagation and Assay in Cell Culture

A number of cell lines including the primary human embryonic kidney (HEK) cells or continuous epithelial lines, such as HEp-2, HeLa, KB, HEK 293, and A549, have been used for propagation of HAdVs. The viruses in monolayer cell culture have a characteristic cytopathic effect (CPE). The cells round up, swell, and detach from the culture surface into grape-like clusters, and the nuclei become enlarged. Eventually the cells lyse, leaving cell debris. This CPE is the result of the infection passing into the “late” stage of infection, when adenoviral DNA, mRNA, and proteins are being made in large quantities, and virions are assembling in the cell nucleus. HAdVs increase glycolysis in continuous cell lines, thereby stimulating the cells to produce large quantities of acid. Rapid cytopathology can be induced within several hours of inoculating concentrated crude virus preparations, and the effect is not related to viral replication. Rather, it is caused by the penton base component of the free viral penton capsomere. Nuclear morphologic changes in infected cells have also been used for diagnostic purposes.[725]

Biological Characteristics

A general description of the biological characteristics including the structural proteins and the genomic structure is outlined in the preceding chapter.

Phylogeny and Human Adenoviral Species

The marked overall pattern of host specificity suggests that tight long-term association with their hominine hosts has governed HAdV evolution. However, there is evidence for natural host switches mediated by cross-species transmission, supporting the zoonotic origin of some HAdVs.[47,123,124] Studies in fecal samples from wild African great apes and humans, involving ancestral host reconstruction, support the notion that HAdV-B, in particular, originated in gorillas, and individual recombinants were transmitted to other apes and humans, presumably via the fecal–oral route, more than 100,000 years ago. However, while HAdV-B, -E, and -C have a high prevalence in gorilla and chimpanzee populations, HAdV-D has never been detected in great apes.[260,261] However, there is not only evidence for anthropozoonosis (transmission from animals to humans), but also for zooanthroponosis (transmission from humans to animals), indicating that adenoviruses are continuously crossing host/species barriers.[47]

Together with other mammalian adenoviruses, HAdVs are classified into the genus *Mastadenovirus*, and are further parsed into seven species termed A-G, with further subdivision of species B into subspecies B1 and B2, as briefly outlined above.[307,426,561,606,708,759] Species designation depends on several of the following characteristics: phylogenetic distance (>5% to 15%, based primarily on distance matrix analysis of the DNA polymerase amino acid sequence), genome organization (characteristically in the E3 region), nucleotide composition (G + C%), oncogenicity in rodents, host range, cross-neutralization, ability to recombine, number of VA RNA genes, and hemagglutination.[225] More than 30 simian (simia = monkey, ape) adenoviruses (SAdVs) display a sequence identity to their human counterparts to such an extent that they have also been included in the taxonomy of HAdVs within species B, C, E, and G.[225] Previously, HAdVs were identified, characterized, and classified by serum neutralization (SN) and hemagglutination inhibition (HI) assays, but more recently genomic and bioinformatic analysis of the entire viral genome has superseded serological methods for the typing of novel viruses.[18,225,307,426,561,606,708] The viruses belonging to individual HAdV species display high similarity to each other at the nucleotide level and do not commonly recombine with members of other species. The grouping into different species reflects, in part, the general cell tropism of the viruses and the resulting diseases and symptoms. Examples of common associations of individual HAdV species with infections at specific locations include gastroenteritis (HAdV-F and -G), pneumonia (HAdV-B, -C, -E), hepatitis (HAdV-C), meningoencephalitis (HAdV-A, -B, -D), cystitis (HAdV-B), and keratoconjunctivitis (HAdV-B, -D), but other HAdV species may also occur at the indicated sites of infection.[149,307,560]

(Sero)typing of Human Adenoviruses

HAdV subtyping below the level of species by SN and HI assays has led to the identification of 51 serotypes (Table 5.1). The hypervariable loops (L1 and L2) of the hexon protein form the SN epitope and are the main determinants of serologic reactivity, while the fiber protein is responsible for HI typing and is a major determinant of tropism. The combination of the SN and

HI tests facilitates more complete virus identification than does either method alone. The first HAdV identified on the basis of genetic analysis was also classified as a novel species (HAdV-G), and received the chronological number 52.[307] Because all subsequently identified novel HAdVs were detected and characterized using computational analysis of genomic data (Table 5.1), it has been agreed to replace the term "serotype" by "type," and criteria for the assignment of new types have been established.[18,605]

Current Status of HAdV Types and Evolution of Human Adenoviruses

The number of HAdVs has been steadily expanding and currently includes more than 100 different types within the species A-G (Table 5.1) (http://hadvwg.gmu.edu/). Novel HAdV types reportedly arise from intra- or interspecies recombination events most frequently occurring within species D, the largest of all HAdV species, presently including over 70 different types. As outlined in Table 5.1, HAdV types 1 to 51 were characterized by serotyping, while the remaining types identified since 2007 were detected and described by genomic and bioinformatic analysis.[307,453,562]

Homologous recombination (HR) and mutation are important evolutionary processes driving genetic variation within HAdV genomes.[562] They are favored by the immune pressure of the host and environmental bottlenecks. In HAdV species B, mutations seem to play a more important role, whereas among the largest HAdV species D, HR between two or more virus types infecting the same cell(s) is the predominant mechanism contributing to genomic diversity.[287,475,562] While rapid selection of novel capsid gene sequences is apparently the main factor for the diversity in HAdV species B, recombinant types have also been described.[133,285,747]

HR of tumorigenic adenoviruses *in vitro* has been documented already in the 1970s,[655,719] and it was shown to occur predominantly between HAdV types belonging to the same species, within regions of high sequence homology.[560] The recent availability of WGS and bioinformatics has permitted the description of recombination events within genomes of HAdV species A, B, and D, particularly within the penton base, hexon, and fiber genes.[436,559,561,706] Recombination of capsid protein genes may diversify the tissue tropism of novel HAdV types, thereby potentially enhancing the pathogenicity and virulence of the new viruses.[133,229] In HAdV species C, recombination events between the genes encoding major capsid proteins are rare, and the recently identified recombinant type HAdV-C89, displaying a novel penton base sequence, has remained an exceptional observation.[133] The evolution of HAdV-C has mostly occurred at the subtype level, because the early gene regions E1 and E4 implicated in recombination events within this species are not considered in the type definition. Nevertheless, such recombinations at the subtype level may influence the virulence of HAdV-C strains.[133] The requirements for recombination events appear to include coinfection of individual cells with at least two different adenoviruses displaying very similar nucleotide sequences at the recombination hotspots in the genome, and long-term viral persistence in the host.[362,460,696] In bacteria, a signal for recombination between homologous DNA is the *c*rossover *h*otspot *i*nstigator (Chi) nucleotide sequence. This was first identified in bacteriophage lambda and then in bacterial DNA and later was shown to mediate recombination between them. The octanucleotide Chi sequence in *Escherichia coli* induces the conversion of the RecBCD enzyme from a helicase to an

exonuclease, producing single-stranded (ss)DNA that can invade homologous double-stranded (ds)DNA during recombination. Chi-like nucleotide sequences adjacent to the junction of conserved and hypervariable gene segments in HAdV-D may therefore be an important signal for HR. This notion supports the concept that local bacterial flora might enhance natural recombination mediated by Chi-like nucleotide sequence motifs at HAdV-D recombination hotspots.[287] Indeed, recent experimental evidence indicated that coinfection with two different HAdV-D types in the presence of *E. coli* lysate increased the recombination. This effect was attributed to the bacterial RecA protein, which binds to the Chi-like adenoviral sequences located directly adjacent to the coding sequence for penton base hypervariable region 2.[393] The viruses may therefore repurpose the bacterial recombination machinery, and the authors proposed that free Rec proteins present in the gastrointestinal (GI) tract upon bacterial cell death could facilitate the evolution of HAdV species by HR. This concept supports the occurrence of transkingdom interactions between bacteria of the intestinal microbiome and enteric viruses.[393] The emergence of new HAdV-D types in patients with AIDS indicates a role of multiple persisting viruses under impaired immune surveillance.[113,562] HAdV-D genomes seem to recombine more frequently than do other human adenoviral species, and several of the currently more than 70 HAdV-D types have apparently emerged via recombination between hexon and fiber coding regions.[562] The majority of novel HAdV types identified by genomic analysis belong to species D, and they were shown to include sequences derived from multiple other types from the same species. For example, HAdV-D53 resulted from recombination in penton, hexon, and fiber regions of HAdV-D22, D37, and D8, respectively. Similarly, HAdV-D67 was identified as a recombinant between HAdV-D9, D25, D26, D33, and D46.[325,453] The latest additions to the rapidly evolving genus D include the types HAdV-D100 (a recombinant of hexon D17, fiber D30, and a novel penton base recombined from D38 [HVR1] and D48 [HVR2]), HAdV-D101 (a recombinant of hexon D37, fiber D45, and a novel penton base recombined from D59 [HVR1] and D67 [HRV2]), HAdV-D102 (a recombinant of hexon D38, fiber D30, and a novel penton base recombined from D62 [HVR1] and D54 [HRV2]), and HAdV-D103 (a recombinant of hexon D33, fiber D30, and a novel penton base recombined from D37 [HVR1] and D48 [HRV2]) (Table 5.1; http://hadvwg.gmu.edu).

Moreover, current data provide evidence for the occurrence of recombination between different HAdV species, and even between human and simian adenoviruses (SAdVs).[123,717] Computational analysis of HAdV-E4, the only representative of species E, indicated that this virus is of zoonotic origin and has evolved through two interspecies recombination events with lateral partial gene transfer. HAdVE-4 contains 97% SAdV-E26-like genome chassis with a hexon containing the L1 and L2 regions from a HAdV-B16-like virus, which may provide compatibility with the new host.[123,667] Adaptation of the virus to the new host could also be related to a further recombination event leading to the acquirement of a NF-1 binding site motif, which is required for efficient viral replication.

Molecular evolution of HAdVs by HR can result in new viruses displaying different tissue tropism and increased virulence. Improved knowledge of HR might therefore facilitate prediction of potential emerging HAdV types. In addition to their role in the evolution of novel HAdV types, it is important to understand the recombination mechanisms, if adenoviral vectors are to be used in human patients who might coincidentally be infected with a wild-type virus. Moreover, the occurrence of viral recombinants with lateral DNA and epitope transfers between HAdVs and SAdVs must be borne in mind when chimpanzee adenoviruses are considered as vectors for gene

delivery in human patients to exploit the lack of immunoreactivity to these viruses (see below).

Key Antigens

The clinically important HAdV antigens include primarily the three capsid proteins: hexon, penton base, and fiber. Most early studies indicated that the hexon, and to a lesser extent the fiber proteins, contain most of the epitopes recognized by neutralizing antibodies, but the penton base displays neutralizing epitopes as well.[96,257,440] The neutralization properties of polyclonal antibodies are often concordant with the inhibition of HAdV-induced hemagglutination (HA) of red blood cells. However, the HA functions are a property of the fiber,[497] which apparently must be linked to the penton base for complete HA to occur. Because of recombination within species in clinical isolates, it is not uncommon to isolate a virus that demonstrates discordant reactions in the neutralization and HA inhibition reactions.

Studies in naturally infected humans found that the majority of neutralizing antibodies were directed against the hypervariable regions of hexon, but some were also directed against the fiber and possibly the penton base.[558,646] In contrast, other published data suggest that HAdV-C5 neutralizing antibodies to fiber are more common than those to hexon in the naturally infected population, but immunization with a replication-defective HAdV-C5-based vector raised more neutralizing antibodies to capsid proteins other than fiber.[96] Most studies in animal models investigating infections with HAdV-C5-based vectors found that the predominant neutralizing antibodies are directed at hypervariable hexon regions.[385,558,750] Mechanisms by which neutralizing antibodies function include virus aggregation, virus destabilization, blocking virus–receptor interactions, and integrin-mediated internalization.[626] One study provided evidence that the HAdV-C5 neutralizing antihexon monoclonal antibody 9C12 inhibits adenovirus infection by blocking microtubule-dependent translocation of the virus to the microtubule-organizing center following endosome penetration.[626] Another study based on using the same monoclonal antibody as well as polyclonal HAdV-C5 neutralizing antibodies concluded that the cellular cytosolic protein TRIM21 binds to the antibody in the internalized antibody–virus complex, and targets the virus to the proteasome for degradation.[446]

There are species- and type-specific epitopes on both hexon and fiber. Type-specific domains have been mapped to unique sequences in loop 1 (amino acids 281 to 292) and loop 2 (amino acids 441 to 455) of the hexon by generating neutralizing antibodies to peptides from each of these regions, and this epitope is referred to as the ε determinant.[440] Loops 1 and 2 had previously been shown by crystallography to be on the surface of the virion. Differences in the HA properties of rhesus and vervet monkey erythrocytes for two important subtypes of HAdV-B11 (HAdV-B11p and HAdV-B11a) have been related to nucleotide sequence differences in the shaft and knob region of fiber. The knob region of fiber, which has HA properties that are used for HI tests, includes the γ determinant. The subtypes HAdV-B11p and B11a display some differences in tissue tropism in that B11p can persist in the urinary tract and B11a causes acute respiratory tract infections. These properties may be related to the changes in fiber polypeptides, otherwise displaying identity for 92.3% of their amino acids.[440] There are antibodies apparently reacting with conserved hexon domains from all human types, as determined by the complement fixation (CF) test and serologic techniques, such as immunofluorescent (IF) antibody and enzyme-linked immunosorbent assays (ELISA).

HAdV-specific $CD4^+$ T lymphocytes have been detected in peripheral blood in nearly all

naturally infected humans of all ages.[61,84,274,397,500] When peripheral blood mononuclear cells (PBMCs) were stimulated in bulk culture (e.g., by incubation with intact HAdV particles, HAdV-infected cell extracts, purified HAdV proteins, or with pools of peptides that span various HAdV proteins), $CD4^+$ T lymphocytes specific to hexon were identified in healthy donors.[174,600,752] Other studies using peptides corresponding to parts of several HAdV proteins identified a number of $CD4^+$ T-cell epitopes, including the dominant HLA DP4-restricted H910-924 epitope, located in the base of the hexon protein, which is conserved among HAdV types and detectable in PBMCs from the majority of healthy adults analyzed.[601] Many other $CD4^+$ T-cell epitopes located in the conserved regions of HAdV-C5 hexon that are conserved across HAdV types have been identified.[398,399,600,751] In a study that analyzed PBMCs from 44 healthy donors, 10 $CD4^+$ T-cell immunodominant hexon epitopes were detected in more than 50% of subjects examined, and the HLA restriction element for some of these peptides is known.[600,751] In addition to the more frequently observed HAdV- and hexon-specific $CD4^+$ T cells, hexon-specific $CD8^+$ T cells have also been detected in PBMCs from healthy donors. These cells are cross-reactive with various HAdV types, secrete IFNγ (interferon gamma), and display cytolytic activity in culture.[274,308,398,751] $CD4^+$ and $CD8^+$ T cells specific for HAdV proteins other than hexon, including penton base and DNA polymerase, have also been identified.[174,308,399] There is increasing evidence that hexon-specific cytotoxic T lymphocytes (CTLs) are protective in humans.[398] Indeed, mixtures of $CD4^+$ and $CD8^+$ cells specific for hexon and other HAdV proteins were shown to be effective upon adoptive cell transfer for infections by various HAdV types in allogeneic hematopoietic stem cell transplant (SCT) recipients or in primary immunodeficiencies.[2,173,194,310,336,399,400,537,595,751] The therapeutic effect is believed to be mediated by the coordinated action of the adoptively transferred $CD4^+$ and $CD8^+$ T cells.[751]

Infection of Experimental Animals

Similar to other mammalian or avian AdV species, HAdVs are mostly host specific in their replication cycle, and even nonhuman primates are poor hosts for HAdVs. HAdV species C can replicate in the lung of cotton rats, permitting to study the pathogenesis of HAdV-mediated pneumonia in these animals.[531] An ocular model of infection with either HAdV-C5 or HAdV-D8 has been described in cotton rats, and the clinical manifestations, including subepithelial corneal opacities, were similar to epidemic keratoconjunctivitis (EKC).[327] The animals shed the virus, developed specific antibodies to the infecting virus, and were able to transmit the infection to control cotton rats. A similar ocular model was reported in New Zealand white rabbits after topical or intrastromal inoculations of HAdV-C5.[103,569] The virus appeared to replicate, and most of the animals developed a humoral immune response. There were findings of blepharitis, conjunctivitis, iritis, corneal edema, and subepithelial corneal infiltrates that were consistent with immune-mediated clinical disease. The HAdV-C5 New Zealand white rabbit model has been used to evaluate the antiviral activity of several compounds including cidofovir, 2′-3′ dideoxycytidine, *N*-chlorotaurine, and dexamethasone povidone–iodine, and the results provided a basis for ensuing clinical trials.[101,103,517,568,569]

A number of groups have explored mouse models for studying HAdV-mediated pathogenesis to evaluate oncolytic (replication-competent) HAdV vectors for cancer gene therapy. HAdVs can infect cells of virtually all mammalian species including murine cells, especially if high multiplicities of infection are used (~100 plaque forming units per cell). Early HAdV proteins are

expressed at good levels, and HAdV-C5 DNA replication was documented in Syrian hamsters, indicating that these animals are a suitable permissive immunocompetent model for HAdV pathogenesis and testing of oncolytic HAdV vectors, in contrast to mice where no evidence of vector replication has been obtained.[662,727,745] HAdV-C5 replicates modestly in cotton rat cells,[638] canine cells,[661] and porcine cells.[304] In three Syrian hamster cancer cell lines, the burst size (virus yield per cell) was about 1,000, only 10-fold less than in A549 cells.[662] Moreover, Syrian hamsters displayed HAdV-C5 replication in the liver following intravenous administration, and efficient (~4-log) replication in the lungs following intranasal or intratracheal administration.[662,745] Due to the permissiveness of Syrian hamster tissues for HAdV-C5 and the availability of numerous Syrian hamster cancer cell lines, these animals have been used as a model to investigate the toxicology and antitumor efficacy of oncolytic HAdV-C5-based vectors.[59,131,672,674,675,744] Immunocompetent and immunosuppressed (by treatment with cyclophosphamide) hamsters bearing subcutaneous tumors formed by injection with various Syrian hamster cancer cell lines were treated by intratumoral injection with a variety of oncolytic HAdV vectors.[48,129,130,132,330,634,748] In general, these studies showed that oncolytic HAdV-C5-based vectors suppress the tumor growth, and that a rapid adaptive immune response to the vector appears to eliminate the vector from the tumor.[617] Syrian hamsters have also been used to study the biodistribution and toxicity of oncolytic HAdV-C5-based vectors in advance of clinical trials.[351,456,631,745] Immunocompetent, newborn, and immunosuppressed Syrian hamsters have been used to evaluate compounds inhibiting HAdV replication, and a mouse model was used to test the virostatic compound cidofovir against disseminated murine AdV type 1 infection.[135,673,726] HAdVs inoculated into a variety of rodent species cause a number of tumors. Pronounced oncogenicity in newborn Syrian hamsters has been demonstrated for HAdV types A12, A18, and A31, and much has been learned about the mechanism of action of the genes in the E1A and E1B regions from these viral models. The integrated HAdV-A12 sequences in these hamster tumors are a model for understanding epigenetic consequences of foreign DNA integration.[140,141] In addition to rodent animal models,[411,450,579] porcine cells were recently shown to provide a valuable model for preclinical testing of engineered oncolytic chimeric HAdV-C5/3 vectors[361] (see section on Adenoviruses as Vectors for further details).

PATHOGENESIS AND PATHOLOGY

Entry into the Host

Adenoviruses enter susceptible hosts by oral, nasopharyngeal, or ocular infection. Experimental data have identified several receptors, attachment factors, and facilitators as HAdV binding partners, which display steric features complementary to components of the viral capsid or to virions in complex with host proteins.[163,177,209,386,497,718,729] Currently known receptor molecules include the coxsackie and adenovirus receptor (CAR), CD46, desmoglein-2 (DSG2), integrins, sulfated glycosaminoglycans (GAG), and sialic acid–containing oligosaccharides, including the disialylated GD1 glycan as well as polysialylated glycoproteins[86–88,405,499,637,642,711] (Fig. 5.1). Additionally, two related proteins, CD80 and CD86, co-stimulatory molecules from the immunoglobulin superfamily that are present on

mature dendritic cells and B lymphocytes, were shown to serve as attachment receptors for members of HAdV species B via the fiber knob domain, and can be utilized for infection of otherwise nonpermissive cells.[618] The diversity of HAdV receptors contributes to the broad tropism of these viruses, and structural studies are thus an important source of information on HAdV–host cell interactions. Moreover, studies in murine models identified the macrophage scavenger receptor SR-A6 (MARCO) as an adenovirus type–specific virus entry receptor involved in the sensing of infection with HAdV and recombinant adenoviral vectors. This receptor is important for production of IFN type I, and may therefore play a role in innate antiviral immunity.[445,641]

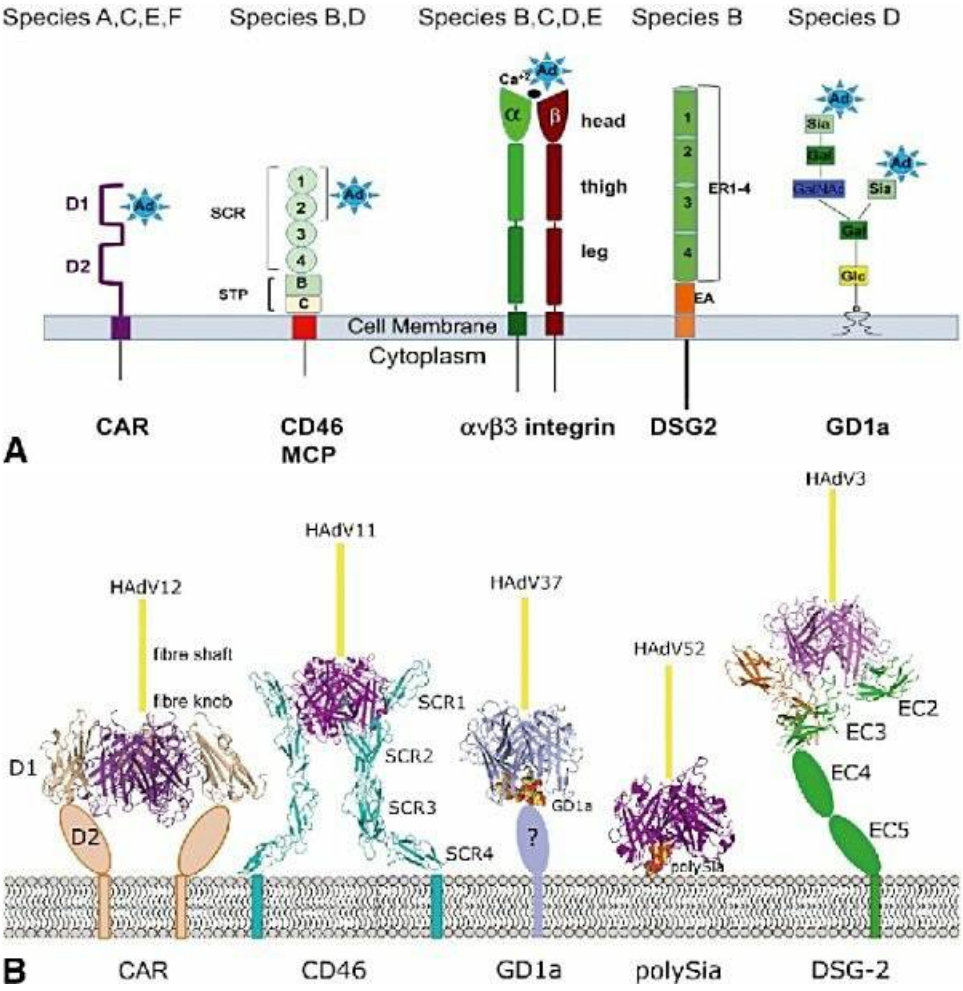

FIGURE 5.1 Cell receptors for adenovirus attachment and internalization. **A:** The diagram indicates the HAdV species using the CAR, complement receptor (CD46/MCP), vitronectin-binding integrin αvβ5, the glycolipid-anchored receptor GD1a, or desmoglein 2 (DSG2). Sialic acid residues on certain receptors have been shown to be the actual site of virus fiber interaction. **B:** Structural view of HAdV binding types to attachment receptors (examples of individual HAdV types). The trimeric knob is shown in shades of purple; the trimeric fiber shaft is represented by a yellow line (length not to scale). Domains not featured in structures are represented with cartoon shapes. ([Panel A] from Nemerow G, Flint J. Lessons learned from

adenovirus (1970-2019). *FEBS Lett* 2019;593(24):3395–3418. Copyright © 2019 Federation of European Biochemical Societies. Reprinted by permission of John Wiley & Sons, Inc. The CAR receptor is a 46-kDa transmembrane protein involved in the formation of tight junctions of polarized cells, where it mediates cell-to-cell adhesion. Moreover, it was recently shown to also regulate synaptic transmission in neuronal communication, and to play an important role both in controlling recruitment of immune cells and in tumorigenesis.[505,578,730] It mediates recognition of the fiber knobs protruding from the viral capsid, thereby anchoring the virus to the cell. This high-affinity receptor interaction, which operates in most HAdVs, with the exception of representatives of species B, is unable to promote virus entry into cells.[111] HAdVs of species B can be differentiated based on their receptor usage. Members of HAdV subspecies B1 predominantly utilize CD46 as a receptor. The binding is mediated by fiber knobs of the virus, which recognize the receptor with different affinities. The membrane protein CD46 is expressed on virtually all cells, where it acts as a cofactor for inactivation of different complement components. Members of HAdV subspecies B2 utilize DSG2 as their high-affinity receptor, a calcium-binding transmembrane glycoprotein from the cadherin protein family, but HAdV-B11 was shown to use either CD46 or DSG2.[711,712,714] When the HAdV fiber binds to DSG2, opening of intercellular junctions results in increased access to receptors trapped deep within the junction, but the dissociation of the intercellular junctions may also facilitate the lateral viral spread in epithelial cells and, potentially, the penetration into subepithelial cell layers and the bloodstream.[711] The fiber protein on HAdVs mediates viral entry via interaction of its most distal structure with host cell receptors, and phylogenetic analysis of HAdV-D types associated with EKC revealed that they form a unique clade characterized by a shared amino acid composition of the fiber knob.[286] Proteotyping analysis showed that it is possible to predict human corneal cell tropism by identifying specific amino acids at a critical position of the fiber knob, with evidence for positive selection.[287] Different representatives of HAdV species D associated with EKC appear to bind to α2,3-linked sialic acid present in the GD1a ganglioside on the corneal cell surface.[28,499]

Unlike the great majority of HAdVs, HAdV-G52 displays a long and a short fiber protein. While the long fiber binds to the CAR receptor, the short fiber knob forms transient electrostatic interactions with long chains of polysialic acid (polySia), rendering CAR and polySia the most efficient attachment factors for HAdV-G52.[404] The fiber knob can also interact with monosialylated and disialylated glycans, albeit with lower affinity. Only polySia-containing glycoproteins on target cells therefore appear to serve as efficient receptors for HAdV-G52.[405] Since polySia is highly expressed on various cancer cell types displaying very aggressive and invasive properties, exploitation of HAdV-G52 might provide the basis for developing oncolytic vectors (see below) targeting particularly tumors characterized by elevated polySia expression. The low seroprevalence and reduced liver tropism of this HAdV type further support this notion.[405]

A recently described additional receptor-independent mechanism of HAdV entry into cells is the use of exosomes.[110,111,621] Exosomes are nano-sized, membrane-bound vesicles with a

diameter of 30 to 150 nm that are generated during endosome maturation,[81] and are secreted into the extracellular environment by many eukaryotic cell types.[110,306] They act as carriers of nucleic acids, lipids, and proteins, and their composition reflects the subcellular origin and the physiology of the parent cells.[110,306] Exosomes can carry viral genomes and act as vehicles for viruses facilitating entry into host cells, thereby providing a mechanism of evasion from the immune system.[111] It has been demonstrated that HAdV-C5 can exploit exosomes for cellular entry in CAR-deficient cells by binding to these particles and entering cells via phosphatidylserine or different binding proteins.[621] The exploitation of exosomes loaded with HAdVs would be advantageous for therapeutic applications in cancer treatment owing to the evasion from host immune response and broader tropism of virus delivery. However, prior to moving towards clinical application, several challenges need to be met, including the low production yield and short half-life of the vesicles as well as the lack of knowledge about their possible immunogenic properties or toxic effects.[111,281,347,768]

It is necessary to consider that the administration of HAdV-based vectors *in vivo* may display different modes of cell entry, as suggested by studies in murine models proposing a CAR-independent mechanism, but it is unclear whether this pathway also operates in humans. The coagulation factor X (FX) binds to the adenovirus capsid and protects the virion from natural antibody and classical complement-mediated neutralization in both mice and humans.[145] The findings in murine models indicated that infection of hepatic cells occurred through HAdV binding to FX, directing the complexes to hepatocellular receptors, including heparin sulfate proteoglycans[700,701] (Fig. 5.2). The high-affinity interaction of several HAdVs with FX may facilitate bridging of the hexon protein in the viral capsid to heparin sulfate proteoglycans expressed on the surface of hepatocytes. The virus complexed with FX binds to the cell surface through the serine protease domain of FX rather than through a direct interaction of the virus with the cell surface.[323,700] Once bound to the cell surface, efficient and rapid intracellular transport of the virus remains dependent upon engagement of α_v integrins via the penton base protein.[51] Virus internalization, facilitated by a secondary interaction with cellular integrins, is mediated by the loops of viral penton base proteins containing an Arg-Gly-Asp (RGD) motif.[493,756] If the CAR receptor is involved, the fiber shaft may need to undergo strong flexion to facilitate simultaneous engagement of the virus with CAR and integrin receptors to form the tethered ligand assembly.[175,177,434,731,756]

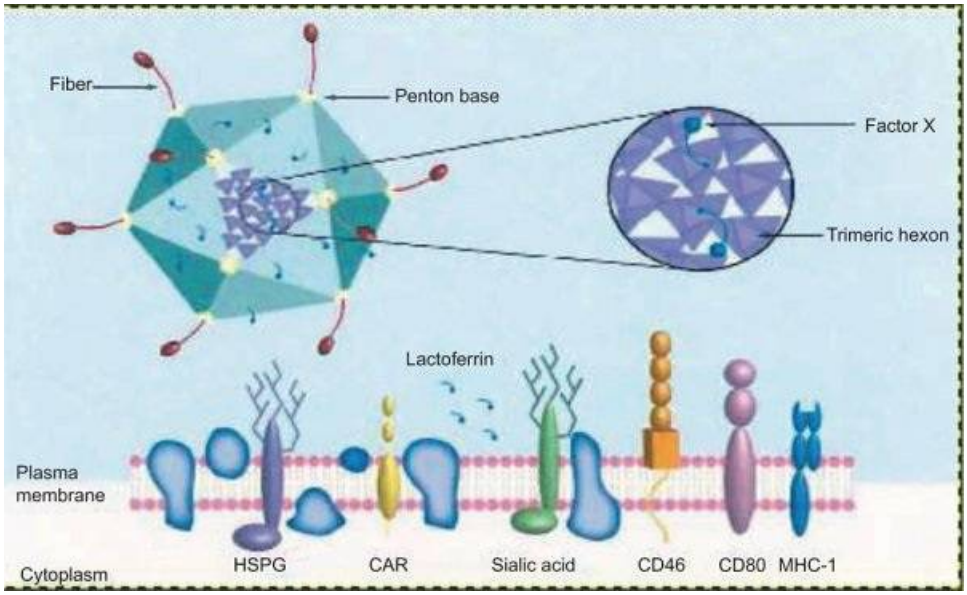

FIGURE 5.2 Coagulation factor X–mediated HAdV binding to liver cell receptors including heparin sulfate proteoglycans (HSPG). While the receptors are generally membrane proteins, other ligands are present in a soluble form, such as lactoferrin and coagulation factor X, which are used as a bridge between the virus and the cell, to target the liver. The receptor usage depends on the HAdV type and the targeted tissue.

After the interaction with host cell receptors and integrin-mediated endocytosis, the virus particles undergo uncoating, with dissolution of the viral capsid in the endosome. The removal of various scaffolding proteins is important for virulence. Thereafter, the virus is transferred through the cytoplasm along microtubules into the nucleus by dynein (cytoskeletal motor protein)-dependent translocation.[340]

Sites of Primary Replication and Spread of the Virus

The original observation of HAdVs in tonsils and adenoids indicate that these tissues of the oropharynx are an initial site of entry and replication. Initial replication of HAdV types causing respiratory disease most likely occurs in the nonciliated respiratory epithelium, although some limited replication and persistence can also occur within lymphocytes.[422] The apical surfaces of ciliated respiratory epithelium in the lower airways do not display the CAR receptor and are therefore difficult to infect by HAdV types requiring this molecule for cellular attachment. However, disruption of the integrity of cell-to-cell contact can facilitate basolateral infection of such polarized epithelial cells via this receptor.[712] Manifestations of HAdV infection are often topically restricted to the eyes or the pharynx, but contiguous extension into the lungs can occur. A possible molecular mechanism facilitating spread of the virus over respiratory epithelia can be mediated by the fiber protein, which is synthesized in great abundance in the infected cells and binds to CAR on the basolateral surface upon release from lysed cells. This binding disrupts the CAR homodimers in tight junctions, thus increasing paracellular permeability.[612] This, in turn, allows the virus to escape onto the apical surface of the respiratory epithelium, thereby making it possible to infect other areas of the respiratory tract. While various HAdV types (e.g., HAdV-

C5) are mainly associated with upper respiratory tract infections, a few pneumotropic HAdV types (E4, B3, B7, B14p1) can cause severe lower respiratory tract infections like pneumonia and acute respiratory distress syndrome (ARDS), even in immunocompetent patients. The highly pathogenic HAdV-B14p1 virus was shown to infect differentiated human bronchial epithelial cells efficiently from the apical surface using the DSG2 receptor and to induce proinflammatory cytokines as potential virulence factors. Infectious virus progeny is also released via the apical surface, thereby promoting endobronchial dissemination of the infection from the upper to the lower respiratory tract.[383] Moreover, dissociation of the intercellular junctions by binding to DSG2 may facilitate spread of the virus locally and into deeper tissue layers, mediating access to the bloodstream.[711] The occurrence of systemic infection characterized by viremia, which is observed particularly in the immunocompromised patient setting, is discussed below. Since CAR is expressed on endothelial cells, viremia caused by HAdV types utilizing this receptor might be promoted by the fiber protein via the mechanism described above.[409,549] The successful use of oral, live, microencapsulated HAdV vaccines by the military to prevent ARDS suggests that, if the respiratory tract can be physically bypassed by the viruses, intestinal virus replication causes an immunizing rather than a virulent infection.[93,552] While some HAdV types including particularly F40 and F41 are a common cause of intestinal disease, various HAdV types can replicate in the intestine without causing gastroenteritis.

Tissue Tropism in the Host

The general affinity of HAdV species to individual tissues is outlined above, but members of the largest species D show particularly great variability in their tropism ranging from growth in ocular to GI and respiratory tissues.[288,362,561,706] Adenoviral keratoconjunctivitis, which is a major cause of ocular morbidity, is most commonly caused by representatives of species D, including types D8, D19, and D37, but can also be mediated by HAdV-E4, C5, B3, B7, B11, and B14.[437] GI manifestations are mainly associated with HAdV-F40 and F41, but G52 and different members of species D have also been observed.[307,422,437,452,453] Respiratory tract involvement has been associated mainly with HAdV-B3, B7, B16 and B21, E4, and various members of species C.[467] The knowledge about the basis of tissue tropism has been expanding,[386,565,623,637] and the indicated examples demonstrate that certain adenoviruses have a strong tropism to specific tissues. However, the same clinical manifestations can also be caused by other HAdV types and species, thus requiring diagnostic screening methods with broad specificity.

Chemical Defense and Immune Response

In the airways, the virus must penetrate the surface fluid, and sialic acid present in the mucus may bind and inhibit HAdV species D types that use sialic acid as a receptor.[499] The virus must also survive chemical defenses of the host. These include a large variety of antimicrobial peptides that are able to neutralize microbes directly. Among these peptides are the defensins, a family of small cationic amphipathic peptide molecules divided into two classes, α- and β-defensins.[234,252,720,721] The α-defensins HNP1 and HD5 were to shown to neutralize HAdV types of species A, B1, B2, C, and E but not species D and F.[627,628] The defensins bind HAdV particles outside the cell, block uncoating of the virion, and restrict the release of virions from endocytic vesicles.[627] Thousands of α-defensin molecules bind to sensitive virus types, and neutralization of the virus depends on binding to critical determinants in a region spanning the

fiber and penton base proteins. Binding to these determinants is proposed to prevent the release of fiber from the virion, the first step in the uncoating process within the endosome.[628] HNP1 is expressed primarily in neutrophils, monocytes, lymphocytes, and natural killer (NK) cells, while HD5 is expressed mainly by Paneth cells in the intestine.[234,253] The role of defensins in HAdV infections has recently been demonstrated in human enteroids representing a primary intestinal cell culture system, which indicated potent HAdV-type restricted neutralization by the enteric human alpha-defensin HD5.[254]

Similar to other viral infections, HAdV is controlled by innate and adaptive immune responses.[23,24,106,240,516,617] The first steps of immune response include the activation of a systemic proinflammatory state by the release of various cytokines, and the attraction of immune cells to the sites of infection.[23] Innate effector cells, particularly NK cells, which can destroy virus-infected cells in a nonspecific fashion, are recruited and activated.[69,240] Moreover, rapid secretion of antiviral cytokines such as IFNγ, TNF (tumor necrosis factor), IL (interleukin)-1, IL-2, and macrophage inflammatory proteins (MIPs) is triggered by HAdV and targets different steps in the viral life cycle, thereby limiting the amplification and spread of the virus. The presence of specific cytokine signatures was reported in pediatric SCT recipients with localized and invasive HAdV infection. Patients with invasive infections had increased levels of the proinflammatory cytokines IL-1β, IL-6, IL-8, IL-12, IFNγ, and TNFα. Simultaneous release of other cytokines associated with invasive HAdV infection includes also IL-17, IL-18, OSM, MIP1α, and IP10.[233] Induction of IL-6 and IL-8 does not require HAdV gene expression and likely occurs via interaction of the virion with integrins on the cell surface. Early proteins of HAdV derived from E1A, E1B, E3, and E4 as well as the virus-associated (VA) noncoding RNAs are able to antagonize innate immune responses of the host.[240] The E1A proteins block the assembly of IFN-induced transcription factors, and VA-I, a 159 nucleotide noncoding RNA, binds to the double-stranded RNA-dependent protein kinase R (PKR). This kinase mediates antiviral activity by attenuation of viral protein translation, and inhibition of the kinase by VA-I RNA enables HAdVs to evade this defense mechanism.[146,682,702] Moreover, HAdVs display different mechanisms enabling them to counteract the induction of type I IFNs (IFNα and β), which are an important part of the innate response to viral infection. For example, the HAdV-encoded E1B 55 kDa protein mediates transcriptional repression of IFN-inducible genes, thereby facilitating viral replication.[80] Another example includes the E3-19K transmembrane glycoprotein encoded in the E3 region, which is localized in the endoplasmic reticulum and binds to newly synthesized MHC (major histocompatibility complex) class I molecules. This leads to inhibition of intracellular transport and cell surface expression of class I molecules, thereby impairing antigen presentation to CD8+ cytotoxic T cells. In this way, HAdV-infected cells can evade recognition and T-cell attack. Furthermore, the E3 14.7K protein is a potent inhibitor of TNF-mediated apoptosis.

In addition to providing the first line of defense, the innate immune system supports proliferation and differentiation of the adaptive immune response mediated by T and B lymphocytes. The generation of HAdV-specific T cells facilitates lysis of infected cells by a perforin-dependent mechanism.[235] Although the large number of existing HAdV types implies that the expression of antigens representing potential T-cell targets can be expected to be highly polymorphic, T cells raised against HAdV, including the CD4 and CD8 subsets, were shown to display cross-reactivity against different adenoviral species.[398] These observations indicate that such T cells recognize conserved sequences of amino acid residues from a structural protein of

HAdV.[335] Although the HAdV-derived penton protein was identified as a relevant target of the anti-HAdV immune response, the hexon protein, which contains generic antigenic components common to all adenoviral species, has been regarded as one of the most important immunodominant T-cell targets.[600,669] Hence, HAdV exposure during the childhood and the ensuing generation of cross-reactive cytotoxic T cells is believed to lead to broad HAdV immunity in adults.[273] Neutralizing antibodies (see section on Key Antigens) are protective against disease manifestation in the previously infected host or against reinfection with the same HAdV type, but do not eliminate the carrier state.[170,664]

Healthy individuals usually carry HAdV-specific T cells, which can be identified by various methods, such as IFNγ secretion assays, cytokine flow cytometry, or MHC class I multimers.[195,600] The absence of HAdV-specific T cells has a negative impact on the course of HAdV infections, and conversely, reconstitution of HAdV-specific T-cell response correlates with viral clearance.[173,751] The findings that many CD4- or CD8-restricted hexon epitopes are shared among different species and types of the virus suggest that T cells with such specificities can be protective against most, if not all, HAdVs. This fact can be exploited for vaccine-based or adoptive T-cell transfer immunotherapy for treating HAdV infections, as outlined in the Therapy section below.[310]

Virulence

The emergence of novel HAdV types and strains can present with altered patterns of tropism and virulence. While the severity of HAdV-E4 infections in outbreaks appears to depend more on preexisting conditions in patients than on genetically determined viral virulence factors, the increased viral pathogenesis conveyed by HAdV-B7 has been attributed to a genetic change.[547] Studies performed in HAdV-B7 isolates from an outbreak among students in China revealed a mutation in the VA RNA gene associated with increased expression of the viral packaging protein L1 52/55K. This viral genetic change apparently mediated faster viral growth leading to increased clinical virulence.[740]

In addition to mutations, intraspecies and, less commonly, interspecies HAdV recombination increases the rate of molecular evolution, and results in novel HAdV types that could theoretically have increased viral fitness, altered cell tropism, and increased virulence. However, HAdV recombination often remains unnoticed because of the self-limited nature of the infections.[107] Mutations or recombinations resulting in a more pathogenic HAdV genotype causing outbreaks of more severe disease facilitate the identification of such genetic changes, as demonstrated for the emerging variant HAdV-B14p1.[15,548] It was shown that infection of primary human bronchial epithelial cells with HAdV-B14p1 resulted in increased expression of IP-10 and I-TAC, two proinflammatory chemokines implicated in ARDS, and the authors suggested that these molecules are potential virulence factors related to infection by this highly pneumotropic virus.[383]

In order to understand the reasons for increased transmission and the mechanisms of increased pathogenicity and virulence of outbreak strains, epidemiological and clinical studies must be coupled with appropriate research approaches. Sequencing and bioinformatics studies can assess viral genes and the encoded structural proteins that might result in altered sensitivity of the emerging virus to preexistent neutralizing antibodies in a given population and identify

potential mechanisms of altered biological properties.[107] Differences in the knob domain of the fiber gene and the L1 loop domain of the hexon gene have been implicated as determinants of tissue tropism and virulence in HAdVs. The fiber protein is of great importance for virus–cell interactions, thus explaining its importance as a virulence factor. Recent studies in an emerging, highly pathogenic fowl adenovirus confirmed the important role of fiber and hexon genes as determinants of virulence.[761]

Persistence and Latency

HAdVs are capable of establishing persistent infections, similar to herpesviruses and other viral species.[193,367,422,521,547,572] Due to their ability to enter different cell types via a number of receptors discussed above, persistence of HAdV infections has been reported for a variety of sites such as tonsillar or adenoidal T lymphocytes, lung epithelial cells, brain tissue, and, very importantly, intestinal lymphocytes, as addressed in more detail below.[366,367,422] A recent study reported the presence of persistent nonproductive HAdV infection with representatives of species C, B, and E in the majority of children with hypertrophic adenoids and palatine tonsils, while epithelial and subepithelial tonsillar cells seem to be critical for virus production and shedding in nasopharyngeal secretions.[532] Studies in a humanized mouse model suggested the presence of persistent cellular reservoirs in the bone marrow,[564] but this observation has not been confirmed in the human clinical setting. Attempts to model HAdV latency in different human lymphocyte cell lines using representatives of species C indicated permissiveness for HAdV infection in both T- and B-cell lines, and showed the ability to maintain the infected cell lines for long periods, with production of small amounts of infectious virus in two of the cell lines tested (BJAB, Ramos). Based on their observations, the authors concluded that quiescent viral genome could persist in nondividing lymphocytes indefinitely and, in dividing lymphocytes, the viral genome could persist by replicating sufficiently to compensate for loss due to dilution.[758] A study using human tonsil and adenoid tissues indicated that the presence of viral DNA from different HAdV-C types peaks at 4 years of age and declines thereafter. Viral DNA replication occurred in most donor samples by lymphocyte stimulation in culture, suggesting that HAdV-C types can establish latent infections in mucosal lymphocytes, and that stimulation of these cells can cause viral reactivation resulting in infectious virus production.[193] This notion was supported by a study in pediatric allogeneic SCT recipients suggesting that the observed HAdV-associated complications were attributable to reactivation of persistent virus rather than to infection *de novo*.[690]

Owing to their genetic heterogeneity, HAdVs display broad tissue tropism and can infect several cell types. Not surprisingly, therefore, currently available evidence indicates that they can persist in a latent state in a variety of susceptible cells following primary infection. Latency is characterized by expression of viral proteins by the host cell without replication of a complete virus. In addition to the persistence in tonsillar lymphocytes,[193,572] latent HAdV infections were described to occur in intestinal T lymphocytes and in lung epithelial cells, where they seem to play a role in the pathogenesis of obstructive airway disease.[249] Evidence for long-term HAdV persistence in the ocular surface following conjunctivitis has been provided,[333] and the central nervous system (CNS) was identified as a sanctuary for adenoviral persistence.[367] Importantly, the entire GI tract is a common location of HAdV persistence in children.[366] Other sites of HAdV persistence have also been suggested, but the experimental evidence is limited.[212,407,766]

Evasion from immune surveillance is a prerequisite for the establishment of persistent infections in permissive cells and tissues. Immune escape of adenoviruses can be mediated by different mechanisms. Specific viral proteins can block responses to anti-inflammatory and cytolytic cytokines, intrinsic cellular apoptosis, as well as innate and adaptive cellular immune responses.[590,723] Moreover, proteins encoded by the E3 region in the HAdV genome can protect infected cells from Fas ligand–induced apoptosis and from destruction by cytotoxic T cells. The T-cell attack is reduced or prevented by E3-mediated down-regulation of MHC class I molecules, thereby affecting antigen presentation.[222,415,462,503,533,603] Recent evidence indicates that the HAdV early genes required for viral replication can be repressed by IFN-mediated binding of E2F/Rb proteins to the E1A enhancer region, thus leading to inhibition of immediate early viral transcription. Both IFNα and IFNβ were demonstrated to suppress lytic viral replication and to promote persistent infection.[767] It is conceivable therefore that intrinsic IFN production provides the basis for the commonly observed establishment of HAdV persistence in lymphocytes.[192,193,362,366]

Persistence and Reactivation in the Gastrointestinal Tract

Rising Adenovirus Copy Numbers in Stool Precede Invasive Infection

Although different cells and tissues had been reported in the literature to carry persistent adenoviruses,[193,366,367,564,572] the notion that the GI tract is a very important site for persistence of these viruses has been considered common knowledge for many years, despite the fact that there was no direct evidence providing proof for this concept. More than a decade ago, screening data assessing the presence of HAdVs at different sites in pediatric transplant recipients revealed that patients who develop viremia test positive in stool samples before the virus becomes detectable in peripheral blood (PB).[424,425] This observation has stimulated a systematic study addressing the correlation of HAdV appearance and quantity in stool with the risk for invasive infection in children undergoing allogeneic SCT. The study included more than 130 pediatric transplant recipients and indicated that the observation of viremia is almost invariably preceded by HAdV positivity in serial stool specimens.[425] However, the proportion of patients with HAdV positivity in stool exceeded by far the percentage of patients who developed invasive infection (37% vs. 12% in the indicated study). Molecular analysis by a quantitative PCR-based approach covering the entire spectrum of HAdV types known at that time suggested that the kinetics, and ultimately the passing of a certain threshold of HAdV copy numbers in stool, permit the identification of patients at high risk for invasive infection. Rapidly increasing HAdV copy numbers exceeding the threshold of 10E6 copies/g of stool were shown to indicate a greater than 70% risk for viremia, while none of the patients displaying maximum HAdV copy numbers in stool below this threshold experienced viremia during the entire observation period.[425] The ability to differentially assess the risk for ensuing viremia by serial monitoring of stool samples, using the indicated threshold level of HAdV copy numbers, was statistically highly significant.[425] Very similar observations were subsequently made by several other investigators, thereby confirming the tight correlation between HAdV positivity in stool and subsequently in PB.[114,167,269,300,402,635] The virtually invariable presence of increasing virus levels in serial stool samples prior to invasive infection in the pediatric transplant setting indicated that the GI tract apparently serves as the most important compartment for HAdV expansion, and further

supported the notion of the intestine being the central site of HAdV persistence and reactivation in children.[369]

Adenoviruses Persist in Mucosal Lymphocytes and Replicate Effectively in Epithelial Cells

To investigate whether and where HAdV persistence might occur in the intestine, biopsy material derived from more than 140 largely immunocompetent children, who had undergone elective diagnostic endoscopy of the upper and lower GI tract for a variety of clinical indications, was investigated. Analysis by a pan-HAdV PCR assay indicated presence of the virus along the entire GI tract, with the highest prevalence in the ileum, in approximately one-third of the individuals tested[366] (Fig. 5.3). Analysis of the biopsy specimens by *in situ* hybridization or immunohistochemistry revealed virus signals in mucosal lymphocytes, while the epithelial cells in this cohort were essentially free of virus signals (Fig. 5.4A and C). When the same analyses were performed in pediatric transplant recipients with documented HAdV reactivation, who underwent diagnostic endoscopy for suspected intestinal graft versus host disease, *in situ* hybridization and immunohistochemistry performed on biopsy sections showed massive signal accumulation in the epithelial cells (Fig. 5.4B and D).[366] These studies provided the basis for a conceptual model suggesting that intestinal lymphocytes facilitate long-term persistence of the virus but do not provide an environment conducive for efficient viral replication, possibly due to their IFN production.[767] Rather, viruses leaking from these cells could enter and replicate in intestinal epithelial cells, and subsequently become detectable in stool. If the immune surveillance is severely impaired, HAdVs can massively expand in the entire intestinal epithelium, leading to rapidly rising virus copy numbers in stool. This concept is in line with the clinical observation of extremely high virus levels in the stool of pediatric transplant recipients, which can exceed 10E11 copies/g.[422,425]

Intestinal Adenovirus Persistence May Correlate With the Risk of Posttransplant Reactivation

The documented persistence of adenoviruses in lymphoid cells of the intestinal lamina propria in the pediatric setting may be related to the observation that primary exposure to these viruses

generally occurs already at a very young age.[269,366] The proportion of children displaying HAdV persistence in intestinal biopsies and the percentage of pediatric allogeneic SCT recipients showing viral reactivation during the posttransplant period were quite similar in the studies performed.[366,425] This observation supported the notion that HAdV persistence in the GI tract may directly correlate with the occurrence of virus reactivation in the intestine upon the onset of severe immunosuppression. Further support for this concept is provided by the fact that the distribution of HAdV species found in children with intestinal persistence of the virus was virtually identical to that observed in patients displaying reactivation after allogeneic SCT.[366]

By contrast, there is no evidence for intestinal HAdV persistence in adult individuals at the present time, and it is conceivable that the GI tract might not play a central role as the main site of HAdV reactivation and expansion in the adult immunocompromised setting. Although life-threatening invasive HAdV infections occur in adult SCT recipients (Table 5.2), they appear to be less frequent than in pediatric patients, and the main source of virus reactivation remains enigmatic.[423,653]

TABLE 5.2 Incidence and lethal outcome of HAdV viremia after SCT

Year	Reference	Adults		Children	
		Viremia % of Patients	Lethal Cases	Viremia % of Patients	Lethal Cases
2019	Ali et al.[12]			10.5%	4/19
2018	Fisher et al.[176]			26.2%	13/50
2017	Ramsay et al.[550]	1.5%	3/10		
2015	Feghoul et al.[167]			25%	7/18
2013	Hiwarkar et al.[244]			15%	n.r.
2012	Sive et al.[625]	12%	1/14		
2012	Taniguchi et al.[659]	9%	4/10		
2012	Watson et al.[716]			16%	2/7
2011	Öhrmalm et al.[502]	3%	0/2	15%	0/3

Intestinal Shedding of Adenoviruses Before Stem Cell Transplantation Is Prognostically Relevant

The documentation of intestinal HAdV persistence in a considerable proportion of children raised the question whether shedding of the virus into the stool commonly occurs already prior to the onset of severe immunosuppression related to pretransplant conditioning and, if so, whether it might have an impact on the occurrence of invasive infections during the posttransplant period. These questions were addressed by analyzing a cohort of more than 300 pediatric patients who underwent allogeneic SCT at a single center.[364] Intestinal HAdV shedding prior to

transplantation was documented in 14% of the individuals analyzed, and there was a highly significant correlation with ensuing HAdV-related complications in this subset of patients. Detection of HAdV positivity in stool before SCT correlated with a rapid rise of virus copy numbers very early posttransplant and a significantly more frequent occurrence of adenoviremia. The incidence of viremia within the first 100 days posttransplant in patients displaying HAdV positivity in stool prior to SCT, in comparison to individuals who tested negative for the virus before transplantation (33% vs. 7%), was statistically highly significant. Moreover, patients with pretransplant intestinal HAdV shedding developed adenoviremia already at early time points after allografting.[364] An early onset of invasive infection is clinically relevant, because it implies longer duration of systemic exposure to the virus, while the patients are still heavily immunosuppressed. From the therapeutic perspective, it implies the need to bridge a longer time period until immune reconstitution.[423] The apparent prognostic role of pretransplant intestinal HAdV shedding has led to pertinent recommendations for diagnostic monitoring (Table 5.3).

EPIDEMIOLOGY

Although adenoviruses in general are not mutually pathogenic across humans and animals, simian species were occasionally shown to display antibodies to human AdVs and antibodies to simian AdVs were detected in human sera, in line with the occurrence of anthropozoonosis and vice versa (see above).[158] Indeed, cross-species transmission of a novel simian AdV, causing a

lethal outbreak in a closed monkey colony, to a researcher who was in close contact with the animals has been described,[95] and other similar cases of anthropozoonosis could be documented.[99,717] There is substantial evidence indicating that AdVs have previously crossed host/species barriers and will continue to do so.[47] The high degree of asymptomatic shedding of live AdV in nonhuman primates and the evidence for zoonotic transmissions require caution in close interaction with such animals.[573] Similarly, season-independent respiratory or intestinal HAdV shedding by asymptomatic persons has been documented, and represents a source of infections by different routes.[42,267,362,743]

Most HAdV epidemics in immunocompetent individuals are observed in winter and early spring, but infections in immunocompromised patients occur throughout the year.[289,471,615,741,764] Epidemiological data indicate that the majority of primary HAdV infections occur during the first 5 years of life due to the lack of humoral immunity. In children, HAdV infections account for up to 15% of upper respiratory tract and about 5% of lower respiratory tract inflammatory diseases.[258] In immunocompetent individuals, the infections are mostly mild and self-limiting, but severe and even fatal courses have been reported, as specified below.[70,585,620]

HAdV infections are readily spread within human populations, and outbreaks have been described in crowded settings including medical facilities, such as hospitals and nursing homes,[55,324,580,710] military bases,[320,510,566] and schools.[36] The HAdVs-associated outbreaks can cause GI disease,[506] pharyngoconjunctival fever,[410] febrile respiratory illness,[746] and/or keratoconjunctivitis.[166,201,414] Individuals infected with HAdV are extremely contagious during the incubation period, which typically ranges from 4 to 8 days but can last up to 24 days, depending on the HAdV type involved.[422] The HAdV types commonly linked to outbreaks include HAdV-B3, E4, B7, D8, B14, and B55, and these viruses are regarded as more virulent and likely to spread.[70,196,223,340,382,438,541,597,733] The predominant HAdV types detected in association with disease differ among different geographic regions and countries and change over time by spreading across continents and replacing hitherto dominant strains, as documented by the abundance of globally occurring outbreaks.[111,438,652,760]

Transmission

Transmission can occur from an infected person to other individuals via respiratory routes, fecal–oral contamination, and/or direct contact, such as shaking hands. Respiratory transmission via coughing or sneezing is a predominant mode of transmission, but fecal–oral transmission can occur through contaminated food or water, including for example, public swimming pools due to ineffective chlorine treatment[46] (see also section Stability and Inactivation). Hence, infections in the immunocompetent host are typically caused by exposure to infected individuals via inhalation of aerosolized droplets or direct conjunctival inoculation, but transmission may also occur by fecal–oral spread including recreational freshwater or tap water, contact with infected tissue, airflow filters, contaminated fomites, or environmental surfaces, due to the stability of HAdVs in the environment.[406,410,574,630,710,769]

Although exogenous infection by nosocomial or community acquisition in the inpatient setting is a rather rare cause of HAdV-related diseases, outbreaks of infections on hematology or transplant wards as well as in eye clinics resulting in closures have been

documented.[77,377,384,457,482,507] Many reports described HAdV spread via local outbreaks in common areas, such as camps, playgrounds, dormitories, and schools.[89,238,280,414,763] Appropriate control measures, including frequent hand washing, sanitizing surfaces, staying at home when ill, avoiding close contact with people who are sick, and covering nose and mouth when sneezing or coughing, may therefore be pertinent to minimize the transmission of HAdV infections and prevent outbreaks.[111]

The transmission dynamics and the high levels of morbidity caused by HAdV infections in military camps have been documented by various investigators.[41,317] Interestingly, HAdV infections do not commonly spread to civilian personnel in contact with the military, and HAdV-related acute respiratory disease (ARD) was far less frequent in similarly congregated college students, suggesting that additional factors affecting young recruits, such as more crowded sleeping conditions or the fatigue associated with basic training, could be factors contributing to the pronounced morbidity in this setting. A study performed in military recruits after discontinuation of the vaccination program, which lasted more than a decade (1999–2011), revealed an increase in the percentage of soldiers seropositive for HAdV-E4 from 34% at enrollment to 97% by the end of the study. Potential sources of HAdV transmission included the presence of virus on surfaces in living quarters, including pillows, lockers, and rifles as well as extended pharyngeal viral shedding over the course of several days. The introduction of recruits, who were still shedding adenovirus, into new training groups was also documented.[574] Because of the crowded setting in military living quarters and easy transmission of infections, vaccination against the most prevalent HAdV types E4, B7, and B14 in military recruits has been highly recommended and reintroduced in 2011[54,318,320] (see section Vaccine).

Prevalence of HAdV Species and Types

Most HAdV species appear to circulate globally, but predominant types differ between countries or geographic regions and change over time.[14,219,318,337,343,417_419,496,615,739,757] Transmission of new strains across continents may occur and lead to replacement of hitherto dominant HAdV types.[319] The adenoviruses reported to be most commonly associated with human disease worldwide are HAdV-C1, C2, C5, B3, B7, B21, E4, and F41,[13,20,33,90,437,543,741,760,764] with great predominance of the HAdV types F41 and F40 in patients with gastroenteritis.[29,376,413,540]

Epidemic forms of HAdV-related disease involving primarily types E4 and B7 have been extensively described in military recruits, including also recent reports on outbreaks,[36,358] but the reintroduction of vaccination programs has greatly improved the situation (see section Vaccines).

In immunocompromised patients in the transplant setting, some of the most commonly reported adenovirus types include HAdV-C1, C2, C5, A12, A31, B3, B11, B16, B34, and B35, with strong predominance of species C in most but not all instances.[328,425,461,486,534] Transplant centers from different geographic regions reported a prevalence of HAdV species C in the range of 80% of all adenoviral infections observed.[150,372,422,424,425] Sequential or concomitant coinfections with different adenoviruses from the same or from different species are quite commonly observed both in the immunocompetent and immunocompromised patient settings[206,379,654] (Figs. 5.5 and 5.6), and may thus play a role in the generation of recombinant HAdV types.

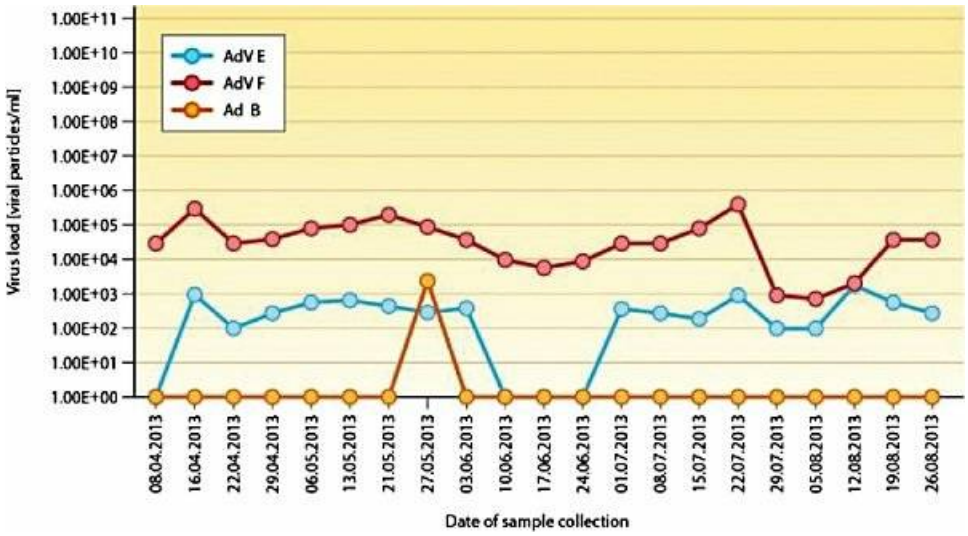

FIGURE 5.5 Adenoviremia with multiple HAdV species. Different HAdV types or species can be detected in peripheral blood and/or other sites, both concomitantly and sequentially. The example displayed shows a rare constellation with invasive infection associated with HAdV species E, F, and occasionally B, during the posttransplant course (*x*-axis) of a pediatric patient. This observation highlights the fact that very unusual findings are possible, which must be accounted for by the implementation of appropriate diagnostic techniques for HAdV detection and monitoring. The *y*-axis indicates the virus copy number per mL of blood determined by real-time PCR. (Reprinted from Lion T. Adenovirus infections in immunocompetent and immunocompromised patients. *Clin Microbiol Rev* 2014;27(3):441–462. Ref.[422])

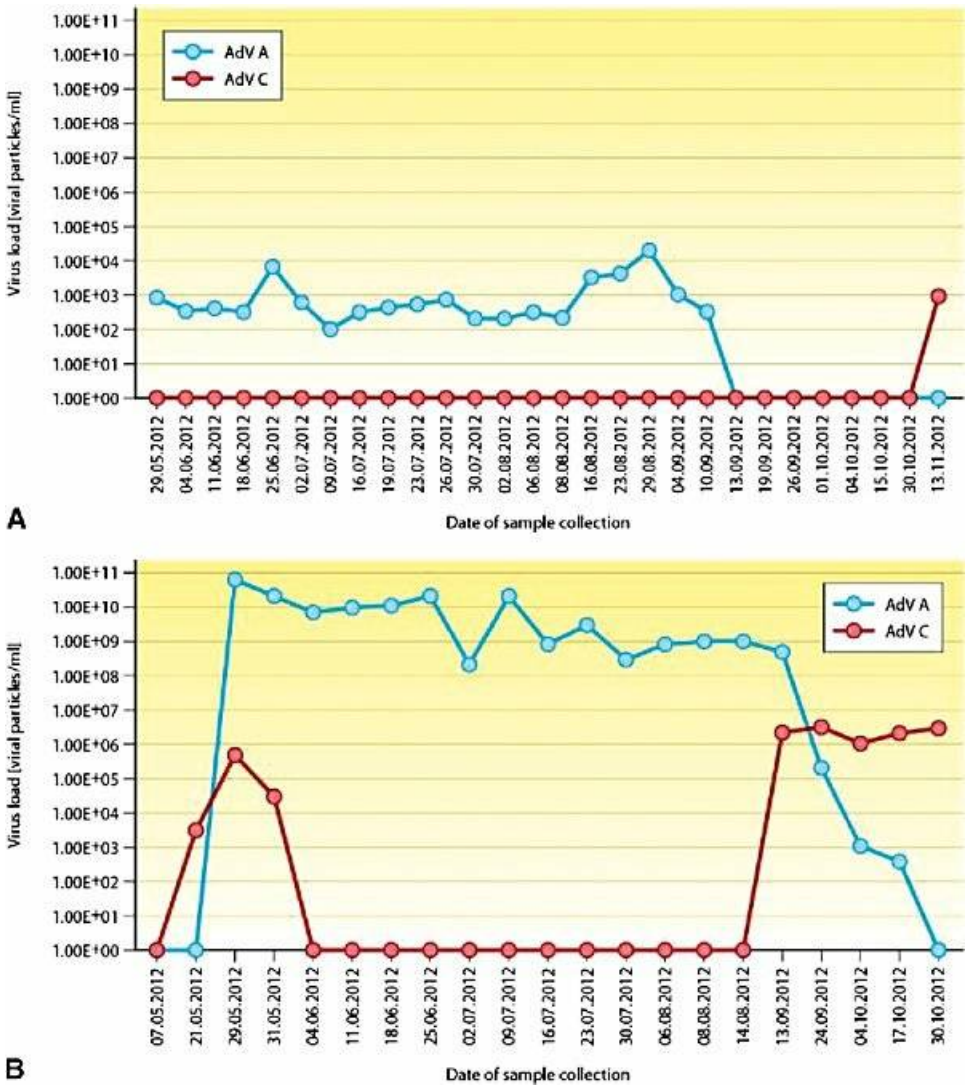

FIGURE 5.6 Course of adenoviremia with switch of HAdV species A to C. Kinetics of HAdV viremia during the posttransplant course in a pediatric patient revealing disappearance of DNAemia caused by HAdV species A below the detection level of real-time PCR, and recurrence of HAdV positivity in peripheral blood after about 6 weeks of negative PCR findings with HAdV species C **(A)**. The switch observed in peripheral blood was preceded by corresponding kinetics of HAdV viral loads in serial stool specimens **(B)**. (Reprinted from Lion T. Adenovirus infections in immunocompetent and immunocompromised patients. *Clin Microbiol Rev* 2014;27(3):441–462. Ref.[422])

Serological surveys have provided estimates for the prevalence of specific HAdV infections. Neutralizing antibodies against HAdV-C5 were found in the great majority (>70% to 100%) of the populations in Sub-Saharan Africa, Northern India, Thailand, China, and Brazil, while the indicated prevalence in Japan, Europe and the United States was somewhat lower (40% to 70%).[32,94,144,158,296,451,522,648,663] Neutralizing antibodies against HAdV-C6, which has been evaluated as an alternative vaccine vector, have been identified in about half of subjects tested,

but the titers were mostly low.[34,451] A study performed in the United States found a seroprevalence of HAdV-C2 of greater than 80%.[22] Seroprevalence studies have also been conducted for less common HAdV types, also to assess their potential exploitability as vectors, and provided variable results in different geographic regions. For example, antibodies against HAdV-B35 were found at low frequencies (0% to 10%) in Europe and the United States, a somewhat higher (<20%) prevalence was detected in Japan, Thailand, and Sub-Saharan Africa,[22,32] and the findings for HAdV-B11 revealed a seroprevalence of 10% to 30% in sub-Saharan Africa and Japan.[255,663] For HAdV-D26 and D28, the seroprevalence in the United States was determined to be ≤10% with low titers, but the percentage for D26 was considerably higher in countries such as Brazil or Thailand, and reached 60% to 80% in sub-Saharan Africa.[32,94,158,312,451] The indicated examples highlight the regional differences in the seroprevalence of specific HAdVs, possibly affecting the broad applicability of vectors based on individual HAdV types. It should be noted that the serological studies described above refer primarily to neutralizing antibodies, and the total prevalence of HAdV antibodies is higher. Further, a very high proportion of adult humans carry HAdV-specific T cells, including primarily $CD4^+$ but also $CD8^+$ subsets, which appear to display broad reactivity due to cross-reactive (often hexon-derived) epitopes.[61,94,274]

Stability and Inactivation of Adenovirus

As nonenveloped viruses with a well-organized capsid and a double-stranded DNA genome, HAdVs are expected to be stable. They can survive for long time periods in liquid and have been identified as the most prevalent enteric viruses in environmental waters worldwide.[523] They also remain stable on surfaces in a desiccated state and can retain their infectious properties even after several weeks in moisture-free environments. It was shown that HAdV titers are not lost after shipment of simulated conjunctival samples to a reference laboratory, even after several days at ambient temperatures.[567] The stability of the virus at low pH is a matter of debate, but HAdVs are resistant to gastric and biliary secretions and can therefore be detected at high loads in feces.[454]

The long-term stability of HAdVs in surface and ground water is well recognized,[556] and a study on the prevalence and quantity of HAdV in drinking water and river water in South Africa revealed presence of the virus in greater than 5% of drinking water samples, with predominance of HAdV species D, and in greater than 20% of river water samples, with predominance of enteric types of the virus.[684] Urban wastewaters in Italy were shown to commonly contain different HAdV types including mostly F41, and considerably less often the types B3, A12, and C5, with implications for waterborne HAdV–related health risks.[277] Adenoviruses were also identified in recreational waters in Brazil including freshwater and sea beaches, with common detection of viable HAdV species C and F.[197,199,215] Similar findings were also made in a number of other geographic areas.[5,263,309,359,439]

The risks of infection in swimming pool water were recently reviewed.[46] Based on the observation that HAdVs are the most UV-resistant viruses, their detection has become a key indicator of water quality, and environmental protection agencies and water-treatment companies are developing and employing protocols for adequate detection and elimination of adenoviral contamination in water sources and systems.[153,164,242,647]

As nonenveloped viruses, HAdVs are resistant to many disinfectants. Effective decontamination of surfaces and equipment is of paramount importance, particularly in transplant and intensive care units to prevent this mode of transmission in immunosuppressed patients.[62] A study addressing the efficacy of germicides examined 21 different products for their ability to inactivate HAdV-D8 and concluded that the disinfectants to be used for effective environmental surface disinfection may include products providing approximately 1,900 parts per million (ppm) available free chlorine, 65% ethanol with 0.63% quaternary ammonium compound (QAC), 79.6% ethanol with 0.1% QAC, or 70% ethanol. These disinfectants should be allowed to contact all environmental surfaces for at least 1 minute.[575] For disinfecting ophthalmological equipment, the authors recommend 70% ethanol or approximately 5,000 ppm chlorine. High-level disinfectants such as 0.55% *ortho*-phthaldehyde, ≥2.4% glutaraldehyde, or 0.2% peracetic acid (PAA) may also be used, but equipment must be compatible and rinsed thoroughly.[575] The virus-inactivating properties of different surface disinfectants including PAA-based, QAC-based, and 2-propanol-based products have recently been tested, and the virucidal efficacy of the PAA-based wipe was deemed most efficient.[37] Moreover, potassium peroxymonosulfate has been successfully evaluated as a disinfectant for prevention of EKC acquired by nosocomial infections in ophthalmological clinics.[230]

A number of studies have employed ultraviolet light to inactivate microbial pathogens including HAdV.[191,408,539] Photochemical treatment (PCT) has also been used to prevent transfusion-transmitted disease resulting from viral contamination. The photosensitizing compound 8-Methoxypsoralen (8-MOP) combined with long-wavelength ultraviolet irradiation (UVA) inactivates many viruses, but toxicity limits its use in animals and humans. The toxicological and photosensitizing properties of riboflavin (vitamin B2) make it suitable for virus inactivation in preparations for biological use.[63] The combination of amotosalen-HCl and UVA for cross-linking of pathogen-derived DNA has also been successfully used to inactivate a wide range of pathogens including viruses in platelet concentrates and other blood products.[416,484,584,622] A system based on using the frangible anchor linker effector (FRALE) compound amustaline (S-303) with labile alkylating activity revealed a robust pathogen reduction profile, permitting efficient elimination of HAdV titers (by 5-logs) in whole blood products.[53,67,481] Ultraviolet light–based inactivation of enteric adenoviruses was also shown to be feasible in water, although HAdV-F species are among the most UV-resistant water-borne viruses.[138,539]

Ozone is a powerful disinfectant against all types of waterborne pathogens, including viruses, and was shown to be also effective against HAdV when applied in water and wastewater.[728] Moreover, the virucidal potential of gamma radiation against HAdV may be exploited for disinfection treatment of sustainable water supplies or polluted waters.[523,524] Chlorine is, however, the most widely used disinfection product for water,[200,313,490] and the required chlorination doses for disinfection of water from enteric viruses, including HAdV, have been recently reviewed.[544] However, chlorine-based disinfection can produce toxic by-products, rendering the search for alternative agents a relevant task. In this context, various natural and synthetic compounds including *N*-chlorotaurine (NCT), bromamine-T (BAT), and grape seed extract (GSE) were recently tested for inactivation of HAdV in water, and showed promising results.[190]

CLINICAL FEATURES

HAdVs were initially isolated mainly from military recruits with acute febrile respiratory disease, and were subsequently associated with a number of clinical manifestations including upper and lower respiratory tract infections, keratoconjunctivitis, gastroenteritis, cystitis, meningoencephalitis, myocarditis, and hepatitis but also with noninflammatory conditions such as obesity.[97,121,160,437,447] HAdV infections are readily transmittable and in some instances highly contagious. Although the clinical courses are usually mild and self-limiting, infections may cause local outbreaks with severe courses, occasionally leading to lethal outcomes even in immunocompetent individuals.[10,40,92,585] However, adenoviruses play a particularly important role in patients with strongly impaired immune response, where viral disease is associated with high morbidity and mortality, and infections in this setting are an important focus of the present chapter.

HAdVs can commonly infect and replicate at various sites of the respiratory tract as well as in the eye and the GI tract. Less frequently, HAdVs can infect the urinary bladder, the liver, and occasionally the pancreas, the myocardium, or the CNS. Many HAdV infections are subclinical and result in antibody formation conveying protection against exogenous reintroduction of the same HAdV type. Common illnesses associated with various HAdVs are described in the following paragraphs. It is important to bear in mind, however, that detection of HAdV in clinical specimens does not necessarily imply a cause and effect relationship with the disease, particularly when highly sensitive molecular detection methods are used, and screening is restricted to a limited number of common viral pathogens.

Respiratory Diseases

Endemic Adenovirus Infections in Young Children

About 7% of upper respiratory tract infection cases in children below 5 years of age are attributable to HAdV.[292,515] The usual symptoms include nasal congestion, coryza, and cough. Other patients may have an exudative tonsillitis that may be clinically indistinguishable from disease caused by streptococcus A infection. The respiratory symptoms are often accompanied by systemic manifestations, such as generalized malaise, fever, chills, myalgia, and headache. Commonly observed types of the virus include HAdV-C1, C2, C5, and C6, and less frequently B3 and B7, which are endemic in most populations.[31,64,161,337,412,489,632,713,736,764] Sporadic cases may reveal symptoms indiscernible from other viral respiratory infections, such as influenza, parainfluenza, or respiratory syncytial virus.[515] If conjunctivitis accompanies the signs and symptoms already described, the disease is designated as *pharyngoconjunctival fever*, most commonly associated with HAdV types B3, B7, and B14. HAdVs also cause lower respiratory tract infections in children, and are probably responsible for about 10% of pneumonias in the pediatric setting.[516] Moreover, HAdVs were identified as the most common pathogens associated with a pertussis-like syndrome, and coinfections by *Bordetella pertussis* were identified in a proportion of patients.[442,576]

Acute Respiratory Disease in Adults

In adults, HAdV types from subspecies B1, including B3, B7, B16, B21, and B50, as well as HAdV-E4, are commonly associated with ARD, whereas representatives of subspecies B2, including B11, B14, B34, and B35, have been more frequently associated with urinary tract and opportunistic infections in immunocompromised patients.[611] Without significant circulation in North America, HAdV-B14 emerged as a significant cause of acute and sometimes severe ARD in 2006 and was subsequently characterized by genomic and bioinformatic analysis.[606] Initially, the infection was recognized in three military bases under continuous systematic surveillance,[468] but widespread outbreaks associated with several deaths were demonstrated thereafter in North America and several other geographic areas.[70,75,76,159,262,319,469] The only unique characteristic identified in the HAdV-B14p1 variant implicated in several documented outbreaks was a deletion of two amino acids in the knob region of the fiber protein.[319] Low antibody titers against HAdV-B14 in recruits sampled at admission to training camp and initial detection of HAdV-14p1 in cities on the US West Coast, which represent major ports of entry into the country from Asia, suggest that travel and commerce played a major role in the introduction of this HAdV variant into the United States.[319] Older age, chronic underlying condition, low absolute lymphocyte counts, and elevated creatinine levels were associated with severe illness. In most instances, no epidemiological link could be established between individual cases.[159] Adenoviral pneumonia can present with severe radiological findings,[79,511,657] and has been associated particularly with the HAdV-B types including B3, B7, B14, B21, B55, HAdV-C types C1, C2, C5, and HAdV-E4.[76,90,317,318,597,658,762] A number of reports on HAdV-associated respiratory disease with severe courses and sometimes fatal outcome have been recently published.[74,198,762]

Acute Respiratory Disease in Military Recruits

In many respects, ARD is similar to the description of respiratory infection in children. The syndrome was predominantly associated with HAdV-E4 (92.8% in a study conducted 2004–2006),[206] and less commonly with HAdV-B7. After 2005, coincidently with similar findings in civilian populations, simultaneous emergence of diverse infections attributable to HAdV-B3, B7, B14, and B21 was observed.[468] Some cases of ARD in young military recruits had a fatal outcome related to the pneumonitis that may accompany and complicate other, milder, respiratory symptoms. A significant increase in severe and fatal cases was observed upon emergence of HAdV-B14 infections in US military facilities,[468,495] but the prominent role of this HAdV type could not be confirmed by another study in US military recruits with HAdV-associated pneumonia.[691] Further aspects of this disease are discussed in the sections Epidemiology and Vaccines. In recent studies, HAdV was shown to be the most common viral pathogen identified in Korean military hospitals in soldiers displaying pneumonia, with the highest prevalence of HAdV-B55 and HAdV-E4.[241,358]

Ocular Infections

EKC is a major cause of ocular morbidity in developed and developing countries, and no efficacious therapeutic options are currently available. Epidemiologically, ocular infections can occur sporadically or affect large groups of contacts. When the source of infection is recreational water, the number of affected individuals may be high. The incubation period of EKC ranges

from 2 days to 2 weeks. Patients are contagious after the onset of symptoms and for up to 2 weeks thereafter.[352] The infection presents as follicular conjunctivitis with edema of the eyelids, pain, lacrimation, and photophobia, often followed by corneal subepithelial infiltrates. The infection is often unilateral with hypertrophy of the draining preauricular lymph nodes, but may be associated with multiple lymph node involvement and symptoms of systemic infection, with flu-like symptoms such as myalgia and fever. It can lead to the development of corneal opacities, blurred vision, and other sequelae, which can persist for months or even years. The infection is highly contagious and responsible for outbreaks around the globe, highlighting the importance of accurate diagnosis and rapid containment. The infection has been associated with various HAdV-D types including particularly D8, D37, and D64 (previously designated as 19a), and the recombinant types D53, D54, and D56 were recently identified by molecular typing strategies as emerging etiologic agents of EKC infections worldwide. Recombination events among circulating HAdV-D types represent a source of new infectious disease threats, and the growing number of HAdV types permitted genomic and phenotypic analyses to determine EKC-related pathological properties.[202,287,305]

In a recent study on HAdV-positive EKC patients, species D was most common (63% of the cases), but as many as four species including also HAdV-B, E, and C, and a total of 21 different types were detected.[392] The findings are largely in line with an earlier study that revealed the presence of HAdV-B3 and B7, HAdV-E4, and HAdV-C2 in addition to a variety of HAdV-D types.[763] Differential diagnosis and discrimination from infections by other agents, such as *Chlamydia trachomatis*, HSV1 (herpes simplex virus), EV70 (Enterovirus 70), or CVA24v (Coxsackievirus group type A24) can be difficult.[326]

Recent observations suggest that distinct innate immune responses to HAdV infection of the conjunctiva and cornea involving, for example, NK cells and IFN type 1 may be mediated by stimulation of specific pattern recognition receptors dependent on the cell entry and trafficking. While it was generally believed that HAdVs enter host cells via dynamin-dependent, clathrin-mediated endocytosis before trafficking along microtubules to the nucleus for replication, recent data revealed that the viruses utilize a variety of entry mechanisms, including macropinocytosis and caveolin-mediated pathways. The specific mechanism of entry appears to depend largely on the specific pairing of cell and virus type, and multiple pathways can be exploited. Novel insights into ocular surface immunology may provide the basis for therapies manipulating immune responses to infection with the aim of improving clinical outcomes.[86_88,98,516]

Hemorrhagic Cystitis

Hemorrhagic cystitis (HC) is a significant cause of morbidity and occasionally even mortality in SCT or organ transplant recipients. The reported incidences range from 6% to 30% in patients undergoing SCT, and are related to the use of chemotherapeutic agents, such as cyclophosphamide or busulfan, or to viral infections involving the human polyomaviruses BKV and JCV, HAdVs, and rarely other viral pathogens. Clinical manifestations of HC include microscopic to gross hematuria with clot formation that can lead to urinary tract obstruction and sometimes renal failure.[477] Infections involving HAdVs were reported to account for 3.9% and 9.8% of HC cases among pediatric and adult HCT recipients, respectively,[204,477] involving particularly different HAdV-B types, such as B7, B11, B21, B34, B35, and less commonly other HAdV species and types.[182] Transplanting organs from HAdV-seropositive donors to

seronegative recipients appears to be a potential risk factor for severe disease, and donor-transmitted infection in kidney transplant recipients has been associated with HC, allograft tubulointerstitial nephritis and graft loss. Moreover, disseminated HAdV infections with fatal outcome have been described in renal transplant recipients.[182,371,688] Rising HAdV levels detected by PCR screening in peripheral blood and urine correlate with HC, but no clear threshold for diagnosis could be established.[355] Standardized monitoring and treatment of HAdV infections in the organ transplant setting has not been established, and the treatment modalities employed include supportive care measures such as hyperhydration, forced diuresis, continuous bladder irrigation, and/or blood transfusions.[477] In patients not responding to reduction of immunosuppression, cidofovir is commonly used for treatment of HAdV-related disease, although evidence provided by randomized clinical trials is missing.[182]

Meningoencephalitis

Although HAdV has been recognized as a relevant viral pathogen implicated in neurological diseases, particularly in immunocompromised patients, it has been rarely observed in infectious syndromes of the CNS.[121,520,693] In immunocompetent individuals, including particularly children, HAdVs are a rare cause of CNS disease. The disease spectrum is variable, ranging from mild aseptic meningitis and fully reversible encephalopathy to severe, potentially fatal, acute necrotizing encephalopathy.[577,596] The HAdV species and types isolated from cerebrospinal fluid (CSF) in patients with CNS infections were quite diverse. Reported cases include HAdV-A31, B3, B7, C2, D26, and D49.[143,186] Moreover, HAdV-F41 was identified in a recently published case of neonatal meningoencephalitis.[656] Presentations of HAdV infections as isolated CNS disease involving species C and D, without detectable viremia, were documented in two children after SCT.[186] Cidofovir infusions (5 mg/kg weekly) were administered with concomitant reduction of the immunosuppressive treatment, and this regimen was successful in one of the patients. It is necessary to bear in mind, however, that intravenously administered cidofovir does not seem to cross the blood–brain barrier efficiently.[186] HAdV-related meningoencephalitis appears to be a rare event, which is not associated with typical clinical or radiological signs. Because of the severity of such infections, systematic PCR-based HAdV-screening in the CSF is required in cases of unexplained neurological symptoms in severely immunocompromised patients, even if PCR testing of blood samples remains negative.[186]

Gastrointestinal Diseases

Diarrhea is a major cause of death in the pediatric population worldwide, particularly among children below five, and even more so below 2 years of age, affecting mainly low- and middle-income countries.[43,428,540,703] Infections by viruses play a leading role, and a variety of viral pathogens have been implicated in gastroenteritis, including rotavirus, norovirus, adenovirus, sapovirus, astrovirus, parechovirus, and bocavirus, which occurred alone or in combination, involving both viral and bacterial pathogens.[4,82,108,268,301,339] In most studies, rotavirus and norovirus predominated, while HAdVs accounted for less than 1% to 30% of pediatric cases of acute diarrhea, often accompanied by vomiting and fever.[4,82,105,376,381,429,530] The adenoviruses most commonly observed in fecal specimens of patients with gastroenteritis across many studies were HAdV-F40 and F41, which are therefore referred to as enteric

HAdVs,[29,105,376,381,479,530,636] but the variety of HAdV species and types reported in this clinical setting is very high, including HAdV-A types 12, 18, 31, and 61; HAdV-B types 3, 7, 11, 14, 16, and 21; HAdV-C types 1, 2, 5, and 6; HAdV-D types 8 to 10, 19, 26, 28, 29, 30, 32, 37, 43 to 46, 64, and 70; and HAdV-G52.[4,113,307,376,381,429,479,530,540] Some geographic regions such as Sub-Saharan Africa appear to have a very high prevalence and diversity of HAdV-D types associated with various infections including gastroenteritis, and subclinical infections with prolonged shedding have been documented, particularly in immunocompromised hosts.[514] Seasonal distribution of HAdV infections remains a controversial topic. The reported seasonal peaks of HAdV infections varied depending on the geographical region and weather patterns of the country. A number of studies, including some of those cited above, reported a seasonal occurrence of GI HAdV infections (e.g., during the rainy season), but others did not identify any seasonal distribution pattern,[127,128,376,636] and long-term intestinal HAdV shedding is known to occur also in asymptomatic children.[422,425,479] The clinical importance of HAdV shedding in the context of allogeneic SCT is discussed below. One of the complications occurring in patients with GI HAdV infections is intussusception, a condition caused by a segment of the intestine invaginating into an adjacent segment. The classical clinical symptoms include intermittent abdominal pain, currant jelly stool, palpable mass and vomiting. The resulting small bowel obstruction, which may ultimately lead to necrosis, perforation, and sepsis, is a life-threatening complication. There are several, also recent, reports on the association of HAdV-related gastroenteritis as a trigger of intussusception, but this condition is likely to be multifactorial.[60,295,348,394]

Celiac Disease

Infectious agents have been implicated in the pathogenesis of many autoimmune diseases. Celiac disease (CD) is an autoimmune disorder affecting patients with a specific genetic predisposition (HLA-DQ2, HLA-DQ8) who are exposed to gluten, the major storage protein of wheat and similar grains. An environmental factor, such as an infectious agent, is thought to precipitate the disease via various pathogenic mechanisms, such as molecular mimicry, resulting in modulation of the host's immune tolerance.[526] It has been shown that partial amino acid sequence homology between alpha-gliadin, a component of gluten, and an early region protein (E1B-58 kDa) of HAdV-A12 results in immunological cross-reaction. This led to the proposal that prior infection by HAdV-A12 could be associated with the development of CD, possibly by immunological cross-reactivity between antigenic determinants shared by the viral protein and alpha-gliadins.[311] However, the results of an ensuing study suggested that persistent HAdV-A12 infection is not a major component in the pathogenesis of CD.[443] By contrast, the only prospective study on CD and viral infection indicated that frequent rotavirus infections might increase the risk of development of CD antibodies in a cohort at high risk,[640] while other studies with retrospective designs have studied adenovirus, enterovirus, and orthoreovirus as potential triggers of CD with conflicting or inconclusive results.[49,311,443] A recent study revealed that frequent exposure to enterovirus during early childhood was associated with increased risk of CD, suggesting that the interaction between enteroviruses and higher gluten intake may lead to a cumulative effect of these factors in CD development.[421] These observations were confirmed in another recent longitudinal study, which indicated that a higher frequency of enterovirus, but not adenovirus, during early childhood was associated with later CD.[314]

Myocarditis

Myocarditis is an inflammatory disease of the cardiac muscle tissue caused by myocardial infiltration of immunocompetent cells following different kinds of cardiac injury. Infectious causes include a variety of microorganisms including many different viruses, bacteria, protozoa, or fungi, but most frequently the myocardial inflammatory process is directed against viral pathogens.[17,38,458,678,685] The viruses most commonly associated with myocarditis were enteroviruses (EV), such as coxsackieviruses A and B, echovirus, and poliovirus, but during the past decades, a shift was observed to parvovirus B19 (B19V) and human herpesvirus 6 (HHV6) as the most frequently detected cardiotropic viruses in endomyocardial biopsies (EMBs).[125,685,692] Nevertheless, other herpesviruses including CMV and EBV also play a role in this clinical context,[17,125] and prominent involvement of adenoviruses in myocarditis is well established, particularly in children.[585] Coinfections with different viruses have been reported to occur in 12% of acute myocarditis cases.[17] Various studies indicated a prevalence of HAdV in EMB analyzed by PCR in 0% to 23% of patients with acute viral myocarditis.[38,50,125,614] A study based on EMB in pediatric heart transplant patients revealed HAdV genome presence in 9.6% of patients, and viral sequences detectable by PCR were associated with decreased graft survival.[478]

The diagnosis can be challenging, because various clinical methods including imaging techniques can be misleading if infectious agents are involved. Accurate diagnosis requires simultaneous histological, immunohistochemical, and molecular biological workup of the tissue, with strong reliance on EMB-based tools as the gold standard.[17,38,374,554] However, a significant limitation of cardiac biopsy is the observation that the myocardium may be affected in a patchy fashion, thus hampering the exclusion of myocarditis by negative biopsy results.[228]

In addition to supportive care, patients with active myocarditis can receive immunosuppressive treatment upon exclusion of viral persistence in the myocardium, but immunosuppression is contraindicated in EV- or HAdV-positive patients.[66,685] Other treatment approaches include immunomodulation by IFNβ, immunoglobulins, and the anti-inflammatory compounds colchicine and canakinumab.[38,685] Moreover, inhibiting the pro-inflammatory cytokine IL-1 (interleukin-1) by blocking the IL-1 receptor with the naturally occurring compound anakinra was demonstrated to be effective against both myocardial inflammation and contractile dysfunction, and was shown to be suitable for treatment of critically ill myocarditis patients.[72,73] Another immunomodulatory approach relying on the use of adoptive regulatory T-cell transfer was shown to improve coxsackievirus B3–induced myocarditis, and mesenchymal stromal cells (MSCs) were demonstrated to be cardioprotective in myocarditis induced by this viral pathogen, by suppressing inflammasome activation in experimental models.[472,509]

Hepatitis

The liver is one of the organs that can be severely affected by HAdV infections in immunocompromised individuals, including particularly pediatric liver transplant or allogeneic SCT recipients, and patients with malignant disorders receiving chemotherapy. In patients with HAdV-associated hepatitis, histological sections of biopsies revealed localized or massive hepatocyte necrosis, often with absence of associated inflammation. The clinical courses can be fulminant, resulting in acute liver failure with high mortality.[512,570,587]

Adenovirus Infections During Pregnancy

A report on the occurrence of hydrops fetalis and fetal tachyarrhythmia associated with intrauterine HAdV infection documented by PCR in a preterm baby[551] sparked the question whether the virus needs to be regarded a fetal pathogen. This notion was assessed by a prospective observational study indicating that echogenic liver lesions with or without hydrops and neural tube defects were significantly more common in the presence of HAdV detectable by PCR in amniotic fluid. The prevalence and seasonal variation of HAdV detection was similar in sonographically normal and abnormal pregnancies, thus raising questions regarding the significance of these findings.[35] Another study addressing the prevalence of virus isolation in amniotic fluid samples revealed HAdV in 1.3% of fetuses with anomalies, while structurally normal fetuses did not show any evidence for this virus.[519] Asymptomatic fetal viral infection in amniotic fluid tested after the second trimester of pregnancy did not increase the risk for adverse perinatal outcome,[470] and recent studies addressing the risks associated with viral infections during pregnancy did not identify HAdV as an important pathogen in this clinical context.[518,545,619] Nevertheless, adeno-associated virus-2 (AAV-2) has been reported to cause trophoblast dysfunction, and placental AAV-2 infections were associated with preeclampsia.[21]

Obesity

Infection with HAdV-D36 has been associated with obesity in humans. This notion is supported by experimental infections in animals including mice, rats, chickens, and monkeys revealing increases in body fat in a large proportion of instances.[134,476] Moreover, studies on HAdV-D36 infections in humans indicated the presence of antibodies to this virus type in approximately 30% of pediatric and adult individuals around the globe, with a wide range of percentages, but the prevalence in nonobese persons was found to be lower.[8,25,629,735] Infection with HAdV-D36 apparently increases adipogenesis in animals and humans, and the E4orf1 protein derived from HAdV-D36 is responsible for increasing glucose uptake.[7,134,168,613] Inflammation induced by the virus was shown to contribute to angiogenesis in adipose tissues, thereby maintaining proper glycemic control and metabolic robustness, and the virus was reported to regulate adipose stem cell differentiation and glucolipid metabolism.[302,349]

The prevention of obesity in mice by an anti-HAdV-D36 vaccine supported the notion of employing a vaccination strategy to prevent obesity in humans as well.[487] It is necessary to consider, however, that obesity is a multifactorial, complex phenomenon influenced by genetic, metabolic, cultural, environmental, and lifestyle-related factors, influencing the propensity for obesity apparently conveyed by HAdV-D36 infection.[30,341] A study performed in military staff failed to show any correlation of HAdV-D36 infection status with increase of the BMI (body mass index), and other variables such as high calorie intake and sedentary lifestyle are important components of the multifactorial basis for obesity.[480,697] Other risk factors for obesity include comorbidities such as diabetes mellitus, hypertension, dyslipidemia, endocrine disorders, genetic factors, or certain medications, for example, antihyperglycemics, antidepressants, antipsychotics, and hormones.[142,165,341,373,390] A possible explanation for the apparent association between HAdV-D36 infection and obesity could be an increased susceptibility of obese individuals to viral infections in general, as suggested by different studies.[139,276,332] Indeed, different viral pathogens including, for example, herpesviruses have also been associated with obesity.[665,698]

These observations provide a basis for additional studies addressing the correlation between metabolic processes and immune response, including particularly the role of IFNs as key immune regulators against viral infections and in autoimmunity, which are emerging as pivotal players in the regulation of adipogenesis.[341,665]

DISEASES ASSOCIATED WITH IMMUNOCOMPROMISED PATIENTS

In contrast to many other community-acquired viruses, adenoviral infections can occur both by exogenous acquisition and by reactivation of persistent virus[513]; however, the latter appears to be far more prevalent in immunocompromised individuals.[422] Recipients of allogeneic SCT represent one of the most vulnerable patient groups due to the severely impaired function of their immune system.[266,395,422,423] This is mainly attributable to the lack of functional CD4 and CD8 T lymphocytes in the early posttransplant period, particularly during the first 100 days after allografting. In this setting, exogenous exposure or viral reactivation can result in invasive infections potentially conferring high morbidity and mortality rates, particularly in children.[424] The reported frequency of invasive HAdV infections in the allogeneic SCT setting is considerably higher in pediatric patients (6% to 42%) than in adults (1.5% to 15%) (Table 5.2), but the clinical manifestations can be equally severe.[12,45,338,389,423,598] Differences in the observed frequencies might be related to the permanent circulation of HAdV among children[705] but could also be attributable to the more prevalent persistence of the virus in the childhood, providing a constantly available source of reactivation. In immunocompromised patients, HAdV infection can cause a variety of clinical syndromes including asymptomatic viremia, localized acute respiratory illness, gastroenteritis, conjunctivitis, urinary tract infection, or disseminated disease. In this population of patients (and less commonly in immunocompetent individuals), HAdV infections can be very severe, and can cause respiratory failure, HC, neurologic disease, and disseminated infection with lethal failure of individual or multiple organs.[41,422,608]

Risk Factors

Major factors conferring a high risk of invasive HAdV infection and disseminated disease include allogeneic stem cell (or organ) transplantation and any severe immunosuppression with lack of cellular antiadenoviral activity. More specifically, the most prominent risk factors include allogeneic transplantations with *in vivo* and/or *ex vivo* T-cell depletion, grafts from unrelated donors or cord blood, treatment with the anti-CD52 antibody alemtuzumab (Campath™) or antithymocyte globulin (ATG), and presence of graft versus host disease (GvHD) grades III-IV associated with the use of immunosuppressive agents.[78,114,244,388,420,457,659] Additionally, severe lymphopenia with CD3+ cell counts below 300/μL PB, and absence of HAdV-specific T cells play an important role in the development of viral disease.[172,213,485,751,752] In contrast to allogeneic SCT recipients, donor-positive/recipient-negative HAdV serostatus appears to be a risk factor for severe courses of infection in patients undergoing solid organ transplantation (SOT).[16,290,422,455]

Evidence from pediatric populations indicates that persistent HAdV infection is a risk factor for viral reactivation and ensuing disease with life-threatening clinical manifestations during phases of severe immunosuppression, including particularly allogeneic SCT and, to some extent, SOT recipients.[45,156,247,364,366,424,512] In individuals displaying invasive infection during the posttransplant course, the risk of multiple organ involvement leading to fatal outcome can be high, depending on a variety of parameters such as the level of immunosuppression, the time of onset, or the treatment options available.[422]

Incidence of HAdV Infections in Immunocompromised Adult and Pediatric Patients

In individuals with various congenital immunodeficiencies, particularly in association with severe combined immunodeficiency (SCID) syndrome, severe and recurrent pulmonary HAdV infections and even lethal disseminated disease are not uncommon,[11,437] with reported fatality rates reaching up to 55%.[149] By contrast, life-threatening disease currently appears to be relatively rare in acquired immunodeficiency associated with HIV, where HAdV infections are mostly associated with acute diarrhea only.[3,491] Other clinical manifestations in this setting have become rather exceptional, which is attributable to the availability of highly effective antiretroviral treatment strategies.[272,694] Before the era of effective antiretroviral therapy, a number of authors reported severe and fatal cases in patients with HIV/AIDS associated with pneumonia, hepatitis, nephritis, meningoencephalitis, and disseminated disease.[342,592]

In patients undergoing chemotherapy for malignant diseases, respiratory infections caused by HAdV have been documented during phases of neutropenia, and lethal HAdV disease has been reported in children receiving chemotherapy for acute lymphoblastic or myeloid leukemia and in adults treated with alemtuzumab or receiving chemotherapy.[303,555,563,639] In SOT recipients, HAdV infections can be asymptomatic, but prolonged and severe courses impacting morbidity, graft loss, and mortality may occur.[56,57,156,180,183,184,239,248,444,465,512,602,604,737] Infections can be acquired *de novo* or via reactivation of latent virus from the recipient or the transplanted organ.[271] The occurrence of adenoviremia has been reported in less than 10% of adult patients after kidney, heart, or liver transplantation. Although the symptoms of HAdV infection were usually mild, and invasive infection did not correlate with organ rejection, severe and even fatal courses have also been described.[182,231,271,587,715] Studies in patients undergoing lung transplantation showed that pulmonary infection with HAdV can correlate with significantly elevated rates of rejection, bronchiolitis obliterans, and mortality.[102,699] In line with the epidemiology of HAdV infections, detection of this virus appears to be more common in pediatric SOT,[248,478] with reported rates of HAdV infection ranging from 3.5% to 38% after liver transplantation,[120,155] 7% to 50% after lung and heart transplantation,[427,431,616] and 4% to 57% after intestinal or multivisceral transplantation.[181,465,525] In children after small bowel transplantation, biopsies often revealed the presence of HAdV, but the occurrence of virus-related disease seemed to correlate primarily with the intensity of immunosuppressive treatment.[181] Adenovirus was the most common infectious agent in this context, and enterocolitis, sometimes mimicking rejection, may occur.[360] In the autologous SCT setting, HAdV infections seem to be a rare event,[1,345,742] while allogeneic SCT represents a major risk factor. In allogeneic SCT recipients, young age was shown to confer an elevated risk of HAdV

infection,[687] and life-threatening disease was invariably associated with adenoviremia, or more precisely HAdV-DNAemia, because the detection is generally based on PCR-based analysis.[157,424]

De novo Infection and Viral Reactivation in Transplant Recipients

In the allogeneic transplantation setting, adenoviral complications can arise from *de novo* infection or reactivation of persistent endogenous HAdV. Exogenous infection can occur by virus transmission from the donor via the graft or from the environment.[690] The occurrence of outbreaks on transplant wards documents the role of environmental sources for HAdV spread.[457,650] However, endogenous reactivation of persistent HAdV appears to be the predominant cause of HAdV-associated disease in severely immunocompromised patients. This notion is supported by the absence of a seasonal pattern of infections in this setting and the finding that the HAdV strain detected prior to allogeneic SCT is generally identical to the strain isolated during the posttransplant period.[687,690] The presence of high neutralizing antibody titers against specific HAdV types before allogeneic SCT permitted prediction of reactivation and viral disease caused by the same HAdV type.[690] Detection of HAdV DNA in feces or nasopharyngeal aspirates in the recipient prior to SCT has been reported as a risk factor for viral dissemination posttranplant.[122,425] Although HAdV reactivation in the immunocompromised setting could conceivably occur at different sites, observations in pediatric allogeneic SCT recipients made over a period of more than 15 years suggest that massive viral replication preceding invasive infection occurs almost invariably in the GI tract.[366,424,425] The monitoring of viral load in serial stool samples during the posttransplant period therefore permits timely assessment of impending disseminated disease,[422,423,425] as outlined below.

Definitions of Adenoviral Infection and Disease

In the past, different groups have proposed definitions of localized and disseminated adenovirus infection, probable and proven/definite adenovirus disease, which were based on various technical approaches to virus detection.[178,425,649] Owing to the fact that highly sensitive techniques based primarily on PCR have become the gold standard for the detection and monitoring of HAdV infections, the ECIL (European Conference on Infections in Leukemia) group has recommended the following definitions[455]:

- Local infection: positive HAdV PCR, virus isolation, or antigen detection in biopsy material or fluids other than peripheral blood
- Systemic (invasive) infection: positive HAdV PCR (viremia/DNAemia), virus isolation, or antigen detection in peripheral blood
- Probable disease: HAdV infection plus corresponding symptoms and signs without histological confirmation
- Proven disease: HAdV infection plus corresponding symptoms related to the infection and histological confirmation of HAdV in the appropriate location

In extension of the above criteria, prospective studies defined intestinal adenovirus disease as reproducible detection of HAdV in stool specimens at levels detectable and quantifiable by real-

time PCR together with enteritis, in the absence of other infections or GvHD, while mere presence of HAdV in stool was regarded as virus shedding only. Disseminated HAdV disease was defined as multiple organ involvement (e.g., hepatitis, encephalitis, retinitis) in the presence of two or more HAdV-positive PCR assays in peripheral blood and other sites tested (e.g., CSF, bronchoalveolar lavage, respiratory secretions, urine), in absence of other identifiable causes. HAdV-associated death was defined as multiple organ failure in the presence of increasing or persisting adenoviral load in peripheral blood, in association with HAdV detection from multiple other sites.[422,425]

Clinical Presentation and Outcome of HAdV Infections in Solid Organ and Allogeneic Stem Cell Transplantation

The most common occurrence of HAdV disease is observed between 2 and 3 months posttransplant, and the first symptoms include fever, enteritis, elevated liver enzymes, and secondary pancytopenia.[454] In SOT recipients, the transplanted organ is often the primary site of HAdV-related disease. Clinical manifestations reported in patients receiving lung, liver, kidney, or small bowel transplantations include pneumonia, hepatitis, nephritis, HC, enteritis, and disseminated disease.[289] The manifestations tend to be more severe in pediatric transplant populations, with reported mortality rates occasionally exceeding 50%,[422] and surveillance of HAdV load in peripheral blood may be instrumental in identifying patients requiring antiviral treatment, in order to prevent fatal disease.[155,715] In adult patients undergoing SOT, the incidence of viremia is lower, often transient and self-limited, with asymptomatic clinical courses. Routine surveillance of HAdV by PCR therefore does not seem to be indicated in adult organ transplant recipients.[270,271]

Data on HAdV infections in the hematopoietic SCT setting are far more abundant. In allogeneic SCT recipients, the spectrum of HAdV-associated disease can range from mild gastroenteric or respiratory symptoms to severe manifestations including hemorrhagic enteritis or cystitis, pneumonia, hepatitis, nephritis, encephalitis, myocarditis, and occasionally, concomitant involvement of several organs, which may lead to lethal outcome with multi-organ failure, as outlined above.[321,422,423,504] Postmortem investigation of the affected organs, including particularly the liver, reveals massive replication of the virus with lysis of the infected cells and release of viral particles into peripheral blood,[185] underlining the diagnostic relevance of viremia. In a study performed in the pediatric allogeneic SCT setting, transplant-related mortality associated with HAdV reached 6% of the entire patient cohort investigated,[424,425] but fatal disease attributable to HAdV infection has been reported in up to 50% of patients with DNAemia.[425,659] The majority of transplant-related deaths attributable to HAdV infection occur within the first 100 days posttransplant.[422,423,425]

It is important to emphasize that the occurrence and overall mortality of HAdV infections is apparently lower in adult patients undergoing allogeneic SCT (<1%), but can also be very high in the presence of HAdV-DNAemia[27,216,659] (Table 5.2). Fatal outcome is particularly frequent in cases of DNAemia associated with disseminated disease, with reported lethality rates reaching up to 60% to 80% both in children and in adults.[188,380,422,423] Clinical observations indicate that the courses of invasive HAdV infection in children undergoing allogeneic SCT can be fulminant, with fatal outcome within a few days after onset of the first clinical symptoms of viral disease.[425]

Timely onset of treatment is important for successful control of HAdV infections in immunocompomised patients, but immediate availability of effective therapeutic strategies is still limited. Rapid and reliable diagnosis of impending HAdV disease is therefore of paramount importance (see section Diagnosis).

EVIDENCE LINKING ADENOVIRUSES TO HUMAN CANCER

The WHO (World Health Organization) estimated that more than 15% of all cancers are attributable to infections, and nearly 10% are linked to viruses.[527] Viruses can contribute to the biology of multistep oncogenesis, and have been implicated in several hallmarks of cancer.[466] To identify viruses contributing to cancer via direct or indirect oncogenesis, the following characteristics were proposed: (a) presence and persistence of viral DNA in tumor biopsies; (b) growth-promoting activity of viral genes in model systems; (c) dependence of malignant phenotype on continuous viral oncogene expression or modification of host genes; and (d) epidemiological evidence that a virus represents a major risk for development of cancer.[770] In contrast to the concept that persistence of virus-specific oncogenes is required to maintain the transformed cellular phenotype, the “hit-and-run” hypothesis raises the notion that viruses can mediate cellular transformation through an initial hit attributable to their mutagenic potential, while maintenance of the transformed state may be compatible with the loss of viral molecules.[494]

Several decades ago, it was demonstrated that HAdV-A12 can induce various tumors in newborn Syrian hamsters, and similar observations were later made in different experimental rodent models with other HAdV types belonging particularly to the species A, B, and D.[205,250,298] The mechanism of malignant transformation has been attributed to the early adenoviral proteins E1A and E1B, which act as transcription factors interfering with important tumor suppressor proteins such as Rb (retinoblastoma) or p53, as well as proteins of the DNA repair machinery, chromatin remodeling, and ubiquitination.[44,354,483] The E1A, E1B, and other regions were found to be integrated into cellular DNA, and the viral genes were expressed as proteins mediating the transformed state. Moreover, the adenoviral E3 and E4 proteins were shown to block the host immune response and the onset of apoptosis.[153,593] The E4 region encodes the products of E4orf6 and E4orf3 acting as oncoproteins, which cooperate with E1A proteins to transform primary rodent cells.[494] These observations indicated a rather complex pattern of interactions between early adenoviral proteins and important cellular control mechanisms, which may contribute to malignant transformation. The well-established tumorigenic properties of different HAdVs in experimental mammalian animal models,[722] and their ability to persist in different cell types in the human host raised questions pertaining to HAdV oncogenicity in human cancer.[367] Nevertheless, the evidence for a possible association of HAdV with human malignancies has remained scarce over many years, although it has been demonstrated that multipotent human mesenchymal stem cells can be reproducibly transformed by the E1A/E1B oncogenes derived from HAdV-C5.[633]

High prevalence of HAdV sequences has been documented in a variety of malignant neoplasms including particularly brain tumors, such as oligodendroglioma, glioblastoma, or ependymoma.[367] Control samples of nonmalignant counterparts of HAdV-positive brain tumors, including specimens of ependymal cells, plexus choroideus, and periventricular white matter also revealed the presence of HAdV DNA in most specimens tested. The identification of HAdV types detected both in malignant and nonmalignant brain tissue specimens revealed predominantly representatives of species B and D and, less commonly, C. The presence of contamination as a possible cause of false-positive results was excluded by confirmatory results obtained by *in situ* hybridization. The CNS was shown to represent a common site of HAdV infection with virus persistence, thus providing evidence for the possible contribution of HAdVs to the multistep process of tumor pathogenesis in brain tissue.[367]

Epidemiological studies indicated a link between *in utero* infection with viruses and ALL (acute lymphoblastic leukemia),[207] and screening of amniotic fluid samples in the second trimester of pregnancy revealed DNA from different viruses detectable by PCR, suggesting that infections *in utero*, including HAdV, are fairly common.[470] Adenovirus DNA was detected at an elevated frequency in Guthrie cards from children who developed ALL,[217] but in subsequent studies the frequency was regarded as too low to permit an association between HAdV and the development of leukemia.[259,689] In a more recent study focusing on lymphoid malignancies including various types of lymphocytic leukemia, malignant lymphoma, and multiple myeloma, adenoviral DNA was only detected in a high proportion of mantle cell lymphoma specimens. The presence of adenoviral sequences identified by pan-adenovirus PCR screening was confirmed in individual cells by FISH (fluorescence in-situ hybridization), and the most prevalent HAdV species detected was C, and less commonly B.[370]

A recent study based on WGS and RNA-seq (RNA sequencing) in a large spectrum of tumor entities revealed adenoviral sequences in several tumor types including renal cell carcinoma, breast adenocarcinoma, prostate adenocarcinoma, head and neck carcinoma, and hepatocellular carcinoma.[753] Samples testing positive for HAdV were identified both in the tumor and in the adjacent nonmalignant tissue, possibly indicating viral persistence in the respective tissues. Virus positivity was observed in nearly half of the renal carcinoma cases investigated, and the virus was detectable by WGS, but escaped detection by RNA-seq, in line with absent or very low expression of viral genes during latent phases.[498] Interestingly, driver gene mutations commonly occurring in renal cancer did not co-occur with HAdV detection, raising the hypothesis that the virus might contribute to cancer development independently from the well-known driver genes. Of note, the outcome of patients with HAdV-positive renal tumors was significantly better than that of individuals displaying virus-negative tumors.[753] Rather surprisingly, these data were not included in a more recently published version of the study.[754]

Although the associations with various malignant tumors are intriguing, it was not possible thus far to provide clear indications for a causal relationship between HAdV infection and tumorigenicity in humans.[533] It is important to emphasize, however, that the studies discussed above addressing HAdV-induced cancer in humans do not rule out a “hit and run” mechanism in which the virus causes changes in cells eventually leading to cancer, but the viral genome is not retained by the cells.[282] This mechanism of transformation has been reported in primary rat cells,[494] raising the possibility that even tumors lacking any detectable virus-specific molecules can display viral pathogenesis. This notion may require consideration when using adenoviral

vectors for gene therapy. At present, the putative implication of HAdVs in human cancer continues posing an intriguing enigma.

DIAGNOSIS

Infections of the upper and lower respiratory tract caused by HAdVs are clinically difficult to distinguish from other respiratory viruses and even some bacterial infections. The appearance of tonsils in small children can be similar to streptococcal or herpesvirus infections. Differential diagnostic considerations also apply to HAdV-mediated (kerato)conjunctivitis, which usually begins unilaterally, with moderate enlargement of the preauricular lymph node, and sometimes with subsequent involvement of the contralateral eye. The symptoms of hemorrhagic manifestations of the urinary tract caused by HAdV infections in immunosuppressed patients can be similar to bacterial infections or drug toxicity affecting the bladder. Due to the difficult clinical diagnosis, laboratory tests are required for reliable HAdV identification, and previously common approaches including viral isolation, cell culture, immunofluorescence-based detection of HAdV-specific antibodies, serological analysis by HI and SN tests, as well as examination by light or electron microscopy were addressed in some detail in the previous Editions of Fields Virology.[724,725] Due to the present dominance of molecular diagnostic approaches, the current chapter is focused on these techniques. The molecular methods employed for qualitative HAdV screening by broad-spectrum (pan-adenoviral) PCR assays, quantitative monitoring by real-time PCR tests, and typing at the levels of species, types and strains, based on specific PCR tests and sequencing techniques, are used in both the immunocompetent and immunocompromised patient settings. In this chapter, the emphasis is placed on HAdV diagnosis and monitoring in patients with severely impaired immune response displaying a high risk for invasive infections.

Diagnosis in the Immunocompromised Setting

Invasive infection defined by the presence of adenoviremia/DNaemia renders serial diagnostic monitoring of PB samples during the posttransplant course of paramount importance. It has been demonstrated that HAdV detection and documentation of rising virus levels in plasma by quantitative PCR (qPCR)-based monitoring precede the onset of clinical symptoms of organ involvement by several weeks,[424] thus offering the possibility for preemptive initiation of treatment. The observation that patients can succumb to disseminated HAdV disease within a few days after presenting with symptoms of systemic infection highlights the need for careful diagnostic monitoring and early implementation of therapeutic measures.[424] Although lethal HAdV infections have been described in both adult and pediatric allogeneic SCT recipients, the reported frequency of invasive infections with severe clinical courses is considerably higher in children, as indicated in Table 5.2.[12,27,122,167,176,216, 244,321,425,502,550,624,625,659,687,704,755] Different groups have tried to define thresholds of HAdV levels in plasma as a trigger for the initiation of antiviral treatment,[388,420,660] but the assessment of absolute virus copy numbers greatly depends on the method used, and published data cannot be readily transferred to other centers without complete harmonization of the technical approaches used. In this regard, the documentation of rising virus copy numbers may be a more universal parameter, which is rather

independent of the particular methodological approach used, as long as a quantitative (at present predominantly molecular) technique is employed. Nevertheless, clinical experience in the pediatric setting has indicated that the initiation of treatment at the stage of invasive HAdV infection, as documented by the presence of viremia, may not prevent disseminated disease with lethal outcome in a number of instances.[422–425,755] These observations have stimulated the search for diagnostic options facilitating early assessment of the risk for systemic infections, and the GI tract was demonstrated to represent the most important compartment for expansion of the virus prior to dissemination in pediatric SCT recipients.[366,425] Although the importance of serial monitoring of stool samples in children during the posttransplant period has not yet been fully recognized by the latest ECIL recommendations,[455] there is now ample evidence supporting the role of intestinal HAdV shedding for early detection of impending invasive infection,[167,269,300,364,425] and the recent recommendations published on behalf of the IDWP (Infectious Disease Working Party) of the EBMT (European Society of Blood and Marrow Transplantation) strongly suggest the inclusion of serial monitoring of stool specimens in the routine diagnostic program in pediatric allogeneic SCT[245] (Table 5.3). In the adult SCT setting, there is currently no indication supporting the role of the GI tract for HAdV expansion before the infection becomes invasive, and testing of PB specimens is therefore the preferred approach for patient surveillance.[245] Although the presence of adenoviremia is reportedly correlated with a high risk of lethal disseminated disease,[422] the appropriate timing for the initiation of treatment is still a matter of debate.

Predictive Value of Viremia and HAdV Replication in the Gastrointestinal Tract

Since spread of the virus into peripheral blood is a characteristic sign of disseminated HAdV disease, and viral load values correspond to the severity of organ pathology,[236] quantitative monitoring in plasma or serum has become an essential screening tool after allogeneic SCT, as specified in more detail below. Additionally, there is growing evidence that HAdV detection and surveillance of virus proliferation kinetics in stool provide early information on impending invasive infection and HAdV disease.[300,401,425] Viral persistence in the GI tract and shedding of HAdV into feces is a common finding, which reportedly occurs in more than one-third of pediatric patients after allogeneic SCT, and may not necessarily be associated with clinical symptoms of intestinal infection.[366,422,423] Detection and quantitative surveillance of HAdV in serial stool samples revealed two distinct patterns indicating the risk of invasive infection. Patients displaying very slow or absent proliferation kinetics in serial analyses, with maximum HAdV loads below 10E6 virus copies/g of stool, apparently have a very low risk of adenoviremia. By contrast, patients showing rapid proliferation exceeding the threshold of 10E6 virus copies/g, and sometimes revealing extremely high viral loads of more than 10E11 copies/g, have a very high risk of experiencing viremia and disseminated disease (see section Persistence and Reactivation in the GI Tract).[425] These observations were largely confirmed by other groups,[114,167,269,300,402,635] and will expectedly have important implications for future diagnostic and treatment strategies.

Diagnostic Screening

Conventional approaches to HAdV detection at affected sites such as peripheral blood, stool, urine, bronchoalveolar lavage, and nasopharyngeal aspirates or swabs formerly included primarily immunofluorescent staining for antigen detection and viral culture.[149,289,344,387] However, due to the limited sensitivity and, in case of viral culture, rather long time to readout, these methods have been largely supplanted in routine clinical diagnostics by molecular screening approaches generally relying on PCR-based techniques.[289,363,365,425] Owing to the superior sensitivity and specificity of molecular tests facilitating equally effective detection of all HAdV types in any diagnostic material, PCR assays have become a standard screening tool.[455] Despite the predominance of certain HAdV species in specific clinical settings including immunocompromised patients, employment of broad-spectrum HAdV screening assays is necessary in order to permit reliable detection even of rarely occurring HAdV species and types with adequate sensitivity (Fig. 5.5). Several groups have established such "pan-adenoviral" assays based on PCR, exploiting the sequence information available at the respective points in time.[148,150,237,265,363] The HAdV screening assays target conserved regions within the HAdV genome, most commonly within the hexon gene, but the inclusion of additional target regions, for example, within the fiber gene, may be required to ensure reliable detection of all known types with comparable sensitivity.[148,363,365] Due to the fact that the spectrum of newly identified HAdV types identified by the implementation of genomic analyses has been expanding, established assays need to be updated in order to facilitate reliable coverage of the entire range of HAdVs.[363] Since the newly identified HAdV types generally result from recombination events within the same or different human species of the virus,[562] the target regions of established PCR assays are preserved in most instances, thus permitting equally sensitive detection of the new recombinants. Nevertheless, this issue requires careful attention, as exemplified by one of the early HAdV screening assays based on the sequence information accessible at that time.[148] The test was originally demonstrated to cover all 51 known HAdV (sero)types with comparable detection limits. Alignment with genomic sequences of subsequently published HAdV types revealed that the primer/probe combinations of this real-time PCR assay can be expected to reliably cover nearly all hitherto identified HAdV types, with two exceptions. The sequence of HAdV-A61 revealed a few mismatches in the target region of the downstream primer, possibly affecting the sensitivity of detection. This finding required the addition of an appropriately modified primer to the reaction, and subsequent confirmation of this adaption *in vitro*. The second exception was HAdV-G52, which displays the greatest similarity to a simian adenovirus (SAdV-1), and would not be reliably covered by the assay. This example highlights the need to control and adequately adapt established diagnostic assays based on newly identified HAdV types, if the test is expected to serve for "pan-adenoviral" screening.[363] The availability of complete genomic sequences of all currently known HAdV types greatly facilitates appropriate modifications of established assays and the development of novel tests. The same requirements apply to commercial HAdV assays that are FDA approved in the United States and/or CE marked in Europe. A number of such kits have been introduced including the Adenovirus R-gene™ kit (BioMérieux, Lyon, France), ELITe MGB®Kit kit (ELITech Group Molecular Diagnostics, Puteaux, France), FilmArray® RP (BioFire Diagnostics, Inc, Salt Lake City, UT, United States), eSensor RVP (GenMark Diagnostics, Carlsbad, CA, United States), xTAG RVP *FAST* and xTAG RVPv1 (Luminex Molecular Diagnostics, Toronto, Canada), Prodesse ProAdeno™+ Assay (Hologic Gen-Probe, San Diego, CA, United States), and Anyplex II RV16 (Seegene, South Korea), and the list is probably not exhaustive. Most of the indicated kits cover multiple viruses and are only approved for qualitative analysis of respiratory specimens. Studies

comparing the performance of such kits indicated a particularly high variability for HAdV detection, and inadequate identification of certain HAdV types by some of the tests.[109,350,528] The monitoring of patients in the immunocompromised setting requires tests permitting reliable detection of all potentially relevant HAdV types in different clinical specimens, and accurate quantitative assessment of viral loads. Among the currently available commercial kits, this requirement appears to be met by the Adenovirus R-gene kit,[299,365] and possibly by the ELITe MGB® kit, although the latter seems to be approved for whole blood analysis only.

It is important to emphasize that the lower detection limit for HAdV detection in clinical specimens, including particularly peripheral blood, should be in the range of 10E2 virus copies/mL in order to prevent false-negative test results, and to permit early initiation of treatment according to some of the published guidelines.[420]

Relevance of HAdV Detection and Quantification at Specific Sites

A prospective study in pediatric patients undergoing allogeneic SCT, which focused on screening of HAdV at different sites including throat, stool, urine, peripheral blood, and occasionally other sites, revealed that detection of adenovirus at multiple (i.e., more than 2) sites reflects the presence of invasive infection. However, at that time detection of HAdV in peripheral blood was the only site permitting risk assessment of disseminated disease.[424] A number of studies provided similar findings,[150,157,188,216,321] rendering peripheral blood the most important source for clinical surveillance of HAdV infections in the immunocompromised setting. The time point of HAdV DNAemia may be of prognostic relevance: some studies showed that patients showing DNAemia before day 100 after allogeneic SCT developed life-threatening disseminated disease in more than 60% of instances despite antiadenoviral treatment, whereas later onset of viremia did not seem to be associated with disseminated HAdV disease.[424,425] Interestingly, other reports suggested that HAdV detection in nasopharyngeal aspirates of children prior to allogeneic SCT is a strong predictor for ensuing adenoviremia and may therefore provide an indication for postponement of transplantation, if possible.[122,420] In fact, HAdV may be persistently detectable in nasopharyngeal secretions in some pediatric patients,[291,322] and these observations therefore require careful consideration.

Despite the clear diagnostic and prognostic relevance of HAdV DNAemia, only a proportion of high-risk patients with this finding develop overt disease. A number of groups have therefore attempted to identify virus load levels that could serve as a rational basis for the onset of preemptive antiviral treatment. However, the thresholds suggested by different authors were highly divergent, ranging from 10E2 (in individuals with high risk) to greater than 10E6 copies/mL,[157,188,216,388,420,660] thus rendering generally applicable conclusions difficult. Moreover, the measured absolute values are, at least to some extent, dependent on the individual technique used, and in absence of appropriate interlaboratory standardization, the values cannot be readily adopted by or exchanged between centers. Other authors have shown that rapidly rising viral loads are detectable in peripheral blood prior to onset of clinical symptoms of HAdV disease, suggesting that the monitoring of viral titer kinetics may be a more readily applicable parameter.[424,599] Moreover, in addition to facilitating prediction of HAdV-related disease, surveillance of HAdV copy number kinetics in peripheral blood is also instrumental for assessment of the response to therapy.[189,420,425] In some studies, a decrease in viral load by at

least one log within 2 to 3 weeks of antiviral treatment was regarded as a minimum requirement for adequate response,[424,425] but there are no generally accepted guidelines for diagnostic definitions of response at the present time.

The relevance of HAdV replication kinetics and peak load levels in stool specimens of pediatric allogeneic SCT recipients for risk assessment of invasive infection has already been indicated above. Since timely onset of antiviral therapy appears to be critical in this setting, and starting treatment upon detection of HAdV viremia may be too late in a number of instances,[173,369,424,425] it is essential to identify the earliest possible time points for rational initiation of therapy. In view of the high risk of invasive infection and disseminated disease in children displaying rapid HAdV proliferation kinetics in serial stool specimens with peak levels exceeding 10E6 virus copies/g, systematic screening of intestinal excretions should be part of the diagnostic routine during the posttransplant period. The median time span between detection of HAdV loads in stool exceeding the indicated threshold and first appearance of the virus in peripheral blood was 11 days in one of the studies performed,[425] thus providing a rational window of opportunity for early onset of therapy, with the aim to prevent invasive infection (Fig. 5.7).

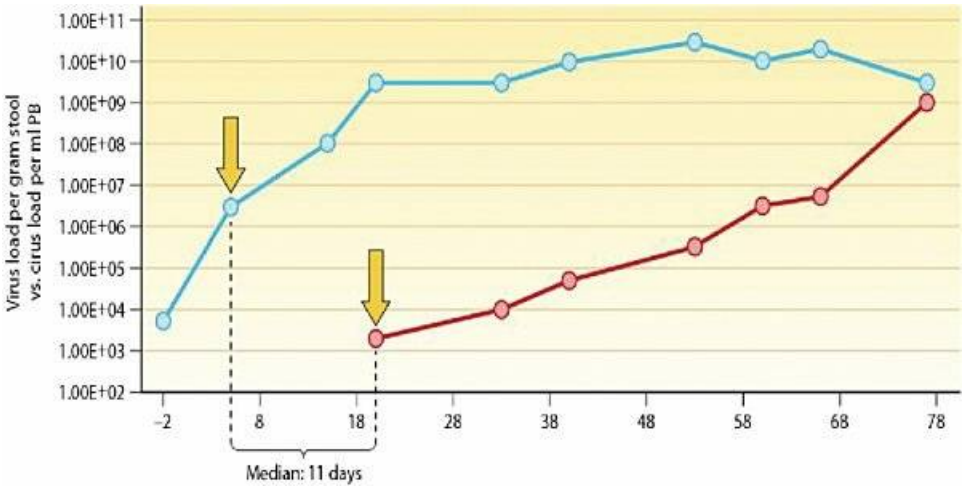

FIGURE 5.7 Temporal correlation between intestinal HAdV infection and viremia. The median time span between the observation of rapidly rising HAdV copy numbers in serial stool specimens (*blue line*) exceeding the threshold of 10E6 virus copies/g of stool (*left arrow*) and the first detection of viremia (*right arrow*; *red line*) was 11 days, providing a rational basis for early onset of treatment. Adenovirus Typing

Identification of adenoviruses at the level of species, (sero)types, and even strains is of relevance for epidemiological studies and for precise documentation of nosocomial outbreaks. For the selection of optimal treatment, HAdV typing is currently of lesser importance because, with the exception of ribavirin (see below), available therapeutic strategies are independent from the

HAdV species present. However, in view of the fact that different HAdV species and types may occur contemporaneously or sequentially in individual patients[151,372,460,696,766] (Figs. 5.5 and 5.6), typing may permit better understanding of the dynamics and evolution of HAdV infection.

Typing was traditionally performed by serological methods, but these approaches have mostly been replaced by molecular techniques based on PCR amplification of specific target regions coupled with different detection formats such as fragment length analysis, hybridization to species-specific probes, or sequencing.[147,315,553,764] Molecular typing methods are more rapid, are readily applicable, and can provide better discriminating capacity. Owing to the decreasing costs of next generation sequencing (NGS) approaches, whole genome analysis[307] may become the method of choice for detailed HAdV typing in the foreseeable future even in the routine diagnostic setting.

Molecular HAdV Detection and Monitoring of Viral Load

The importance of appropriate diagnostic HAdV monitoring is underlined by the fact that the morbidity and mortality in immunocompromised patients with invasive infection can be very high, in both the pediatric and adult settings (Table 5.2). In such patients, particularly in the pediatric allogeneic SCT setting, adenoviruses can be detected in a variety of clinical materials.[422–424] Although it has been reported that HAdV detection in respiratory specimens of pediatric transplant recipients is of prognostic relevance for invasive infection,[122] there is strong evidence supporting the essential role of serial stool monitoring for early prediction of impending adenoviremia.[114,167,269,288,300,402,425,635] Hence, monitoring of stool specimens has been widely adopted as a routine diagnostic tool in children undergoing allogeneic SCT.[203] Moreover, monitoring of PB specimens is generally employed in both the pediatric and adult allogeneic SCT settings to identify patients at high risk for HAdV-related systemic disease and to assess the response to antiviral treatment approaches[203] (Table 5.3).

Technical Considerations for Diagnostic Testing

From the diagnostic perspective, it is important to emphasize that the technical approach, which mostly relies on quantitative PCR testing, needs to cover the entire known spectrum of HAdV species and types, in order to prevent missing any potentially life-threatening infections by these viruses. Essentially, any HAdV species can occur in the severely immunocompromised setting, but geographic differences in the distribution of HAdV species exist, based on reports of invasive infections from different centers.[422] In many regions, representatives of HAdV species C predominate, followed by species A and B, while members of other HAdV species are rather rare in immunosuppressed patients, and often occur only in combination with one of the more common species.[422] However, different HAdV species or types can occur concomitantly or sequentially, underlining the need to employ diagnostic tests displaying very broad specificity for quantitative HAdV detection (Figs. 5.5 and 5.6). Due to the permanent expansion of the HAdV spectrum (Table 5.1), it is necessary to monitor and potentially adjust the assays used, as pointed out previously.[365,422]

Patient Surveillance Based on the Monitoring of Stool

Recent recommendations published on behalf of the European Bone Marrow Transplant

Association (EBMT) have highlighted the importance of HAdV detection and monitoring in stool samples of pediatric SCT recipients[245] (Table 5.3). The relevance of pretransplant assessment of intestinal HAdV shedding has been recognized, and molecular screening at specific time points has been suggested by the expert panel (Table 5.3). Moreover, based on initial data highlighting the importance of HAdV monitoring in stool in the pediatric SCT setting,[425] which were corroborated by several other investigators,[114,167,269,300,635] pertinent recommendations for diagnostic surveillance have been provided (Table 5.3). It is necessary to bear in mind, however, that HAdV levels above 10E6 virus copies/g of stool, which were originally described as the critical threshold for the risk of impending invasive infection,[425] may need to be adjusted according to the quantitative readout of the specific method used. By contrast, the use of rapidly increasing HAdV copy numbers in serial stool specimens as a dynamic parameter may be applicable regardless of the particular quantitative technique employed. Data obtained from serial monitoring of stool specimens may provide a basis for early initiation of antiviral treatment, with the aim to reduce HAdV-related morbidity and prevent invasive infection. However, due to the current lack of data on systematic stool monitoring in the adult SCT setting, the recommendations for diagnostic exploitation of feces are presently restricted to pediatric transplant recipients only (Table 5.3).

Patient Surveillance Based on the Monitoring of Peripheral Blood

In adult organ transplant recipients, viremia is often asymptomatic, and the risk of progression to adenoviral disease in the presence of HAdV DNAemia with or without specific cutoff values for viral loads remains unknown.[180] Routine screening for HAdV is therefore not recommended at present, although adenovirus infections in this setting can be severe and affect morbidity, mortality, and graft survival, particularly in young children.[180]

In line with the latest ECIL recommendations for HAdV diagnostics in SCT recipients and patients with leukemia, monitoring of PB specimens by quantitative PCR, based on the presence of a defined risk profile, is regarded as the cornerstone of diagnostic surveillance.[12,455] Indeed, prior to the identification of the important role of stool monitoring in the pediatric SCT setting, a decade ago,[425] HAdV surveillance in transplant recipients was largely based on PB monitoring only, and different investigators tried to define thresholds of HAdV copy numbers requiring the initiation of treatment. The indicated thresholds varied, as outlined above, also depending on the individual risk profile.[210,388,420,660] However, as indicated, the virus quantity determined depends on the specific method employed, and the numbers therefore cannot be easily transferred between centers without aligning the methodological approaches. It has been shown that increasing HAdV copy numbers can be detected in PB prior to the onset of clinical symptoms indicative of organ involvement, and the average time span between the first log increase in viral load and the appearance of disseminated disease was several weeks.[424] These observations indicated that a dynamic parameter of documented viral expansion in PB might be a more universally applicable approach to identifying patients who require treatment, which would be independent of using completely harmonized molecular methods. However, the reported mortality in SCT recipients with adenoviremia is high (Table 5.2), and it is questionable therefore whether the initiation of antiviral treatment in this setting should be triggered by specific thresholds or dynamic parameters of viral expansion. In view of the limited efficacy of current treatment options, it might be reasonable to initiate treatment upon HAdV detection in

PB at any level, upon consideration of the individual risk for disseminated disease.

The IDWP-EBMT recommendations for the employment of PB monitoring in the SCT setting are outlined in Table 5.3.[245] Recent studies have addressed the prognostic role of diagnostic parameters including HAdV peak levels (PL) and the time-averaged area under the curve (AAUC) of virus copy numbers in PB. The latter parameter reflects the overall exposure to the virus by assessing the viral burden over time, and was therefore presumed to provide potentially more reliable prognostic information. The predictive value for patient outcome reflected by all-cause, nonrelapse, or HAdV-related mortality was determined, and was significant for the parameters tested.[369,755] However, since nonrelapse mortality also encompasses death attributable to graft versus host disease, treatment-related toxicity, and other infections, and all-cause mortality also includes disease relapse, correlation with these criteria may overestimate the actual contribution of HAdV to lethal outcome. In one of the studies looking at HAdV-related mortality, peak virus levels in PB below 10E4 copies/mL and low AAUC levels correlated with a low probability of succumbing to the viral infection,[369] thereby providing diagnostic markers of potential prognostic relevance.

PREVENTION AND TREATMENT

Approaches to Antiadenoviral Treatment in Immunocompromised Patients

The optimal time point for initiation of antiadenoviral treatment in the immunocompromised setting has been a matter of discussion, and certainly depends on the individual risk situation and the treatment options available. Prophylactic therapy against HAdV infections is not performed due to the limited efficacy and toxicity of currently available antiviral agents,[455] but preemptive treatment is warranted due to the unfavorable outcome of symptomatic disease.[245] In pediatric SCT recipients, HAdV detection in stool prior to SCT has been associated with an elevated risk for early onset of invasive infection, and it was suggested that postponing elective transplantations and providing early preemptive treatment might be a sensible option in high-risk constellations.[364] Moreover, in the pediatric SCT setting, an algorithm has been proposed suggesting the onset of preemptive therapy based on the detection of expanding HAdV copy numbers in stool exceeding the threshold of 10E6 virus copies/g, which had been identified as critical for the risk of invasive infection.[422] The presence of low-level viremia can reportedly resolve spontaneously, particularly in the presence of established or incipient immune reconstitution (lymphocyte count >300/mL). However, treatment strategies aiming at the prevention of invasive infection appear to be reasonable, due to the considerable proportion of severe or even lethal courses of infection in patients displaying adenoviremia[245,388] (Table 5.2). Based on these considerations, the recent recommendations published on behalf of the Infectious Diseases Working Party of the EBMT suggest the initiation of antiadenoviral treatment in patients with rapidly rising HAdV levels in stool above the threshold defined as critical[245] (Table 5.3). This recommendation is applicable in pediatric SCT recipients, where intestinal HAdV reactivation and expansion is a virtually invariable finding prior to systemic infection.[422]

Additionally, it is strongly recommended to start treatment in the presence of adenoviremia greater than 10E3/mL in lymphopenic patients with less than 25 CD3+ T cells/µL PB[245] (Table 5.3). Due to the important role of immunosuppression as a risk factor for potentially life-threatening HAdV infection, the first therapeutic measure should be tapering of any immunosuppressive treatment, whenever clinically possible.

Current Treatment Modalities

Present recommendations for treatment of HAdV infections focus on immunocompromised patients including particularly allogeneic transplant recipients who apparently carry the greatest risk of severe and life-threatening clinical courses. The approaches pursued may include prophylaxis, preemptive treatment based on virus detection prior to the onset of clinical symptoms, sometimes linked to specific thresholds of viral load, or therapeutic (symptomatic) treatment in the presence of virus-related disease. At present, there is little evidence for a beneficial effect of HAdV prophylaxis, and the ECIL does not recommend prophylactic antiviral therapy with currently available virostatic drugs.[455] In SOT recipients, the indication for therapy in mild or asymptomatic HAdV infection in not clear, since prospective studies have shown that adenoviremia may be present without any clinical symptoms, and may clear spontaneously.[271] Some authors therefore recommend antiviral treatment only in symptomatic patients.[437] By contrast, in patients undergoing allogeneic SCT, preemptive treatment is strongly advocated by all major guidelines in order to inhibit or slow down viral replication, with the aim to prevent overt disease until immune reconstitution from the allograft permits clearance of the infection.[245,420,455] The principal options for preemptive treatment include (a) the tapering of immunosuppressive therapy, which should be performed whenever possible, (b) antiviral drugs, and (c) immunotherapy in case of failure of the previous lines of treatment.

Antiviral Drugs

Most abundant evidence for the *in vivo* efficacy of antiviral therapy against HAdV in the preemptive or symptomatic settings is available for cidofovir,[16,71,179,187,214,357,420,433,435] but the clinical effect of the drug as treatment for overt viral disease is apparently limited.[346,391] The compound is a nucleotide analog of cytosine inhibiting preferentially viral DNA polymerase and viral replication by more efficient competitive incorporation into DNA.[85] Since cidofovir is already a monophosphate, it shows poor oral bioavailability but does not require a viral enzyme (e.g., thymidine kinase) for its phosphorylation, which is required to phosphorylate ganciclovir (see below), and cidofovir can be converted to the di- and triphosphate forms by cellular enzymes. These triphosphorylated acyclic nucleoside phosphonates have a generally higher affinity for viral DNA polymerases than for cellular DNA polymerases, thereby providing specificity for virus-infected cells. They act as inhibitors of the viral DNA polymerase, for which the triphosphate is a substrate, and they function as DNA synthesis chain terminators through a variety of mechanisms.[118] Although resistant mutants have been described *in vitro*, cidofovir apparently displays efficacy against all HAdV species,[85,168] and is currently the primary anti-HAdV agent for preemptive therapy, although it is not approved for this application.[119,420,422,423,425] Cidofovir is a substrate of OAT1 (organic anion transporter 1), which is prevalent in renal tubules, and prolonged exposure of the kidney to the compound leads to nephrotoxicity.[726] The drug is used as induction therapy at a dose of 5 mg/kg/wk for 2 weeks

and at 2-week intervals thereafter.[455] Alternatively, a schedule of 1 mg/kg three times a week in combination with hyperhydration and probenecid has been suggested to reduce renal toxicity,[245,420] and the required duration of therapy is linked to the clinical and molecular response, determined by a rather individually defined reduction of viral load.[420,425] Clinical results of preemptive treatment with cidofovir in the context of allogenic SCT are controversial, with studies reporting success rates of approximately 70% or more, and others reporting rather poor responses.[420,425,651] The efficacy in transplant recipients has been shown to depend on at least partial immune recovery.[243,455,695,755] The limitations of treatment with cidofovir include its low bioavailability and poor correlation of pharmacologic effects with the prescribed dose.[112] Moreover, the nephrotoxicity mediated by cidofovir can be dose limiting and sometimes severe, and frequent monitoring of renal and tubular function as well as concomitant hydration and uroprotection with probenecid are recommended.[420,455] The use of intravesical cidofovir for HC in SCT recipients, applied at 1 to 5 mg/kg in 100 mL saline via an indwelling catheter for 1 hour, revealed good efficacy and low toxicity.[6,246,591]

Ribavirin is a nucleoside analog of guanosine displaying *in vitro* activity against DNA and RNA viruses, and the mechanisms of action may include inhibition of viral polymerases, viral RNA capping, and increased mutation rates in newly synthesized DNA.[403,488] Analysis of HAdV isolates revealed consistent sensitivity of all types belonging to species C only, and the evidence for therapeutic efficacy of the compound *in vivo* is controversial.[256,488,671] Ribavirin is therefore not generally recommended for treatment of HAdV infections.[353,455] However, despite the conflicting results on the activity against HAdV *in vivo*, the low nephrotoxicity of ribavirin and the documented *in vitro* efficacy against HAdV species C may justify its use in specific clinical situations.[52,423] Oral, intravenous, and aerosol therapy with ribavirin has been used,[115,609] and the compound has been applied in a clinical study at a dose of 20 mg/kg in combination with cidofovir as preemptive therapy in the presence of infections caused by representatives of HAdV species C in the pediatric allogeneic SCT setting.[425] However, the actual clinical benefit of this treatment remains unclear.

Ganciclovir is a synthetic analog of 2′-deoxy-guanosine, which requires phosphorylation to ganciclovir monophosphate by a viral kinase, and subsequently, formation of ganciclovir diphosphate and triphosphate catalyzed by cellular kinases. Ganciclovir triphosphate is a competitive inhibitor of deoxyguanosine triphosphate (dGTP) incorporation into DNA, and preferentially inhibits viral rather than cellular DNA polymerases. Moreover, it is a poor substrate for chain elongation, thereby disrupting viral DNA synthesis. A possible benefit of ganciclovir against HAdV infections in allogeneic SCT recipients has been suggested.[58] However, since adenoviruses (in contrast to members of the herpesvirus family) lack viral thymidine kinase, and cellular kinases are inefficient in phosphorylating the compound, the anti-HAdV efficacy of ganciclovir is predictably modest,[488] although some HAdV types reportedly displayed EC_{50} values less than 10 μM *in vitro*.[91] Based on current data, there appears to be no justification for recommending the use of this drug for systemic HAdV treatment,[420,425,455] but the compound used in an ophthalmic gel showed efficacy against HAdV types associated with EKC.[264]

Among other antiviral agents tested, the pyrophosphate analog foscarnet was demonstrated to display no activity against HAdV.[91,488]

A rather recently introduced compound termed brincidofovir (1-*O*-hexadecyloxypropyl-cidofovir, formerly CMX001) is an orally bioavailable lipid conjugate of cidofovir displaying substantially less nephrotoxicity than the parent drug, and considerably higher anti-HAdV efficacy, with EC_{50} values in the submicromolar range.[91] The largely absent nephrotoxicity is attributable to the fact that brincidofovir, in contrast to cidofovir, is not a substrate for OAT1 in the renal tubules.[668] The compound is effective against a variety of DNA viruses, and has been successfully employed for treatment of viral infections in allogeneic SCT recipients and other settings, although resistant mutations may arise.[294] Clinical observations on the efficacy against HAdV showed promising results, and several reports on severely affected immunocompromised patients highlighted the lifesaving potential of this agent.[26,65,114,464,550,645,683] Brincidofovir provided orally at a recommended dose of 2 mg/kg (and a maximum of 100 mg) twice weekly permitted clearance of the virus in a substantial proportion of patients, even in the absence of immune reconstitution, with GI symptoms as the main toxic side effect.[210,243,755] The clinical symptoms and the histological findings in colon biopsies, including edema of the lamina propria, epithelial apoptosis, and crypt injury, are similar to the damages caused by GvHD, infection, or toxicity of the immunosuppressive agent MMF (mycophenolate mofetil).[126] The differential diagnosis is clinically important, however, because of the different treatment modalities required in each setting. A possible solution could be the use of an intravenous formulation of the drug, which did not show any GI toxicity in early studies.[395] Brincidofovir is currently regarded as the most effective antiadenoviral agent, and a recent preclinical study indicated that its combination with valganciclovir (an orally bioavailable valyl ester prodrug of ganciclovir) was more efficacious than either drug alone, permitting substantial dose reduction of both compounds for better control of toxic side effects.[676]

Development of Novel Antiadenoviral Compounds

The lack of safe and efficacious drugs approved for treatment of HAdV infections has stimulated the search for new antiviral compounds including not only novel developments but also the testing of agents currently employed in other clinical contexts for their efficacy against HAdVs.[449] Repurposing of drugs already approved by the regulatory agencies for other indications is an attractive approach due to lower risks and costs in comparison to new developments.[726] In addition to the virostatic agents discussed above, other nucleoside analogs are currently in development. For example, USC-087, an *N*-alkyl tyrosinamide phosphonate ester prodrug of HPMPA (hydroxyphosphonylmethoxypropyl-adenine),[542] the adenine analog of cidofovir, was shown to be highly effective against multiple HAdV types in cell culture, and promising activity was also documented in a Syrian hamster model after oral administration. The compound was therefore deemed eligible as a candidate for further clinical development as an anti HAdV drug.[675] Furthermore, additional lipid ester derivatives were tested *in vitro* and showed anti-HAdV efficacy, particularly against the pneumotropic type B14.[375] Some other nucleoside analogs investigated *in vitro* include N4-derivatives of 6-azacytidine, which were shown to provide high anti-HAdV activity and low toxicity,[9] and filociclovir (cyclopropavir) displaying questionable activity against HAdVs.[91,227]

Besides different nucleoside analogs, a variety of unrelated compounds displaying anti-HAdV potential has been investigated. In a recent study, three salicylanilide-based anthelminthic drugs including niclosamide, rafoxanide, and oxyclozanide, were shown to display anti-HAdV

activity at low concentrations and apparently low toxicity. The mechanism of action of the former two compounds is interference with the transport of HAdV particles from the endosome to the nuclear membrane, while the latter compound targets transcription of the E1A gene, and individual pairwise combinations of these agents displayed strong synergistic effects. Based on these observations, the compounds will be tested in Syrian hamster models of HAdV infection to further investigate their efficacy and safety.[448] Moreover, various salicylamide derivatives related to the lead compound niclosamide are potent inhibitors of HAdV infection, displaying differential activity at various stages of the infectious process, including virus entry, DNA replication, or postreplication steps.[734] The same group also showed that the synthetic steroid drug mifepristone (a progesterone and glucocorticoid receptor antagonist used for treatment of secondary hyperglycemia and for medical abortion during pregnancy) displays pronounced anti-HAdV activity *in vitro*, apparently by interfering with nuclear entry of the virus.[448] Piperazines are a broad class of chemical compounds containing a core piperazine functional group (a six-membered ring containing two nitrogen atoms at opposite positions), and different phenyl as well as urea/thiourea derivatives were shown to display anti-HAdV activity at low concentrations and with low cytotoxicity, thus displaying potential for further development as anti-HAdV drugs.[459,582]

The cardiotonic steroids, digoxin and digitoxin, which are used in clinical treatment of cardiac insufficiency, were demonstrated to display potent inhibitory effects against multiple HAdV species. The compounds alter the cascade of adenoviral gene expression, acting after initiation of early gene expression to block viral DNA replication and synthesis of viral structural proteins. Adenoviruses are dependent on the host RNA splicing machinery for alternative assembly of primary transcripts, and antiviral activity mediated by these steroids could be related to interference with this host cell function. However, the exact mechanism by which the compounds inhibit HAdV replication has yet to be fully characterized.[211]

Examples of other approaches to developing novel anti-HAdV treatment options include synthetic quinazoline–dione, pyrrole, and pyrrolopyrimidine compounds,[329,474] plant-derived compounds such as phenols from black tea or dioscin from air potato,[331,430] RNA interference-based methodologies,[278,279,356,529,586] or inhibition of protein kinases involved in the virus–host interaction, such as the cyclin-dependent protein kinase 7 (CDK7) inhibitor LDC4297 or the clinically approved CDK4/6 inhibitor palbociclib.[275,767] While the development of novel anti-HAdV compounds is a task of paramount importance, repurposing drugs that are well established in the clinical setting for other applications, such as nitazoxanide[162] and various agents indicated above, might represent an interesting alternative or complementary treatment modality for HAdV infections.

Immunotherapy

Measures supporting T-cell immunity play an important role in the armamentarium against invasive HAdV infections.[213,581,751] This is attributable to the current limitations of antiviral chemotherapy and the evidence that T-cell recovery, with reconstitution of HAdV-specific immune response, is essential for effective clearance of invasive infections in immunocompromised patients. The initial steps of antiviral treatment should therefore include tapering of immunosuppressive treatment, whenever possible.[245]

The proportion of HAdV-reactive T cells within the entire lymphocyte population of

individuals who had been exposed to the virus is low. Administration of unselected donor lymphocyte infusion (DLI) can still provide antiviral immunity, but the potentially high frequency of alloreactive T cells and the ensuing side effects are a major impediment to this approach.[420,679] Alternative strategies might consider NK cell–based immunotherapy to abrogate T cell–mediated alloreactivity.[68,218,293,334,588,732] In order to greatly reduce or prevent alloreactivity, isolation of HAdV-specific T cells from peripheral blood of the original stem cell donor has been exploited for treatment of HAdV infections in allogeneic SCT recipients not responding to antiviral chemotherapy, and different approaches to the generation of such cells have been established. Regardless of the HAdV species the donor has been exposed to, the HAdV-reactive T cells are expected to be cross-reactive with all HAdV types because the hexon, the main constituent of the viral capsid, is the immunodominant T-cell target containing several epitopes conserved among adenoviruses.[398] One of the early successful attempts of adoptive T-cell transfer was based on the isolation of donor-derived mononuclear cells, their stimulation *ex vivo* with HAdV antigen, and magnetic separation of reactive T cells secreting IFNγ, which included both CD4+ and CD8+ T cells. The cells were infused without further *in vitro* expansion, and the results indicated that the efficacy of this treatment does not depend on the dose of infused cells, because even very low numbers of HAdV-specific donor-derived T cells expand easily *in vivo* in the presence of constant antigen challenge mediated by the viral infection.[173] The most critical parameter for the success of treatment was appropriate timing, that is, the early T-cell transfer upon detection of viremia.[173] These observations indicated that rapid availability of T cells for adoptive transfer by methods requiring only short or no *in vitro* expansion is important. Based on this notion, a number of different approaches to selection of HAdV-specific T cells have been introduced. The considerable variety of approaches includes, for example, different types of MHC multimers facilitating clinical-grade enrichment of HAdV-specific or multivirus-specific T cells displaying low or absent alloreactivity.[589,670] The MHC multimer technology requires knowledge of immunodominant HLA-restricted peptide epitopes and facilitates the isolation of antigen-specific CD8+ T cells (MHC class I multimers) or CD4+ T cells (MHC class II multimers) of high purity.[152] Short-term *in vitro* expansion under GMP (good manufacturing practice) conditions can render adoptive T-cell transfer available in less than 2 weeks.[83,195,681]

Adoptive transfer of HAdV-specific T cells has been used for more than a decade against invasive HAdV infections failing to respond to virostatic agents.[173,283,537,538,594,595] In view of the apparent importance of timely treatment onset for successful control of the infection,[173] different sources of access to appropriate immune cells have been investigated.

In addition to various approaches to isolating HAdV-specific T cells from the respective SCT donors,[171,173,194,195,508] other sources of virus-specific T cells including third party donors have emerged.[232,536,644,752] Allogeneic third party donors are a particularly important alternative option in cord blood recipients, in patients allografted from HAdV-seronegative donors, and in SOTs from cadaveric donors where donor blood is not available. Healthy seropositive individuals have been exploited to generate partially human leukocyte antigen (HLA)-matched virus-specific T cells for adoptive immunotherapy.[19,152] However, clinical implementation of this approach requires the availability of a large pool of HLA-typed healthy donors, and the use of incompletely HLA-matched T cells bears the risk of complications resulting from alloreactive side effects.[535] Despite the existing concerns, this approach appears to be feasible, and current

clinical results are encouraging.[644] Another methodology pursued is the generation of virus-specific T-cell (VST) lines established from healthy donors with common HLA polymorphisms.[396,680] The employment of banked third-party-derived VSTs was demonstrated to represent an additional safe and readily applicable strategy for rapidly available treatment of severe viral infections in allogeneic SCT recipients,[396] thus further expanding the spectrum of clinical options for effective immunotherapy in immunocompromised patients. It is necessary to bear in mind, however, that the persistence of VSTs derived from peripheral blood is reportedly 14 to 90 days, thus potentially requiring multiple infusions.[501,680] By contrast, virus-specific T cells isolated from cord blood (CB) and expanded *ex vivo* showed long-term persistence after infusion and a decreased risk of GvHD owing to lower alloreactivity.[2,116] Moreover, CB-derived T cells have longer telomeres than do cells from adult donors, thus providing greater proliferative potential. This property coupled with extended *in vivo* persistence might obviate the need for multiple infusions.[116] Due to the large number of global inventories of frozen CB units, development of VST products derived from CB might be exploited as a novel platform for third-party antiviral T cells.[116] Owing to the fact that CB contains predominantly naïve T cells, the process of *ex vivo* VST generation currently takes approximately 1 month.[2] Since rapid availability of HAdV-specific T cells is apparently of great relevance, concepts providing off-the-shelf access to these cells certainly represent an attractive option.[116,221,310,680] However, in pediatric SCT recipients it was shown in a prospective study that the average time span between HAdV expansion in serial stool specimens above the critical threshold and the first appearance of adenoviremia was as long as 11 days[425] (Fig. 5.7). During this time span, it is also feasible to isolate and expand donor-derived HAdV-specific T cells to permit adoptive transfer before or upon the onset of viremia.[194] Alternatively, it may be conceivable, particularly in high-risk constellations, to generate virus-specific T cells already prior to allogeneic SCT, to ensure timely availability of targeted immune therapy. At the present time, due to the current limitations of treatment by virostatic agents, immune therapeutic approaches are an important asset in the armamentarium against HAdV infections in the immunocompromised setting. Adoptive transfer of HAdV-specific T cells is currently one of the most promising treatment approaches in high-risk patient populations,[455] which should ideally be performed in the context of clinical trials in specialized centers.

Vaccines

Outbreaks of HAdV infections, commonly caused by types E4 and B7 in closed or crowded environments such as military recruit camps, have led to fatal courses of pneumonia or myocarditis.[41,317,585] Such events have provided the basis for the establishment of vaccination programs for select HAdV types targeting specific high-risk cohorts of healthy individuals, with a focus on military personnel.[54] Vaccination programs in U.S. military trainees covering the most commonly occurring HAdV types E4 and B7 have been discontinued for more than a decade (see Clinical features-ARD in military recruits), and were resumed with a newly available FDA-approved live oral vaccine against these two HAdV types in 2011, to control the increased incidence of pulmonary infections during the cessation of vaccination. The vaccine comes as two tablets to be taken at the same time and is compatible with concomitant performance of other vaccinations. The viruses replicate once they reach the intestine, and the localized infection is usually asymptomatic, while mediating good systemic neutralizing antibody responses.

Reintroduction of the vaccine resulted in a dramatic decline in HAdV disease burden within the first 2 to 3 years.[104,546] It is recommended by the Department of Defense in enlisted soldiers entering basic training but may also be encouraged in other military personnel at high risk for adenovirus infection.[463] The vaccine is reported to prevent illness caused by these two virus types with an efficacy of 99.3% (95% CI, 96.0–99.9; $p < 0.001$), and the virus isolation rates have fallen dramatically after reinitiation of the vaccination program.[100,251,378] Updates on the vaccine are available on the Web site of the Centers for Disease Control and Prevention (www.cdc.gov/vaccines). The vaccine has only been approved for use in military personnel. This restriction might be attributable to the fact that the vaccine contains live, apparently not attenuated, HAdV strains that can be excreted to the environment and lead to an increased risk of clinically symptomatic transmission, thereby limiting broad applicability in the general population.[93]

As outlined above in the sections Epidemiology and Clinical features, HAdV types other than E4 and B7 have also been associated with febrile ARD in the military, including the types B14 (B14p1), B21, and B55.[93,316] In fact, HAdV-B14 became more common in the US military after reintroduction of the vaccination program covering the types E4 and B7,[546] and the types B14 and B55 have reemerged as prevalent strains worldwide among both military recruits and civilians. There is thus considerable interest in developing innovative HAdV vaccines based, for example, on the use of inactived or replication-defective viruses applicable in the general population.[93] Recently, recombinant trivalent and tetravalent live vaccines directed against the HAdV types B3, B7, and B55 ± B14 were successfully tested in mouse models, where high titers of neutralizing antibodies and effective protection against these virus types could be documented.[432,666] Optimization of the candidate vaccines could, in future, help in preventing respiratory diseases caused by these HAdV types.

ADENOVIRUSES AS VECTORS FOR VACCINATION, GENE THERAPY, AND CANCER TREATMENT

Please see the ebook for this section.

PERSPECTIVES

The exploitation of AdV-based vectors for cancer therapy and vaccination will expectedly play an increasingly important role in the future, provided that ongoing studies reveal adequate efficacy and safety. With regard to the clinical management of HAdV infections, particularly in the immunocompromised setting, recent insights emanating from studies on intestinal HAdV persistence and the role of virus shedding into the stool can set the stage for improved diagnostic

approaches. Consequently, optimized diagnostics will greatly affect the rational and timely onset of antiviral treatment, which was shown to be a prerequisite for successful therapy facilitating improved control of adenoviral infections. The encouraging data provided by studies testing brincidofovir in SCT recipients with adenoviremia are hampered by the fact that the producer has terminated clinical development of the drug, because the stringent requirements for clinical approval have not been met by the data available to date. Currently, the drug is still available on the basis of compassionate use, but the long-term supply is more than questionable. Due to the urgent need for effective treatment of HAdV infections in immunocompromised patients, loss of this therapeutic option in the future would have a negative impact on the ability to successfully control life-threatening infections by adenoviruses. This unexpected circumstance should stimulate experimental research directed towards the development of novel antiviral agents and/or towards repurposing compounds approved for other applications to expand the anti-HAdV treatment options. Combined and dose-adapted therapies will possibly improve the efficacy of treatment and reduce the toxicity of some commonly prescribed virostatic drugs. Detailed understanding of the mechanisms mediating HAdV reactivation and the transition from persistent to lytic infection during immunosuppression might provide the basis for rationally designed innovative therapeutic strategies.

If the safety, efficacy, and feasibility of HAdV-specific or multivirus-specific T-cell transfer can be firmly established, it is reasonable to envision that this treatment will be successfully employed not only in the settings of preemptive and symptomatic therapy but also as prophylaxis in high-risk patients to prevent severe viral diseases. The establishment of allogeneic T-cell donor registries of HLA-typed healthy donors tested for the presence of virus-specific T cells could serve as a rapidly available source for adoptive immunotherapy in immunocompromised patients lacking a suitable T-cell donor. Such T-cell donor registries might provide readily available off-the-shelf products facilitating rapid initiation of immunotherapy in patients carrying a high risk of life-threatening viral infections. Broad availability of banked third-party virus-specific T cells and/or virus-specific T-cell lines could mark the beginning of a new era in combating the threats of viral infections in immunocompromised patients in the foreseeable future. Finally, the omics revolution has advanced our knowledge about the HAdV and host-cell interplay at the RNA and protein levels, and novel insights gained from this research will expectedly lay the grounds for additional innovative treatment options.[765]

CHAPTER 5

Adenoviruses (Addendum to the ebook version)

Thomas Lion • William S. M. Wold

ADENOVIRUSES AS VECTORS FOR VACCINATION, GENE THERAPY, AND CANCER TREATMENT

The employment of AdV-based vectors for therapeutic applications is an attractive approach, because both human and nonhuman adenoviruses are biochemically stable, can be readily produced in high titers, induce both T- and B-cell responses, infect both dividing and nondividing cell types with broad tropism, do not readily integrate into the host genome and remain in episomal state, permit stable antigen expression, and are able to carry large gene expression cassettes of up to approximately 36 kb.[58,92,111,174] The ability to transduce cells with nonviral sequences of such size is provided by high-capacity adenoviral vectors, which do not display any virus coding sequences ("gutless vectors") and only maintain the ITRs (inverted terminal repeats) and the packaging signal of the viral genome.[24,25,42,45,128,136,169] This quality permits simultaneous gene transfer of several expression cassettes, large promoters, and some genes in their natural genomic context.[58] Additionally, adenoviral capsids can be modified to limit or broaden the tissue tropism, and permit genetic modifications to restrict or enhance viral replication in the target cells.[144] However, vector-induced toxicity may pose a barrier to safe, high-dose systemic therapy with HAdV vectors. Clinical use of HAdV-based vectors bears a number of risks including, for example, the possible recombination with wild type virus; organ damage (due to the hepatotropic nature of many commonly used HAdV types, the liver is a key site of virus-induced toxicity); febrile systemic inflammatory responses; neutro-/thrombopenia; and shock.[67] Lessons learned from early unsuccessful trials using HAdV-C vectors included the observation that the CAR receptor for vector attachment was not readily accessible on target cells due to its location on basal and lateral cell surfaces rather than on the exposed apical surface. Moreover, the presence of increasing neutralizing antibodies (NAbs) to the vectors was identified. These findings provided the basis for investigating vectors utilizing other receptors, and vectors that lack preexisting antibodies, including both HAdVs rare in the human population as well as nonhuman adenoviruses.[117] Adenoviral infections can be cleared by various mechanisms, and antiviral immune responses must be considered when designing AdV-based therapeutic approaches, in order to prevent rapid elimination of AdV vectors. The spectrum of AdVs vectorized to date for studies as vaccine, gene therapy, or oncolytic vectors is broad and involves representatives of several adenoviral species.[15,39,40,44,58,116,118,131,153,162,178]

A number of trials have employed AdV vectors for gene therapy, for example, to deliver the correct version of a gene (typically as complementary DNA [cDNA]) to patients displaying a mutation in that gene, and several vectors have been used as vaccines, but the vast majority of clinical trials with AdV vectors have been performed for cancer treatment. The AdV vectors

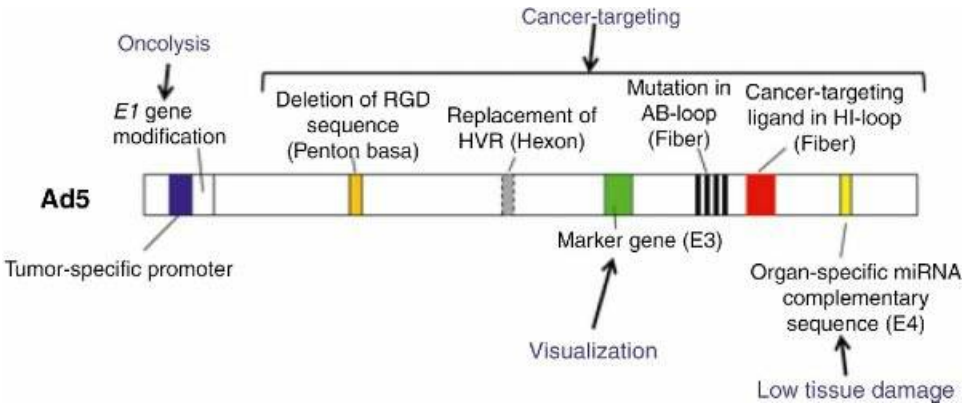
were shown by various trials to be very well tolerated, and the safety of application was documented by safe immunization performed in many soldiers with live HAdV-E4 and HAdV-B7 vaccines.[27,66,164]

AdV vectors can be replication defective (RD) or replication competent (RC), and while RD vectors serve to deliver transgenes into target cells, the intended mechanism of action for RC vectors is (conditional) virus replication in the target cell.[15,44,61,82–84,163] In RD-AdV vectors, one or more viral genes essential for replication are deleted. In early vector constructs, these deletions encompassed the essential E1 region (i.e., E1A and E1B) carrying the inserted transgene and the nonessential (in cultured cells) E3 region, which serves to increase cloning capacity. The broad tropism of these vectors facilitates infection of most cell types and transcription of the inserted transgene. The constructs typically included plasmids with inserted transgenes flanked by AdV genome packaging sequences for the generation of virions, the origin of genome replication next to the ITRs (inverted tandem repeats), as well as sites for recombination with the rest of the viral DNA to reconstitute adenovirions.[173] These vectors were grown using cell lines that stably express the necessary E1A and E1B proteins, such HEK 293, which was generated by immortalizing primary human kidney cells with sheared HAdV-C5 DNA and which carries E1A and E1B regions integrated into cellular DNA.[63] To prevent homologous recombination with the generation of RC vectors, other complementing cell lines lacking AdV sequences that overlap with the vector DNA (e.g., PER.C6 or N52.E6) were introduced.[50,140]

The induction of humoral and cell-mediated immune responses by AdV vectors can result in toxicity, reduced time of transgene expression, and interference with effective readministration of the vector.[147,192] Immunity induced by the common application of very high AdV vector doses of up to 10^{12} virus particles/kg may be different from natural infections with considerably lower amounts of virus.[145] Due to the leaky expression of other AdV genes, including particularly immunogenic virion proteins, by the early (first generation) vectors,[146] additional deletions involving the E4 region and/or the E2 region, and subsequent growth using cell lines that provide the E4 and/or E2 proteins, were introduced in the second generation of AdV vectors for improved control of antivector immunity.[87,126]

Components of the vectors can induce both innate and adaptive immune responses.[141,142,157] Innate responses are stimulated by pathogen-associated molecular patterns including elements of the viral capsid and viral nucleic acids. The so-called pattern recognition receptors (PRRs) driving innate responses induce the production of IFNs and different other proinflammatory cytokines and chemokines. Host antiviral responses are guided by initial binding to individual receptors that induce a signaling pathway leading to expression of chemokines and interleukin-1 (IL-1) mediated by the nuclear factor-κB (NF-κB). Upon virus entry into the cell, different PRRs including the toll-like receptors (TLRs) recognize viral DNA or capsid proteins and stimulate the IFN response, which, in turn, can block adenoviral replication by inhibiting E1A transcription and can eliminate virions from the cell.[161,190] Adenovirus entry generally occurs via endosomes where their double-stranded DNA is recognized by TLR9. Together with other factors, TLR9 leads to expression of chemokines and cytokines including type I IFNs, thereby augmenting the innate response and inducing the adaptive response.[8] Other PRR classes involved include (a) the nucleotide-binding oligomerization domain (NOD)-like receptors acting as cytosolic DNA sensors, resulting in pyroptosis (pro-inflammatory cell death), (b) RIG-1-like receptors

recognizing cytoplasmic viral RNAs and activating expression of type I IFNs via NF-κB signaling, similar to TLRs, and (c) cyclic guanosine monophosphate (GMP)-AMP synthase (cGAMP), sensing DNA and ultimately leading to IFNβ production.[155] In addition to innate responses, AdVs elicit strong adaptive immune responses, often mediated by preexisting immunity attributable to preceding gastric, respiratory, or ocular infections. At the level of humoral response, type-specific NAbs against components of the viral capsid, primarily hexon, play an important role. The antibodies can opsonize the virions, resulting in uptake and secretion of cytokines by activated macrophages.[184] Additionally, virus-specific cytotoxic T cells, which are directed primarily against conserved hexon epitopes and commonly display cross-reactivity to different AdV types, can mediate lysis of virus-infected cells.[93]



To date, hundreds of vaccine trials based on the use of HAdV-based vectors including a multitude of tumor-associated antigens (TAAs) and infectious agents have been performed, accounting for a large proportion of all clinical trials (https://clinicaltrials.gov/ct2/home; http://www.abedia.com/wiley/vectors.php). Many of the currently employed vectors are modified versions of HAdV-C5,[5,111,151,185] which is the best characterized vector system, but the use of these vectors has limitations both in cancer therapy and in vaccination strategies.[75] These limitations are related to the fact that HAdV-C5 is one of the most commonly encountered HAdV types that infects humans around the globe, and the resulting preexistent humoral and cellular immunity against this virus type, mediated particularly by virus-specific T cells, NK cells and cytokines, contributes to decreasing efficacy of the vaccines.[6,52,111] To circumvent the effects of preexisting immunity, alternative vectors based on rare human or animal adenoviruses have been developed. However, worldwide epidemiological studies would be required to determine the seroprevalence of individual HAdV types of particular interest as vectors (e.g., HAdV-B35).[1,99,111] Another important risk in employing HAdV vectors was discovered in a vaccination trial against HIV (HVTN 502 STEP), in which the control cohort of HIV-negative volunteers revealed a statistically significant increased risk for HIV acquisition during the first 18 months after vaccination in individuals displaying high NAb titers against HAdV-C5.[51] The trial was prematurely terminated, and the mechanisms of this side effect were attributed to acute inflammatory responses involving proliferation of HAdV-specific CD4 cells displaying mucosal tropism and elevated susceptibility to HIV infection.[16,71] These observations underlined the complexity of cellular events resulting from preexisting host immunity and HAdV-based vectors.[130,165] Nevertheless, the most extensive use of an AdV vector for vaccine purposes in humans has been immunization against HIV-1.[11,12,20,109,125,152,168,171]

In attempts to prevent problems arising from preexisting immunity, nonhuman adenoviral vectors and HAdV-based vectors derived from types of the virus supposedly displaying low prevalence have been developed. However, immunity against rare human and nonhuman adenovirus types can exist in human populations,[2] and individual HAdV types that are rare in Europe and North America can be highly prevalent in other geographic regions around the globe.[111] Moreover, cross-reactivity of human T cells targeting shared epitopes between different human and even nonhuman adenoviruses needs to be taken into account.[130] A number of alternative HAdV-derived vectors from different species of the virus have been considered based on the increased Nab-mediated resistance directed against HAdV-C5.[21] For example, HAdV-C6, D26, D28, D48, B7, B11, and B35 may display a low seroprevalence in North America and/or Europe, but these types display high prevalences in other parts of the world, thus rendering the

identification of globally applicable vectors difficult.[111] Nevertheless, the employment of HAdV types with low seroprevalence has been one of the main strategies to circumvent preexisting immunity, but the development of nonhuman adenoviral vectors represents an alternative approach of increasing importance.[102] Vectors of simian origin are most advanced,[114] and have reached clinical trials for treatment of various infectious diseases.[4,70,78,91,167] The prevalence of NAbs against simian adenoviruses is mostly negligible in humans, but the titers may be substantial in some geographic areas.[43,47,186] Additional strategies to overcome preexisting HAdV immunity involve the development of nonprimate adenoviral vectors of canine, bovine, porcine, ovine, or avian origin, which are presently in preclinical stages of testing.[111] Moreover, AAV (adeno-associated virus) vectors have been used particularly for human gene therapy, but this vector system seems to have limitations if larger transgenes (>4.8 kb) need to be transduced into target cells.[58] Improved understanding of cellular and molecular interactions between adenoviruses and host immunity is a prerequisite for future vaccine platforms to permit safer targeting of specific populations or even individuals according to their respective serology profiles, considering that exposure to several HAdV types is quite common.[111]

Although preexisting immunity influences the efficacy of HAdV vectors, and therefore poses an important challenge, other criteria are also relevant, because HAdV species and types use different receptors and vary in their tissue tropism and immunogenicity profiles. For example, animals used for preclinical studies, such as mice, do not display general expression of CD46 or desmoglein-2, thereby limiting the ability to test representatives of HAdV species relying on these receptors.[111]

Recent progress in understanding adenovirus biology has enabled improvements in vector safety and gene delivery efficiency in animal models, including genetic and chemical modification of the vector itself, new ways of vector administration, and pretreatment with drugs that suppress innate and adaptive immune responses.[131] The indicated modifications involve, for example, capsid engineering of adenovirus vectors to overcome early vector–host interactions (e-Fig. **5.1**).[65]

e-FIGURE 5.1 Cancer targeting and genetic modification of recombinant adenovirus vectors. The entry of HAdV-C5-based vectors into cells requires two distinct and sequential steps. The initial step is the interaction of the fiber protein with its cellular receptor CAR. The next step, internalization of the virus, is promoted by an interaction between the arginine–glycine–aspartic acid (RGD) sequence of the penton

base and αv integrins on the cell surface. Transductional targeting aims to affect the cellular entry of vectors. This type of targeting can create tissue tropism to new cellular targets by conferring novel ligand-mediated binding properties to receptors and by simultaneously inhibiting binding to natural receptors (detargeting). To detarget an adenovirus vector, the AB-loop of the fiber knob, which is the binding site for CAR, is generally modified. The ablation of binding sites in the adenoviral capsid with integrin and heparan sulfate proteoglycans (HSPG) might be useful to further reduce native tropism. Mutations in the E1 region are introduced or the *E1* gene is transcribed by a tumor- or tissue-specific promoter to restrict viral replication to targeted cancer cells, without affecting normal cells. The RGD sequence in the penton base is deleted and mutation in the AB-loop of the fiber knob is induced to suppress naïve tropism. Ligands are inserted into the HI-loop and AB-loop of the fiber to target cancer cells. The hypervariable region of the hexon is replaced to inhibit interaction with coagulation factor. Organ-specific microRNA (miRNA) targeting sequences are inserted into the E4 region to suppress tissue damage that results from immune reactions. Marker genes such as enhanced green fluorescent protein are inserted in the deleted E3 region for visualization. (From Yamamoto Y, Nagasato M, Yoshida T, et al. Recent advances in genetic modification of adenovirus vectors for cancer treatment. *Cancer Sci* 2017;108(5):831–837. Reprinted by permission of John Wiley & Sons, Inc. Ref.[179])

In attempts to overcome problems related to the use of HAdV-C5-based vectors, a method for direct cloning of adenovirus utilizing linear–linear homologous recombination has recently been introduced, facilitating rapid adenoviral genome modification via linear–circular homologous recombination. Novel adenoviruses can be reconstituted from plasmids bearing the selected adenoviral genome with the desired modification.[188] Moreover, oral administration, in contrast to intravenous injection, can elicit mucosal immune responses, thereby circumventing preexistent antivector immunity.[38] In this regard, representatives of HAdV species F, which are exclusively associated with gastrointestinal disease, might be interesting candidates for oral vaccination or gene therapy targeting the GI tract.[105,180]

Currently, adenoviral vectors are yet unable to induce protective immune responses against some weakly immunogenic antigens. The maximum doses of adenovirus-based vaccines are limited by vector-induced toxicity, leading to vector elimination and diminished immune responses against the target antigen. New technologies for improved adenoviral vaccine vectors are being developed to increase immune responses to the transgene, while maintaining a moderate vector dose. Different genetic-fusion adjuvant technologies that aim to improve antigen presentation in the context of adenoviral vector–based vaccines were recently presented.[119]

Due to the strong immunogenicity of adenovirus components, stimulation of immune responses by adenoviral vectors can be exploited as vaccines or antitumor agents. The employment of adenoviruses with oncolytic properties can induce antitumor immune responses, but it is necessary to maintain a balance between the induction of immune reactions directed against the virus and the tumor, by directing the response primarily towards the tumor. Oncolytic AdVs can be engineered to specifically replicate in tumor cells and lyse them, while healthy tissues are spared.[123,163] Selective replication of AdV in tumor cells can be achieved by generating small deletions in viral genes required for replication in normal cells (e-Fig. **5.1**).

Selection of specific deletions that can be compensated by cancer cell–related phenotype alterations permit restricted replication in tumor cells without affecting healthy cells.[13,62] A well-known example is a small deletion in the viral E1A gene, which prevents binding to and inactivation of the Rb (retinoblastoma) protein. In healthy cells, the factor E2F, which is required for transition to the S phase of the cell cycle, is bound and inactivated by Rb, thereby preventing replication of normal cells, and thus also replication and cell lysis by the AdV vector. The Rb pathway is commonly disrupted in cancer cells, and E2F production is increased, thereby permitting cell cycle progression and virus replication leading to tumor-cell lysis, regardless of the disrupted E1A/Rb interaction.[3,62] Similarly, a deletion in the viral E1B55K gene, which normally inactivates p53, fails to block the normal apoptotic defense pathway and restricts replication of the AdV vector in healthy cells. By contrast, tumor cells carrying mutant p53 are independent from a functional E1B55K gene and facilitate tumor-cell restricted virus replication.[62,179]

Another approach to achieving selectivity for tumor cells is the insertion of tissue- or tumor-specific promoters that are silent in normal cells, to control transcription of E1 genes driving viral replication. An example of this strategy is the establishment of an AdV vector designed with the E1A gene under control of the prostate-specific antigen (PSA) promoter for treatment of prostate cancer.[137,179] Other tissue-specific promoters used for control of E1 expression include, for example, TERT (telomere reverse transcriptase) for E1A expression in cancer cells with high expression of this enzyme or CEA (carcinoembryonic antigen) for colorectal cancer.[57,62,124]

After intravenous injection, Kupffer cells take up most of the AdV vector via scavenger receptors, apparently involving the hypervariable regions of hexon.[22,106] Kupffer cells die during the process but play a major role in the inflammatory response. The affinity of HAdV-C6 for Kupffer cells and hepatocytes is lower than that of the closely related type HAdV-C5, and introducing the hexon hypervariable region of HAdV-C6 into HAdV-C5 can reduce Kupffer cell uptake and liver infection.[79] Representatives of HAdV species B and D also display low affinity for Kupffer cells and liver infection.[143] To evade Kupffer cells and to increase the specificity of AdV delivery to cells lacking the CAR receptor, the fiber of HAdV-C5 has been swapped with that of other HAdV types.[113] In ongoing clinical trials, most of which are based on HAdV-C5-derived vectors, intratumoral injection is often the preferred mode of administration.[90,95] This approach decreases the systemic circulation of the vectors and their subsequent elimination by Kupffer cells and hepatocytes in the liver.[177] Moreover, it reduces their inactivation by NAbs and the complement system, and enables the presence of high vector concentrations at the tumor site, thereby promoting efficient cell transduction with the virus and limiting toxicity to other tissues. A potential disadvantage of this approach is tumor lysis limited to the site of injection and lacking effect on tumor cells at other (metastatic) sites. Another strategy to avoid neutralization of the AdV vectors and their sequestration in the liver or spleen by the mononuclear phagocyte system is the genetic or chemical/physical engineering of vectors coated with different polymers or other protective molecules.[30,33]

Current concepts of adenoviral vector–mediated cancer therapy do not only consider the possibility of virus replication and efficient tumor cell lysis, before the virus is eliminated by the immune system, but also attempt to integrate the antiviral immune response into the antitumor treatment approach. Tumor cell lysis mediated by the oncolytic virus leads to the release of TAAs, and the virus stimulates professional antigen-presenting cells by cellular PRRs, thereby

eliciting immune responses not only to the virus itself but also to TAAs.[107] This immune stimulation therefore facilitates antitumor responses directed also against metastatic cells not transduced with the viral vector.

The death of cancer cells can stimulate adaptive immune response by exposure to damage-associated molecular patterns in the tumor microenvironment (TME), thus inducing antitumor immunological memory. This phenomenon induced by the virus is referred to as immunologic cancer cell death, and the antitumor response is mediated by recruitment and activation of antigen presenting cells, followed by activation of T cells, leading to long-term memory. Antitumor immunity is of greater importance than direct lysis by the oncolytic virus because it permits the generation of tumor-specific T cells, and oncolytic AdVs were shown to induce such adaptive immune responses.[18,19,41,64,97,191]

In addition to the importance of cancer selectivity, the tumor cell–killing efficacy is an essential property of oncolytic viruses. Owing to the fact that AdVs have sufficient genome capacity to incorporate a therapeutic gene vector, various functional genes facilitating more efficient antitumor activity have been included in the design of oncolytic AdVs. These effector genes can be classified into different categories including immune-modulating genes, cytotoxic genes, tumor suppressor genes, and tumor antigens,[3,72,96,100,101,139,156,176,187] examples of which are outlined below.

A number of *in vivo* models have been established to study the efficacy of AdV vectors for cancer immunotherapy. The most common approach has been the use of human tumor xenografts in immune deficient mice, which only facilitates detection of direct oncolysis but permits neither the assessment of antitumor immunity nor the analysis of immunomodulatory molecules expressed by the oncolytic virus. Another model system involves animals that are semipermissive for HAdVs including Syrian hamsters and cotton rats, which display only limited viral replication and dissemination but permit studying rodent immune responses in syngeneic tumor constellations.[97,149] Humanized mouse models currently represent the most advanced *in vivo* test system permitting evaluation of human innate and adaptive immune cell reconstitution.[150] These models permit testing human tumor cells with full replication potential and studying human immune responses to treatment.[183]

One of the important challenges in treatment approaches using oncolytic AdV vectors against solid tumors is limited penetration of the vectors into the tumor bulk, which is attributable to the tight stromal extracellular matrix displaying, for example, fibroblasts and neovascular formation.[154,179] To overcome this hindrance, various strategies have been tested, such as the expression of an epithelial junction opener molecule by the vector,[181] the use of vasoactive molecules, hyaluronidase, or metalloproteinase.[3,62,77] Encapsulation of oncolytic AdV vectors in a gelatin hydrogel was demonstrated to increase the virus concentration in the TME for extended time periods and to decrease antiviral immune responses while improving antitumor efficacy.[76] Another approach to chemical shielding of AdV vectors has been the covalent linking of free amino groups on the capsid protein to the polymer polyethylene glycol (PEG).[110,121,175]

The TME can display highly immunosuppressive properties counteracting the immune response effects induced by oncolytic AdV vectors, thereby preventing successful therapy of large or metastasized tumors. The TME is complex and can display different levels of immunosuppression, which has provided the basis for establishing different classes of immune environment influencing the response to therapy.[17] Tumors may be poorly immunogenic and

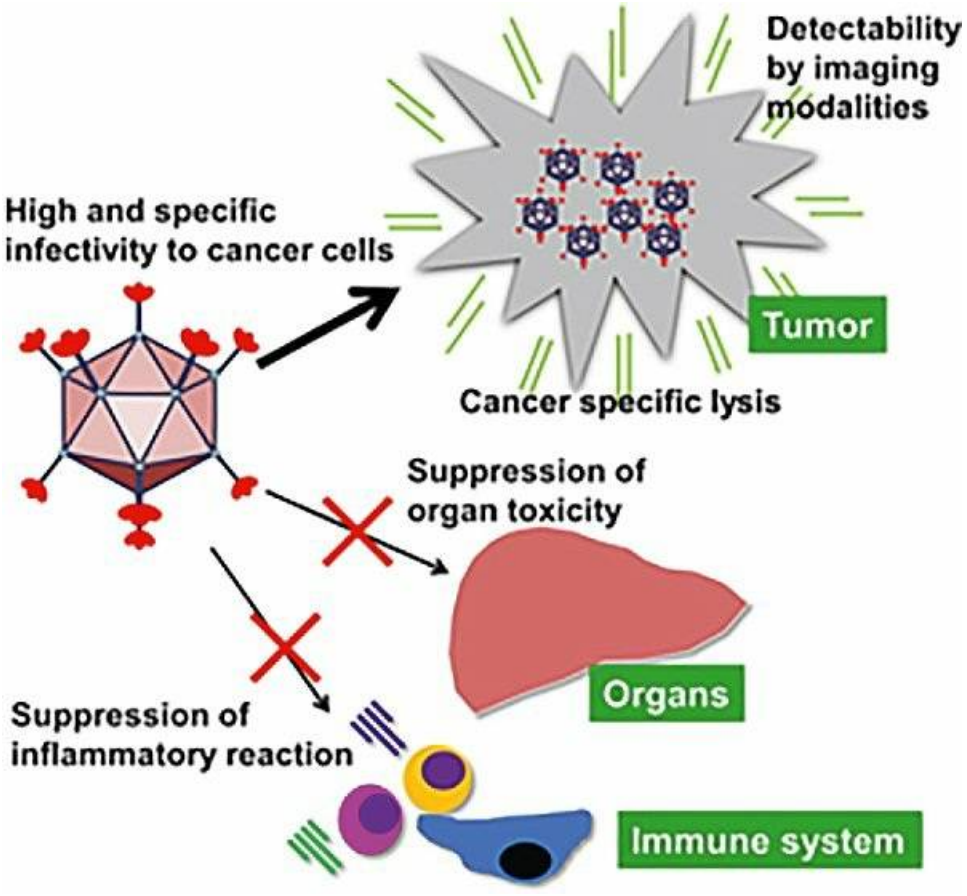
lack immune infiltrate (cold tumors) or display immune cells within the tumor mass (hot tumors), but these cells may not be functional due to inhibitory signals. Hence, increasing the infiltration by antigen-presenting cells or cytotoxic cells may not suffice to induce efficient tumor cell death.[17,144] To tackle this problem, AdV vectors can be modified to deliver molecules facilitating disruption of the TME or to express ligands for immune receptors. The efficacy of oncolytic viruses can also be increased by arming with immunostimulatory transgenes and immune targeting molecules to enhance activation of both innate and adaptive immune cells.[133,134]

The ability of AdV vectors to deliver therapeutic transgenes is being exploited in dozens of clinical trials with AdVs as oncolytic vectors or therapeutic vaccines. Current trials are mostly phase I or II,[10,60] but some ongoing trials against hepatocellular carcinoma, pleural mesothelioma, and bladder cancer are already phase III. Most trials exploit HAdV-C5-based vectors, but in a few instances, other human (HAdV-B11, -B3) or nonhuman (replication-defective simian adenoviral vectors ChAdOx1, ChAdOx2) are used as oncolytic viruses or vaccines (ClinicalTrials.gov).[54] Moreover, AAV (adeno-associated virus) vectors have been employed in successful clinical trials for treatment of hemophilia, and have been tested for antimalaria vaccination.[115,182]

A number of trials employing oncolytic AdVs with the modifications outlined above have been launched. Based on earlier results,[23,28] one of the ongoing trials (phase II) relies on the use of viral vectors expressing the cytokine GM-CSF (granulocyte and macrophage cell stimulating factor), thereby promoting the maturation of macrophages and dendritic cells (DCs) for tumor antigen presentation and initiation of cellular immune responses. This enhanced antitumor response might be sufficient to overcome the generally immunosuppressive environment of tumors. The interim results revealed successful induction of cytotoxic T-cell responses in patients with bladder cancer, and complete tumor response rates in the range of 50% after 6 months of treatment.[127]

Another ongoing trial in patients with glioma evaluates combined therapy with two replication-deficient AdV vectors, one of which expresses herpesvirus-derived thymidine kinase (TK) and the other Flt3L. Death of tumor cells carrying the AdV-TK vector occurs upon treatment with the prodrug ganciclovir, which is converted into an active antiviral compound by sequential phosphorylation (the first step being mediated by TK).[94] The ensuing release of TAAs leads to uptake and presentation by DCs.[53] Since Flt3 is a strong inducer of DCs facilitating their infiltration and expansion within the TME, combined treatment using the indicated AdV vectors resulted in tumor eradication in a murine syngeneic glioblastoma model. Preliminary data from a phase I clinical trial revealed tumor infiltration by inflammatory cells and possibly improved survival.[85,104] Malignant brain tumors have become an important target for treatment by oncolytic AdVs,[90,108,160] and several, albeit not all, early phase clinical trials revealed promising results.[81,86,112,166,170]

Additional preclinical and clinical studies are based on the use of AdV vectors modified to express cytokines, such as IL-12, with NK- and T-cell stimulating properties, with the aim to target the immunosuppressive TME and improve immune effector response against bystander tumor cells.[46] Other examples of oncolytic AdV vectors expressing immunostimulatory factors include constructs displaying IL-2, TNFα, or both. Tumor-restricted expression of these cytokines leads to T-cell stimulation, but also induces antitumor inflammation and production of



other cytokines and chemokines resulting in cancer cell necrosis and apoptosis.[69,138] These vectors have indeed demonstrated enhanced antitumor effects both in animal models and in clinical phase I trials for different solid tumors.[55,129]

Different phase I/II clinical trials, which are currently ongoing, explore the use of RD-AdV vectors expressing the costimulatory molecules CD40L and 41BBL. These molecules are important for maturation of DCs as well as full activation and survival of effector T cells, thereby promoting tumor clearance.[103,144] The concept of using armed oncolytic AdV vectors that combine direct tumor cell lysis and TAA release with the expression of transgenes promoting immune stimulation has the potential to enhance tumor-specific immune responses.

The strong immunogenic properties of AdVs enable their exploitation as vaccines,[7,11,14,32,48,56,80,91,159] but anti-AdV immune responses can hamper the efficacy of vaccination strategies. One of the currently pursued concepts for overcoming this issue is the sequential use of two distinct viruses to achieve effective vaccination. This approach involves the employment of an oncolytic AdV followed by administration of another virus not affected by the robust anti-AdV immune response, as recently demonstrated in a rodent tumor model: a decreased dose of an AdV vector expressing the immunostimulatory cytokine oncostatin was combined with ensuing application of an oncolytic Newcastle disease virus also expressing this cytokine. The combined treatment resulted in significant reduction of the tumor size, while keeping the toxicity profile low,[122] and similar cancer vaccine regimens combining the use of a tumor antigen–expressing AdV vector with a distinct virus also expressing tumor antigens[9,132] are presently investigated in phase I/II clinical trials.

The exploitation of TAAs for immune stimulation is somewhat limited by the fact that they usually represent self-antigens displaying lower immunogenicity. As recently reported, a bifunctional adapter molecule harboring a tumor-specific ligand and the adenovirus hexon domain DE1 for engaging antiadenoviral antibodies has been engineered. The adapter molecule binds to AdV-specific antibodies and retargets them to tumor cells, thereby converting antiviral immune defense into cancer immunotherapy. The therapeutic effect is largely conveyed by NK-cell-mediated stimulation of tumor-directed cytotoxic T cells. Systemic application of the adapter molecule can be T-cell engagers that permit targeting of cancer cell antigens by tumor-infiltrating lymphocytes. Continuous production of the bispecific T-cell engager molecules by locus-restricted oncolytic vectors may display reduced toxicity in comparison to systemic infusion, and may overcome key limitations of current oncolytic virotherapy, as demonstrated in experimental xenograft models combined with oncolytic AdV treatment. The strategy was successfully tested in a preclinical setting. Retargeting of preexisting or virotherapy-induced antiviral antibodies to tumor cells is an intriguing strategy permitting full exploitation of the immunotherapeutic potential of oncolytic viruses.[120] Another related approach is the implementation of oncolytic AdVs expressing bispecific T-cell engager antibodies.[49] The effect can be further enhanced by combination with CAR- (chimeric antigen-modified receptor) T cells, which have shown promising result in the treatment of hematologic malignancies but only limited efficacy in solid tumors. Recent data based on testing in animal solid tumor models indicate that combinatorial treatment using oncolytic AdVs armed with a bispecific T-cell engager and tumor-targeting CAR-T cells has the potential of improving antitumor efficacy, thus paving the way for evaluation in clinical trials.[172] The inhibition of tumor-mediated suppression of immune effector cells can be achieved by using antibodies against the immune checkpoints involved, such as PD-1 (programmed death receptor), PDL1 (programmed death ligand), or

CTLA-4 (cytotoxic T lymphocyte–associated protein; CD152). The use of monoclonal antibodies such as pembrolizumab (anti-PD-1 antibody) or ipilimumab (CTLA-2 antibody) can increase T-cell activation and antitumor immune response.[62,73] Combination of immune checkpoint blockade with oncolytic AdV therapy resulted in synergistic antitumor effects in preclinical models,[29,74,88,89,135,158,189] and clinical trials testing this approach are presently ongoing. Stimulation of the immune system against tumor antigens can also be achieved by coating oncolytic AdV vectors with clinically relevant MHC class I tumor epitopes, such as MAGE-A1 (human melanoma-associated antigen A1).[26] The exploitation of oncolytic AdV vectors as carriers for the delivery of bioactive drugs was also exemplified by loading a naturally occurring histidine dipeptide with significant antiproliferative activity, L-carnosine, on the viral capsid, which demonstrated a significant reduction in tumor growth in xenograft models.[59] Combinations of oncolytic AdV vectors with chemotherapeutic agents such as cyclophosphamide, cisplatin, 5-fluouracil, gemcitabine, mitomycin, or doxorubicin have also been tested,[31,62,68,98,148] and various clinical trials in different solid tumors are currently being pursued. In order to pave the way to broad clinical exploitation of oncolytic AdVs, the required specific properties of the vectors have been defined, including high and specific infectivity in cancer tissues, cancer-specific lysis, inhibition of organ toxicity, suppression of undesirable inflammatory reactions, and detectability by imaging techniques (e-Fig. **5.2**).[179]

e-FIGURE 5.2 Future directions for oncolytic virus research. The highlighted five characteristics would be required for progress in the development of oncolytic viruses.

An alternative to the use of RD-vectors was the development of a novel AdV-vector type termed SC (single-cycle)-AdV.[34] In contrast to RD-AdV vectors that display deletions involving the early genes, the SC-AdV vectors are engineered to contain deletions of late genes of the virus to preserve replication of DNA but prevent production of infectious progeny viruses. The preferred late AdV gene targeted for deletion has been the viral cement protein pIIIA, because cells can produce sufficiently high amounts of this protein to compensate the deletion. The retained ability of these vectors to amplify DNA can be exploited for amplification of vaccine antigen genes.[14] The SC-AdV vectors were shown to produce significantly more antigen than RD-AdV vectors, and generated more robust and persistent immune responses in different animal models upon mucosal or intramuscular immunization.[36,37] Since these vectors apparently mediate protection after a single immunization, there may be no need for vaccine boosts, thereby evading the problem of vector-induced antibodies affecting rechallenge by the same vector. The oncolytic properties of SC-AdV vectors could also be demonstrated,[35] and the vectors are moving towards clinical translation.[14]

Adeno-associated virus as a vector for gene therapy
Summary and conclusions

INTRODUCTION AND HISTORY

Parvoviruses are small, nonenveloped viruses with a linear, single-strand DNA (ssDNA) genome

of about 5,000 bases. The family *Parvoviridae* (Table 6.1) contains two subfamilies: *Parvovirinae* and *Densovirinae*.[91] The latter infect invertebrates and will not be described in detail in this chapter. The *Parvovirinae* are divided into eight genera: *Amdoparvovirus*, *Aveparvovirus*, *Bocaparvovirus*, *Copiparvovirus*, *Dependoparvovirus*, *Erythroparvovirus*, *Protoparvovirus*, and *Tetraparvovirus*. The adeno-associated viruses (AAVs) among the dependoparvoviruses require coinfection with a helper virus for productive infection. The others are autonomous, and although most require the host cell to go through S phase for viral DNA replication but do not induce cell division, some may be able to replicate in nonmitotic cells by other mechanisms related to the DNA damage response.[107] The AAV helper virus is most commonly an adenovirus, but herpesviruses have also been shown to help productive replication.

In the 1920s and 1930s, feline and raccoon diseases characterized by enteritis, panleukopenia, and cerebellar ataxia were recognized as being of viral origin. In the late 1940s, a similar disease was noted in mink; in 1952, it was determined that those diseases were caused by similar small, DNA-containing viruses.[363] Parvoviruses were isolated from rats (Kilham rat virus),[196] and the H-1 virus isolated from human tumor tissue–infected hamsters.[362] Between

1960 and 1962, small particles were observed within adenovirus preparations by electron microscopy, and AAV was identified that depended on coinfection of the cells with adenovirus for replication[21,163,277] or on herpesviruses.[54] The human parvovirus B19 was first identified in 1974 during screening of a diagnostic blood sample (with the code B19). The B19 virus is associated with transient aplastic crisis in patients with sickle cell disease, with the childhood "fifth" disease, and with postinfection arthralgia in older patients. In 1978, a new virus of dogs (canine parvovirus [CPV]) caused myocarditis and enteritis in dogs, and that was derived from a preexisting virus similar to feline panleukopenia virus (FPV).[378] Many additional parvoviruses have been isolated from animals and cell cultures, and by discovery of viral DNA using cloning or sequencing approaches.[186,187,332] Many of the viruses grow poorly or not at all in cultured cells, and many also have not been associated with overt disease in their natural hosts.

BIOLOGY OF THE PARVOVIRUSES

The parvoviruses have small (~26 nm diameter) and structurally stable capsids that bind host cell receptors and small ssDNA genomes with few genes that control their interactions with their hosts, and they replicate in dividing cells, in association with a DNA damage response, or in the presence of a helper virus. Parvoviruses are widespread, and sequencing of DNA shows that several parvoviruses are likely to be infecting most invertebrate and vertebrate animals. The presence of integrated viral DNA fragments in the genomes of many different vertebrate and invertebrate animals also indicates that related viruses have been infecting animals for millions of years.[34,57,186,189,221,281] The viruses transmit between hosts by routes that include fecal–oral, urine, and respiratory spread, and the capsids are stable in the environment and readily transmitted by contaminated fomites. Entry into the body likely involves infection of dividing epithelial or lymphoid cells of the upper respiratory tract, oropharynx, or intestine. The viruses are structurally and genetically simple, and do not induce the host cell to proliferate, and generally appear not to manipulate the host immune responses to high levels. Where the mechanisms have been defined, the host and tissue tropisms are determined by the requirement for dividing cells of the autonomous parvoviruses, by host receptor binding, or by the cell-specific controls of viral gene expression.

AAVs are cryptic viruses and are not clearly associated with any pathology. The AAVs are widespread, and natural hosts appear to include most vertebrates (see Table 6.1). Viral persistence is likely related to the ability of the entire viral genomic DNA to integrate into the host genome, and AAV DNA sequences may be found in many tissues.[134,304] If AAV infects a healthy cell in the absence of a helper virus, the viral genome does not replicate but may establish a persistent infection by chromosomal integration or by forming stable extrachromosomal concatemers of AAV genomes[119]. The integrated AAV genome may be rescued by superinfection of the cells with a helper virus.[76] Extrachromosomal or integrated latency is likely functionally equivalent if the infected cell does not divide; however, in dividing cells, the nonreplicating extrachromosomal AAV DNA would be diluted out. Stressing host cells may allow some limited AAV replication, and this can be achieved by exposure of the cell to genotoxic conditions that include ultraviolet irradiation, ionizing radiation, and cycloheximide.[323,393]

There are complex two-way relationships between AAVs and their helper viruses. AAVs can inhibit the replication of adenovirus in a process that depends on the relative amounts of the two viruses and on the temporal relationship of the coinfection.[68,69] Adenovirus inhibition likely results from AAV Rep protein inhibition of heterologous promoters, and that inhibition is also seen in coinfections of AAV and SV40, papillomavirus, and some herpesviruses.[159,198,209,396]

TAXONOMY AND CLASSIFICATION

The Family *Parvoviridae* has unenveloped capsids of about 25 nm diameter with icosahedral symmetry composed of 60 copies of the capsid proteins. The nucleic acid is single-stranded linear DNA between 4 and 6 kb in length. The classification is frequently updated with changes in the nomenclature.[91] The two subfamilies, *Parvovirinae* and *Densovirinae*, are distinguished mostly on their abilities to infect vertebrate versus invertebrate hosts, respectively. The *Parvovirinae* are subdivided into ten genera: *Amdoparvovirus*, *Artiparvovirus*, *Aveparvovirus*, *Bocaparvovirus*, *Copiparvovirus*, *Dependoparvovirus*, *Erythroparvovirus*, *Loriparvovirus*, *Protoparvovirus*, and *Tetraparovirus*. The *Densovirinae* are subdivided into eight genera (see examples in Table 6.1). Genera are defined by their genomic and biological properties and by their DNA sequence relatedness, biological host ranges, and/or capsid antigenicity.

There is significant variation in the details of the viral genomes and gene expression. Protoparvoviruses may package mostly one DNA strand, or package both DNA strands in variable proportions, and the ssDNA genome has different hairpin structures at each end. There are generally two messenger RNA (mRNA) promoters and a single polyadenylation site near the 3′ end of the -ve strand DNA. The Erythroparvoviruses are related to the B19 human parvovirus, and mature virions contain equivalent proportions of positive and negative sense ssDNA, the DNA molecules contain inverted terminal repeats (ITRs), and there is a single transcriptional promoter and two polyadenylation signals. Amdoparvoviruses are related to the Aleutian mink disease virus (AMDV), whereas the bocaparvoviruses are related to bovine parvovirus and the canine minute virus and include many viruses of humans and other hosts. Dependovirus virions package equivalent numbers of positive- or negative-strand ssDNA genomes, with ITRs of approximately 145 nucleotides—of which the first approximately 125 nucleotides form a palindromic sequence.

Structure of Capsid and General Properties

The particle has a molecular weight (MW) of 5.5 to 6.2 × 10^6 daltons. The buoyant density of the intact virion in cesium chloride (CsCl) is 1.39 to 1.42 g/cm^3,[359] and the sedimentation coefficient of the virion in neutral sucrose gradients is 110 to 122. The virions are resistant to inactivation, even for 60 minutes at pHs between 3 and 9, or at 56°C, but can be inactivated by formalin, β-propiolactone, hydroxylamine, and oxidizing agents. The capsids have T = 1 icosahedral structures and are assembled from 60 copies of between 2 and 4 forms of a single structural protein (with varying names, but generally virus protein [VP]: VP1, VP2, and VP3), which package the linear, ssDNA genome[365] (Fig. 6.1). The capsid structures of all of the parvoviruses share an overall similar structure[4,192,335,365,376,391] (see Fig. 6.1). An eight-stranded, antiparallel

β-barrel constitutes around one-third of the sequence of the structural protein, and some of the large loops connecting the strands of the β-barrel make up the capsid surface. The capsid surface determines host and tissue interactions, forms receptor-binding sites, and makes up the epitopes recognized by antibodies. Antiparallel β-ribbons form a cylinder about the icosahedral fivefold axes, with a channel through the capsid in many viruses.[96,122,192] N-terminal sequences of some VP molecules (VP2 in the Protoparvoviruses) are externalized through that channel, and they may be cleaved by host or other proteases to a shorter form (VP3 in the Protoparvoviruses). DNA packaging also occurs through the channel at one fivefold axis, leaving a short sequence (~20 nucleotides) of the 5′ end of the genome outside the capsid after the genome is packaged, and that has the replication protein (NS1) attached.[95,96,291] The capsid surface structures vary, but they often include one large or three smaller spike-like protrusions surrounding the icosahedral threefold axes of symmetry, depressions about the fivefold axes, and dimple-like depressions at the icosahedral twofold axes[73,365,391] (Fig. 6.1).

(Courtesy of Agbandje-McKenna, University of Florida.)

Conformation-dependent epitopes are important targets of neutralizing antibodies on the exposed surface of the capsids of all of the viruses of vertebrates, and where it has been examined much of the capsid surface appears to bind antibodies, apart from the depressed regions.[151,319,349,366,384,400] Linear epitopes recognized by antibodies include the exposed N-terminus of VP2 of parvovirus full capsids and the N-terminus of VP1 for the B19 parvovirus.[113,213,257]

Functions of the Capsid Proteins

Most autonomous parvovirus and AAV capsids contain combinations of three overlapping proteins—MWs of 80,000 to 86,000 (VP1), 64,000 to 75,000 (VP2), and 60,000 to 62,000 (VP3)—although AMDV, B19, and simian parvovirus assemble from only VP1 and VP2. For the autonomous viruses, VP1 and VP2 are generally derived from alternatively spliced viral messages, and VP3 is generated in DNA-containing capsids by proteolytic cleavage of VP2.

The unique regions of VP1 of most or all parvoviruses contain a calcium-dependent

phospholipase A_2 (PLA_2) enzymatic activity that is thought to be buried within the capsid after assembly, but which becomes exposed during cell entry.[123,354,403] The VP1 unique sequence is exposed on the surface of B19 capsids, which may reflect a difference in the structure of that virus.[113(p1),114] The PLA_2 activities of the different viruses differ significantly.[58] Peptides near the N-terminus of VP1 contain basic amino acid motifs that likely function as nuclear localization motifs during cell entry and capsid assembly.[165,224,371,383]

Genome Structures and Organizations

All parvoviruses of vertebrates have similar genome structures, with terminal repeats required for DNA replication, nonstructural protein genes on the left half of the genome (the 3′ end of the –ve strand DNA), and capsid protein genes on the right half of the genome (Fig. 6.2). Smaller proteins are produced by alternative splicing of some viruses and include the NS2 protein in the viruses similar to minute virus of mice (MVM) and the NP1 protein in the bocaviruses (see later discussion). The functions of the noncoding sequences between the capsid protein and the 5′ terminal hairpin of the autonomous parvoviruses are less well understood; however, in the B19 viruses, there is a short open reading frame (ORF) encoding a protein (p11), and that region may also be involved in regulating the packaging of the viral DNA.[96,97] The smaller ORFs include the NP1 protein in several viruses, the 11 kDa protein in the B19 human parvovirus, and small ORFs that overlaps the VP1 and VP2 N-terminal sequence in an alternative reading frame—the small alternatively translated (SAT) protein of many autonomous parvoviruses, and the assembly activating peptide of the AAV-like viruses.[145,261,345] Other alternatively spliced RNA products have been identified for many viruses, although the predicted proteins produced have generally not been characterized.

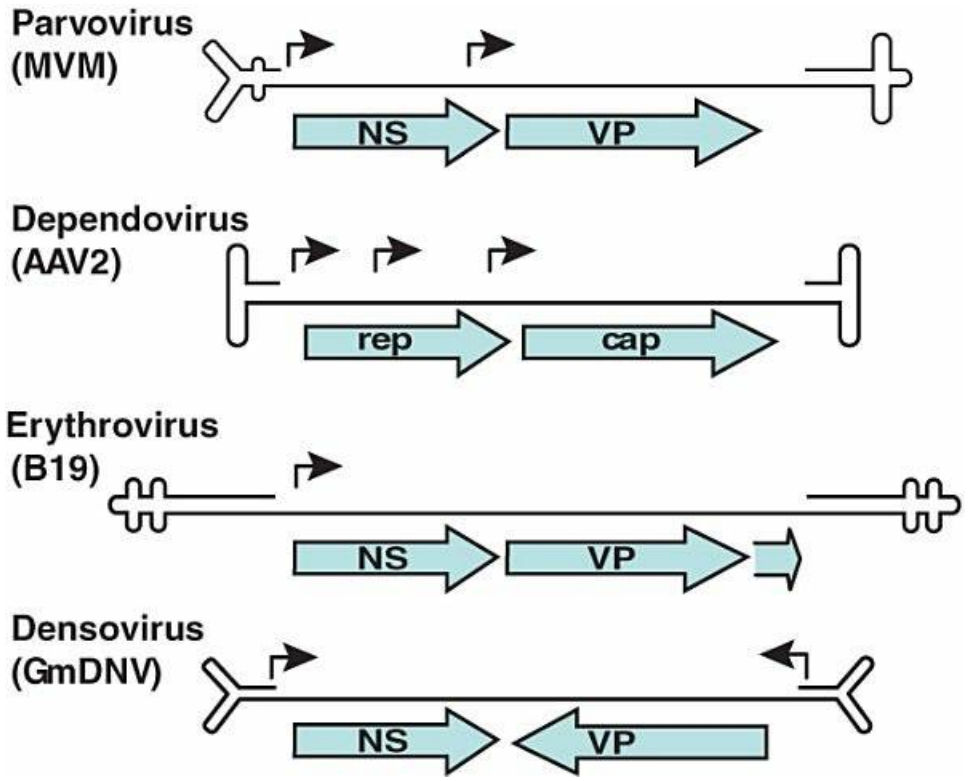

FIGURE 6.2 The genome structures of different members of the *Parvoviridae*, showing genomes of three of the nine genera, the parvoviruses, the dependoviruses, and the erythroviruses, indicating the promoters and open reading frames of the major genes, nonstructural and viral protein. The terminal hairpins are magnified approximately 20-fold relative to the intervening single-stranded sequences.

Epidemiology and Antiviral Immunity

Many autonomous parvoviruses, including CPV, FPV, porcine parvovirus (PPV), and B19 human parvovirus, cause acute infections of their hosts that last for fewer than 10 days. The virus is cleared by the host immunity, and infectious virus is not subsequently shed, although viral DNA may persist in many tissues,[13,164,342] and even in bones recovered from archeological sites.[255] Some parvoviruses show prolonged replication and persistence: Rodent parvoviruses may persist in the kidneys and be shed in the urine, although that is mostly seen in immune deficient mouse strains, while AMDV persists in mink when antibodies are present and may replicate for the life of the animal.[10,43,178,293] For B19 in humans, rare chronic persistent infections occur in individuals who are immunosuppressed, or who do not develop effective immunity.[128,206]

The mechanisms of transmission among the parvoviruses vary and in many cases are not well defined. Carnivore parvoviruses such as CPV and FPV are spread by fecal–oral transmission.[235,236,278] Some rodent parvoviruses also replicate in the intestine as well as systemically, and may also be transmitted through urine after replication in the kidney.[25(p),157,174,215] The human B19 virus replicates primarily in the bone marrow but develops

a very high level viremia—and it is thought to be transmitted by respiratory routes after virus is shed into the lungs or other respiratory secretions.[50,51]

Cell-mediated immunity likely assists in recovery from infection; however, humoral immunity alone can protect animals against infection and is also important for recovery from infection, as immune immunoglobulin G (IgG) can arrest CPV replication in dogs and can terminate chronic human infections by the B19 parvovirus.[51] Antibodies produced in mink reduce titers of AMDV but do not eliminate the virus, thus allowing the persistent infection to occur.[8,10,43,178]

No clear role for antigenic variation in the epidemiology of the parvoviruses has been revealed. Viruses of different genera or species are distinguished by polyclonal sera, but little antigenic variation has been demonstrated within most virus species, and any epidemiologic significance is not known. Some changes altering the antigenic structure of a virus may also alter host range or other properties so that multiple selections may be occuring.[14,72,214,260,314] For MVM, antigenic variants were readily selected with neutralizing monoclonal antibodies in tissue culture or in persistent infections of SCID mice,[225] although it is not known whether similar variation occurs in nature.

Genetic Variation and Evolution

These DNA viruses are replicated by host cell DNA polymerases, but the error rates are likely much higher than seen for the host genomic DNA. The single-stranded DNA genome may make it susceptible to modification, and the mode of DNA replication may lead to significant sequence variation. The temporal rates of sequence variation may be high ($>4 \times 10^{-4}$ variations per site per year) when measured over defined periods.[22,229,330,331,375] MVM mutant strains grown persistently in immune deficient mice or under monoclonal antibody selection showed variation at several sites owing to host or immune selection.[314] Recombination is likely quite common among the parvoviruses.[232,329]

All parvoviruses are related through a distant common ancestor, and the sequences can be subdivided into several clades that show some correlations with the hosts of origin,[232] although there are many variants. Parvovirus-related sequences are integrated into the genomes of many vertebrate and invertebrate animals, mostly as partial or degenerate sequences, which would not generate infectious virus and are less likely to recombine productively with infectious viral sequences.[34,57,161,186,187,221] Despite the high rates of variation seen among contemporary viruses, the genomes of viruses that share significant homology may have diverged millions of years ago. This is seen in the finding of syntenic integrated parvoviral sequences in related mammals, showing that integration occurred prior to the host evolutionary divergence, often 10s of millions of years.

Several different parvoviruses likely infect most host species, and there are numerous examples of viral DNA of otherwise unknown parvoviruses in human or animal tissues and feces[44,126,341] —although fecal viruses may also derive from materials in the diet. For example, within cows, three parvovirus sequences were discovered by searching for nonhost DNAs[11], several erythroviruses have been identified in humans and other primates, and those are related to a chipmunk parvovirus.[75,164,179,332] Sequences of multiple viruses were identified in rodents, bats, opossums, birds, and cattle in Brazil[346], and similar numbers of variant viruses were found

in different wild birds in Australia[370] The human B19-like parvoviruses include three distinct clades that differ by 5% to 20% in sequence; within each clade, the viruses differ by less than 1% to 4%[132,328], and viral sequences recovered from skeletal remains suggest a slower evolution over longer time periods.[255] Many parvovirus strains have worldwide distributions, although geographic clustering may occur.[55,253,375] Significant variation (of up to 16%) was seen in the genomes of AMDV isolates, perhaps owing to the cocirculation and coinfection of animals with variant virus strains.[318,373] Because that virus can form persistent infections with continuously circulating virus, and antibodies appear not to protect, mixed and super infections likely occur.[269]

Infection Pathways

Parvoviruses bind to one or more cell surface receptors, are endocytosed and then traffic within the endosomal system, and are released into the cytoplasm in the vicinity of the nucleus, and the DNA with or without the capsids enters the nucleus. There appear to be no substantial differences between the general features of the infection pathways used by the autonomous viruses and AAVs (Fig. 6.3).

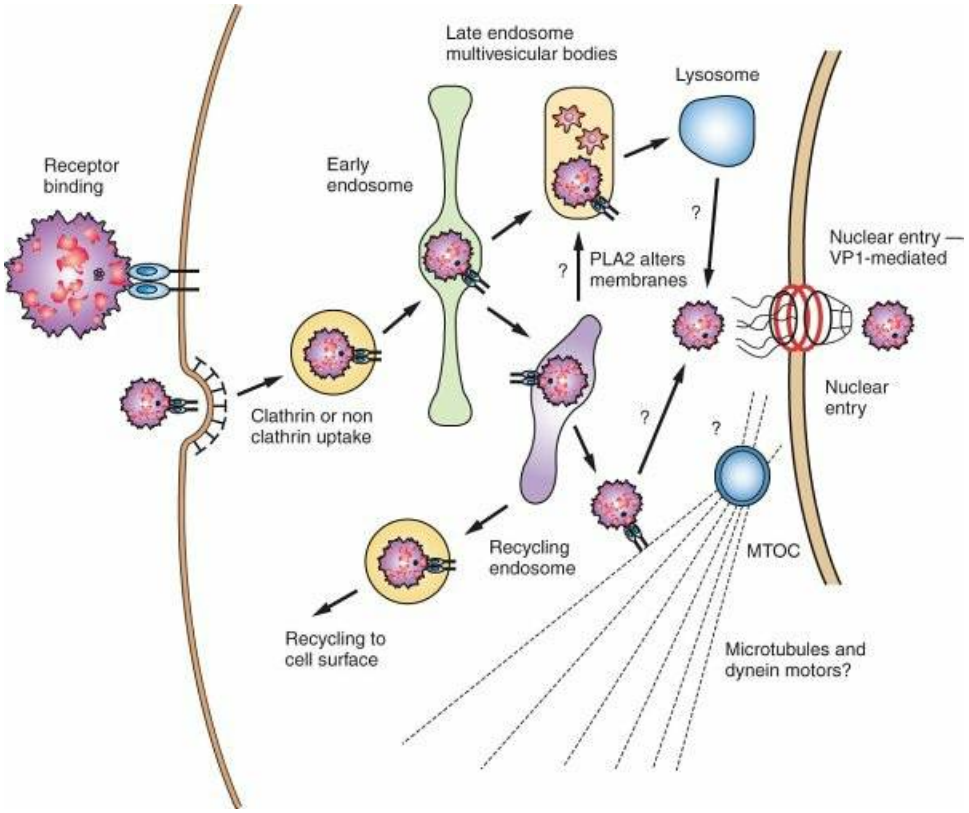

FIGURE 6.3 A general summary of the known or proposed infection pathways of viral capsids from the cell surface to the nucleus, as exemplified by the canine parvovirus binding to the transferrin receptor and being taken up by clathrin-mediated endocytosis. The later steps of the pathway, including sorting the endosomal system of the cell and trafficking within the cytoplasm and into the nucleus, may vary between viruses and are still not completely defined.

Capsid Structures and Cell Infection

The parvovirus capsid is a stable sphere of about 26 nm in diameter (see Fig. 6.1). Flexibility is required during infection to allow genome release and to expose protein structures from within the capsid. The VP1 unique region (between 40 and 230 residues long, depending on the virus) is not required for capsid formation or DNA packaging,[368,371] but that sequence includes a basic amino acid motif, which likely acts as a nuclear localization sequence (NLS), and a phospholipase A2 (PLA_2) enzyme structure, which is active when released from the capsid.[224,239,311,354,371,403] The PLA_2 activity varies widely, with that of PPV showing approximately 100-fold higher PLA_2 activity than the AAV2 or the human B19 parvovirus.[58] The PLA_2 modification of the lipid components of the endosome may allow more efficient viral release.[123] The VP1 unique region has also been reported to contain a proteinase activity.[204]

The capsids show various surface features, including raised regions around the threefold axis of symmetry, a depressed region spanning the twofold axis, and in many cases a pore at the fivefold axis of symmetry that runs through the capsid (e.g., Refs.[5,249,290,335,336,365]) (see Fig. 6.1). The parvoviruses infecting invertebrates show a relatively smooth surface.[191,282] The host ranges and tissue tropisms of CPV and FPV, and of MVM variants, are controlled by a small number of residues on the capsid surface.[3,5,26,185,214]

Variability and flexibility in the capsid structure are important for viral infectivity and capsid functions—in particular, the externalization of VP1 and VP2 N-terminal sequences. Flexibility of surface loops occurs in CPV, FPV, MVM, and AAV capsids at different pHs, and after removal of Ca^{++} or other ions from capsids.[94,321,334] For many parvoviruses and AAVs, the VP1 or VP2 N-terminal regions can be exposed to the exterior in DNA-containing capsids, or after certain mild treatments, and that exposure was increased by changes of residues surrounding the fivefold axis of icosahedral symmetry.[67,93,122,203,291,371]

Cell Receptor Binding

Various molecules mediate parvovirus cell binding and infection. One cellular receptor for parvovirus B19 is globoside or erythrocyte P antigen (glycosphingolipid tetrahexoseceramide), and people who genetically lack P antigen (p phenotype) appear to resist parvovirus B19 infection.[39,48,49,190] However, the role of globoside binding is not well understood, and in some studies capsids did not bind the globoside *in vitro*, and its role may occur after cellular uptake[39]. The α5β1 integrin has been reported as a receptor for infection of erythroid progenitor cells.[380]

Transferrin receptor type 1 (TfR) is used by CPV and FPV for cell infection, and receptor binding controls differences in the host ranges of those viruses.[167,275] Capsids bind through contacts between the TfR apical domain and the capsid threefold spike.[56,214,274] CPV and FPV also bind to some forms of sialic acid but that binding appears not to mediate infection.[223] MVM capsids bind sialic acids, primarily *N*-acetyl neuraminic acid, and hemagglutinate mouse erythrocytes, and cell infection can be blocked by neuraminidase treatment of the cells prior to virus binding.[95] Differences in affinity of binding result in different pathogenicity in mice.[5,152,226]

The AAVs have broad cellular tropisms and infect many hosts. Infection may require more

than one cell surface molecule, and different viral strains use different receptors. Different AAVs have been reported to bind sialic acids, heparan sulfate proteoglycan,[194,357] growth factor receptors,[289,298,382] and integrins.[356] Tropisms of AAV serotypes are at least in part associated with receptors on target cells, and retargeting AAV capsids to alternative receptors may allow transduction of additional cell types.[156,222,258,283,390]

Endocytosis and Endosomal Release

Parvoviruses require receptor-mediated endocytosis for cell infection. Capsids of CPV, H1, and MVM are taken up rapidly into cells by clathrin-mediated endocytosis, and are associated with clathrin-coated pits and vesicles after uptake.[101,220,276] Infection is inhibited by treatment of cells with lysosomotropic agents ammonium chloride (NH_4Cl), chloroquine, or bafilomycin A1, indicating that low endosomal pH is required for infection.[30,276,311] After uptake, capsids may be detected in endosomes by antibody staining or *in situ* hybridization for a number of hours.[154,276,355] The infectious process may be slow, and CPV infection could be blocked by anticapsid antibodies injected into the cytoplasm of cells 4 or more hours after virus uptake.[371,372]

Uptake and endocytosis of the AAV capsids follow similar pathways, and infection may require signaling after receptor binding.[108,288,322,404] Many studies have been aimed at improving the uptake and transduction of cells by use of variant AAVs, or by various approaches to capsid engineering.[65,217,303] Infection is influenced by the activity of the proteasome system, as proteosomal inhibitors can enhance the infection of many AAV vectors.[240,395] The capsids may be retained for long periods in the endosomal system, with some models indicating transport to the trans-Golgi compartment, and there may be a delay before the capsids escape into the cytoplasm.[29,36,109,117,404]

The mechanisms of capsid escape from endocytic vesicles into the cytosol are not well understood, but those likely involve the PLA_2 activity of the VP1 unique region, which enhances the release of the capsids into the cytoplasm, perhaps by modifying the endosomal membrane.[58,113,141]

Transport Within the Cytoplasm

Capsids are released into the cytoplasm from vesicles in a perinuclear location, and further processing and trafficking events likely occur before transport to the nucleus. Cell infection by MVM is affected by the activity of the proteasome, because infection can be reduced by proteasome inhibitors of the chymotrypsin-like activity (*N*-tosyl-L-phenylalanine chloromethyl ketone and aclarubin) but not by inhibitors of the trypsin-like activity, but without clear evidence for ubiquitination or of direct proteolytic digestion of the capsids.[312] Active mechanisms may also transport capsids from other regions of the cytoplasm to the vicinity of the nucleus. Endosomal vesicles transport the incoming virions to the vicinity of the nucleus, and that process, or possible direct transport of capsids, may be blocked by treatment of cells with nocodazole to depolymerize microtubules or by injection of an antibody against the intermediate chain of dynein.[234,353,371,372] By electron microscopy, capsids have been seen to associate with tubulin and dynein structures *in vitro*, and viral capsids may be precipitated from infected cells

along with intermediate chain of dynein.

Nuclear Transport

Nuclear transport is thought to involve the viral capsid or DNA passing through the nuclear pore complex, although injection of MVM capsids into the cytoplasm of *Xenopus* oocytes showed possible permeabilization of the nuclear envelope.[88] Other studies show varying results after injection of parvovirus capsids into the cytoplasm of cells—some show them remaining in the cytoplasm, while others suggest passage through the nuclear pore.[234,372] Nuclear entry may require modification of the capsid to expose NLSs in the VP1 unique region. A VP1-derived peptide mediates nuclear transport when conjugated to bovine serum albumin (BSA),[371] that peptide is exposed on virions entering the cells, and antibodies to the VP1 unique region blocked infection when injected into cells around the time of virus inoculation.[371] MVM capsids have NLS motifs in both VP1 and VP2 (Fig. 6.4). A VP1 unique region that could mediate nuclear transport is required for efficient cell infection by MVM capsids.[224,367]

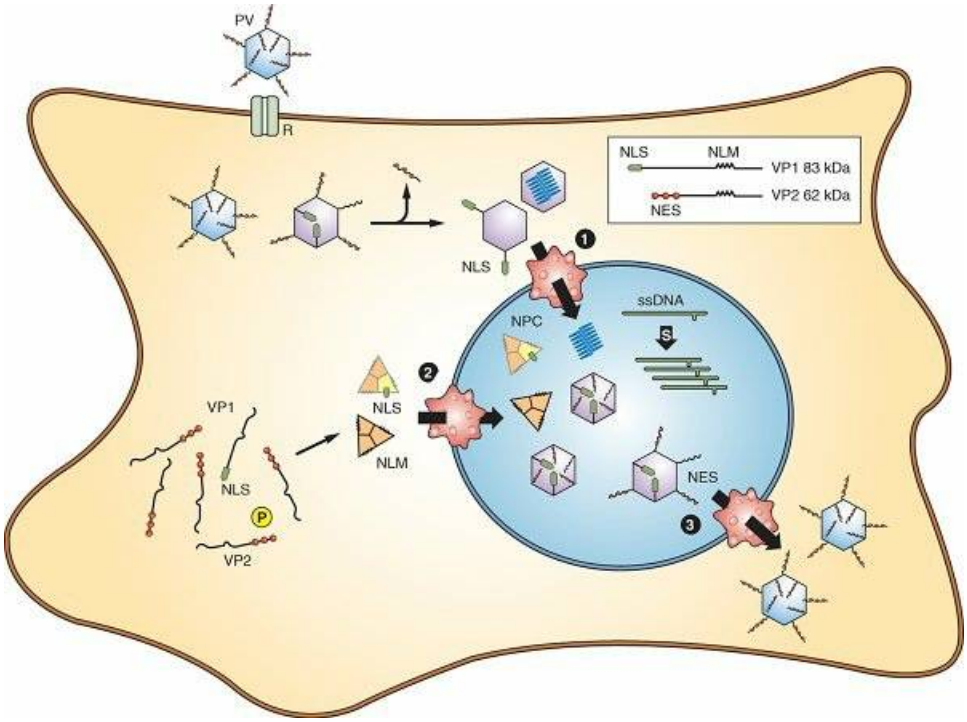

FIGURE 6.4 The nuclear transport of the parvoviral capsid proteins and capsids in the life cycle. Part *(1)* shows the processes include the cleavage of the VP2 N-terminal sequences containing a nuclear export sequence (NES) from the incoming particle and exposure of the N-terminal sequences of the VP1 protein containing a nuclear localization sequence (NLS). Part *(2)* shows association between the VP1 and phosphorylated VP2 results in translocation into the nucleus as timers, where the particles assemble. Part *(3)* shows how the newly assembled particles are transported out of the nucleus and into the cytoplasm using the phosphorylated N-terminus of the VP2 protein as an NES. polypeptides. In: Kerr JR, Cotmore SF, Bloom ME, et al., eds. *Parvoviruses*. London: Hodder Arnold; 2006:291–304. Copyright © 2005 by Taylor & Francis Group, LLC. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.)

Viral DNA Release From the Capsid and Initiation of Replication

The viral DNA genome is released from the capsid for replication, but the process is not fully understood. The DNA may be extracted from the capsid without particle disassembly. DNA-containing capsids have 20 to 30 nucleotides of the 5′ end of the viral genome exposed on the outside of the capsid, with NS1 or Rep protein covalently attached to the 5′ end of that DNA in newly produced capsids. The 3′ end of the viral DNA may also become exposed outside the capsid without capsid disintegration[93,94], and that may initiate DNA replication by the host cell DNA polymerase, which could remove the DNA without capsid disassembly.

Autonomous Virus DNA Replication

The autonomous parvovirus genome is a linear ssDNA with terminal palindromes (Fig. 6.5), and many viruses have different palindromes at each end[20,306] and many primarily package the minus DNA strand.[97] DNA replication has been most extensively studied for the rodent protoparvoviruses. Only two nonstructural (NS) proteins are encoded by most parvoviruses. Replication depends on the DNA replication machinery of the cell and various cellular proteins, and in most cases the cell must pass through S phase.[358,386]

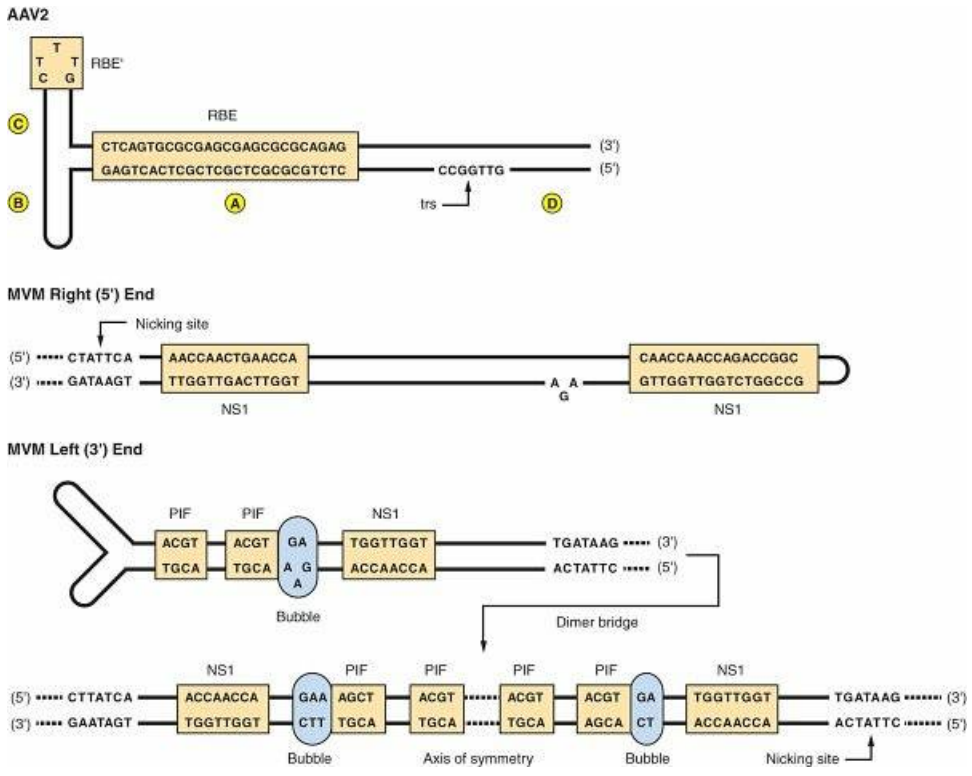

FIGURE 6.5 Comparison of the 3′ and 5′ terminal palindromic sequences of minute virus of mice (MVM) DNA with the adeno-associated virus (AAV) terminal repeat, which is identical at both ends. Also shown is the 3′ dimer bridge that is formed in a dimer replicative intermediate during MVM replication. In each case, the key sequence elements are indicated that area required for AAV Rep nicking at the terminal resolution site (TRS), of NS1 nicking at the 5′ (right end) hairpin, or in the 3′ (left end) dimer bridge. The hairpin sequences are shown in their most stable secondary structure. In the AAV hairpin, B and C by convention are the small internal palindromes flanked by the A palindrome that forms the stem of the first 125 bases. The D sequence comprises the remaining 20 bases of the terminal repeats that are inboard of the TRS.

NS1 is the major parvovirus regulatory protein involved in DNA replication and gene regulation. It is a helicase, adenosine triphosphatase (ATPase), and site-specific nickase, and it becomes covalently attached to the 5′ side of the nick through residue Y210,[23,85,92,95,267] within a motif characteristic of proteins involved in rolling circle replication (RCR motif).[170] NS1 cleaves within the extended duplex form of oriL in the dimer bridge and within the hairpinned form of the right end palindrome, but not the hairpinned form of the left terminal palindrome (see Figs. 6.5–6.7). The left end palindrome contains a short sequence that is not complementary; when extended in the dimer bridge, there is a 5′GA/TC to the right of the axis of symmetry and a 5′GAA/CTT to the left, and cleavage occurs at the 5′GA/TC site and involves a cellular protein (parvovirus initiation factor [PIF]).[81,83] The interaction between NS1 and PIF allows ATP hydrolysis so that the DNA double helix can be unwound and NS1 cleavage of its single-stranded substrate (see Fig. 6.5). PIF is a cellular transcriptional factor of the KDWK motif family, which functions as a heterodimer with subunits of 96 and 79 kDa.[84]

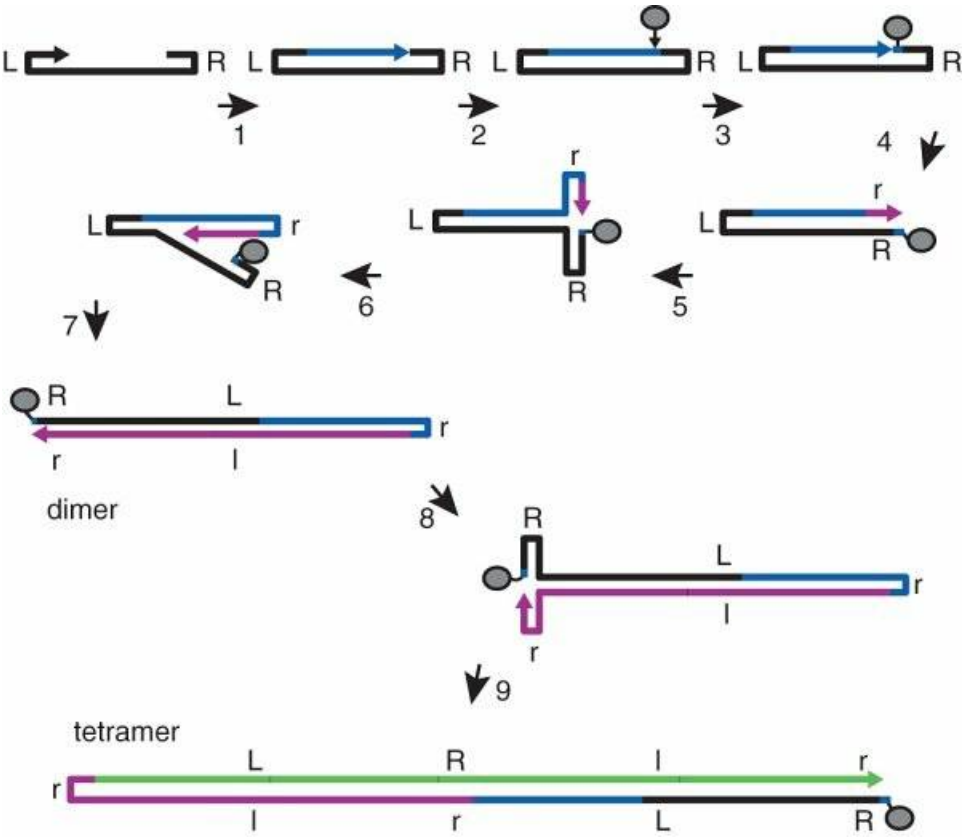

FIGURE 6.6 The replication cycle of the autonomous parvovirus DNA, based on the rolling hairpin model for minute virus of mice (MVM). The viral genome is represented by a continuous line (shaded *black* for the original genome and different colors for the newly synthesized DNAs); the 3′ end is indicated by an *arrowhead*. The letters L and R represent the left-end and right-end palindromic sequences, respectively. Upper and lower case represent the "flip" and "flop" versions of the sequences, which are inverted complements of each other. (Reprinted with permission from Cotmore SF, Tattersall P. Parvovirus DNA replication. In: DePamphilis ML, ed. *DNA Replication in Eukaryotic Cells*. Plainview, NY: Cold Spring Laboratory Press; 1996: 801. Copyright © 1996 Cold Spring Harbor Laboratory Press.)

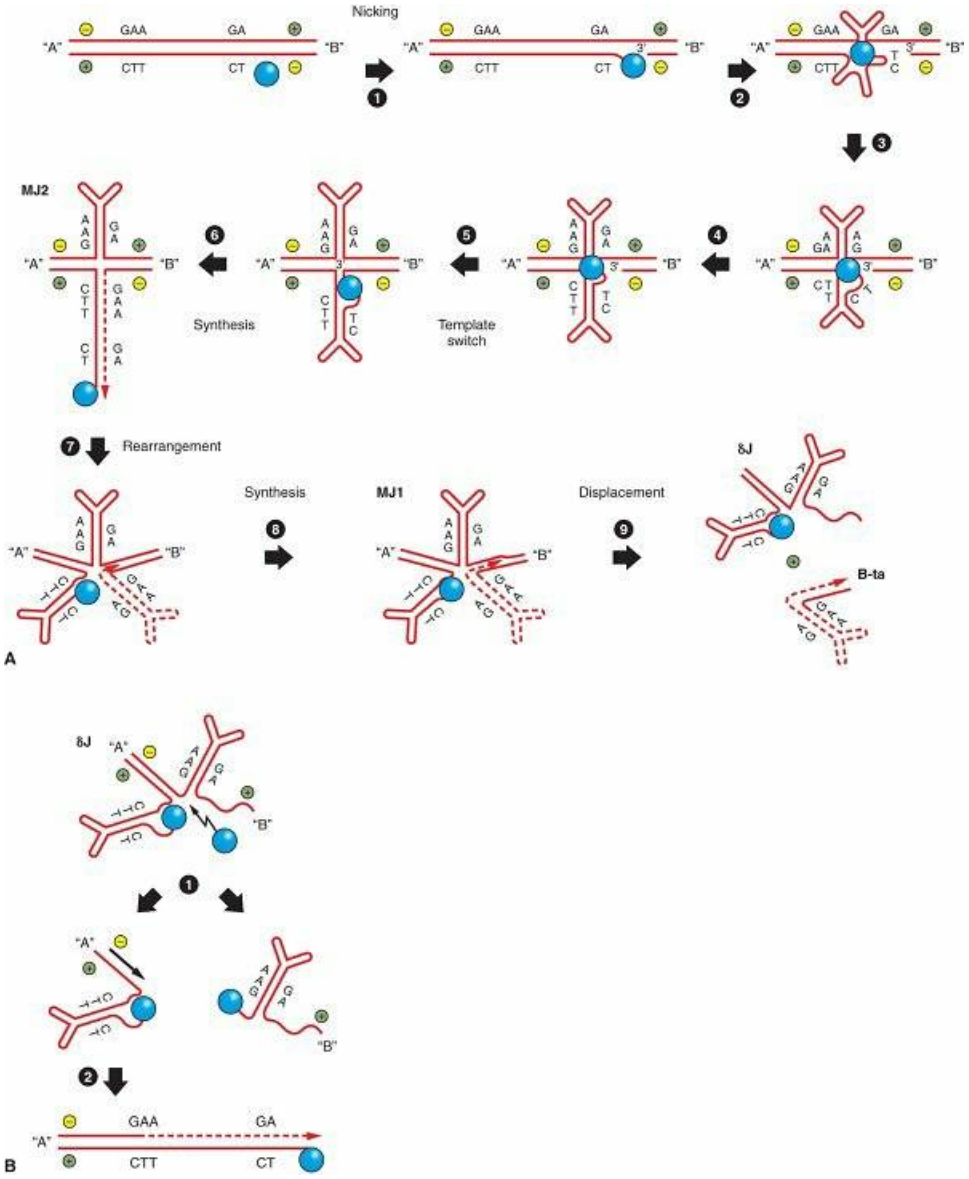

FIGURE 6.7 A: The resolution pathway involved in the replication from the dimer bridge during the replication of minute virus of mice. After nicking the initiation site in the B arm of the dimer bridge (step i), NS1 associates with RPA to function as a 3′-to-5′ helicase (step ii), unwinding the lower strand of the palindrome and allowing the exposed single strands to fold back on themselves, creating a cruciform intermediate (step iii). Branch migration proceeds (step iv), eventually passing the inactive initiation site in the A arm. At this point, the exposed 3′ nucleotide can switch templates and anneal to its complement in the lower cruciform arm (step v). A replication fork assembling at this time will copy and unwind the cruciform arm, synthesizing a palindrome in the flip orientation on the end of the negative sense B strand (step vi). This heterocruciform structure corresponds to the MJ2 intermediate. In a second duplex-to-hairpin transition, the palindromic heterocruciform arm of MJ2 is then melted out and both strands fold back on themselves (step vii), allowing the exposed 3′ end to base pair with inboard sequences in the B arm. A replication fork established at

this 3′ end would copy the lower strand of the B arm (step viii), creating the MJ1 intermediate and progressively displacing the upper strand, leading to the eventual release of a newly synthesized B turnaround form (step ix). The residual δJ intermediate is partially single stranded, having an intact upper strand paired to an NS1-associated lower strand from the A arm. Because this complex carries the active helicase, it is presumed to be a dynamic structure in which the bridge palindrome is periodically reconfigured into a cruciform structure, as shown. **B:** Introduction of a single-strand nick and resolution of the δJ intermediate. The initiation site in the A arm of the palindrome is periodically exposed as a single strand during duplex-to-hairpin rearrangements of δJ (step i). This allows NS1 to attack the initiation site in $OriL_{GAA}$ without the help of a cofactor (step ii). Nicking leads to the release of a positive sense B strand and leaves a base-paired 3′ nucleotide on the A arm (step iii) to prime assembly of a fork that will copy the hairpin, creating an extended form of the A arm (step iv). (Adapted from Cotmore SF, Tattersall P. Resolution of parvovirus dimer junctions proceeds through a novel heterocruciform intermediate. *J Virol* 2003;77(11):6245–6254. Copyright © 2003 American Society for Microbiology. Amended with permission from American Society for Microbiology.)

Other cellular proteins are required or assist in MVM DNA replication, including phosphokinase C (PKC), PKC eta, which is required for NS1 to function in RCR, while PKC lambda phosphorylates NS1 at T435 and S473 so that NS1 can function as a helicase.[89,210,266] Cyclin A is required for DNA replication. MVM replication evokes a DNA damage response, and H2AX, Nbs1, RPA32, Chk2, and p53 are all phosphorylated and recruited to MVM replication centers.[2,316] Parvovirus DNA replication takes place in discrete subnuclear structures (called parvovirus-associated replication structures [PARs]), which contain DNA polymerases α and δ.[31,103,169]

Autonomous parvovirus DNA replication involves a complex series of specific single-stranded cleavages, extensions from base-paired 3′ ends, and the base pairing and resolution of terminal palindromic structures—as shown in Figures 6.6 and 6.7. The 3′ terminal hairpin of the viral genome serves as a primer for complementary strand synthesis (see step 1, Fig. 6.6). The elongating strand is covalently linked to the hairpinned form of the 5′ end of the template to form a linear duplex molecule covalently cross-linked at both ends by DNA hairpins (see step 2, Fig. 6.6). The hairpin at the right end is nicked on the newly synthesized strand by NS1 at a site 18 nucleotides downstream from the original 5′ end, with the NS1 becoming covalently linked to the 5′ end released (see step 3, Fig. 6.6). The 3′ OH released by this cleavage is used as a primer for repair synthesis to fill the gap, so that the right end of the intermediate is now a double-stranded extended form of the original 5′ palindrome, with NS1 covalently linked to the 5′ end of the parental strand. The restored 5′ end is 18 nucleotides longer than the 5′ end of virion DNA (step 4, Fig. 6.6). The extended form of the right end palindromic sequence is denatured so that both strands can form hairpins (see step 5, Fig. 6.6), and the 3′ OH primes DNA synthesis through both strands of the linear duplex monomer, forming a linear duplex dimer (see step 7, Fig. 6.6). The palindromic sequence at the center of the dimer intermediate is termed the dimer bridge, and three sites in the dimeric intermediate are potentially susceptible to single-strand nicking by NS1: two in the covalently closed right end hairpins at each end of the intermediate and a third on the right side of the dimer bridge at GA/TC (nicked at TC; the GAA/TCC

sequence on the left side of the dimer bridge is not cleaved)[98] (see Figs. 6.6 and 6.7). Nicking at TC leaves NS1 covalently linked to the 5′ side of the nick and a free 3′ OH, and the bound NS1 unwinds the helix in the 3′ to 5′ direction, allowing the palindromic sequence of the dimer bridge to form a cruciform structure that can function as a template for the synthesis. When the newly synthesized strand extends beyond the GA bubble sequence, there is a template strand switch where the newly synthesized strand is displaced from the template, forms a hairpin, and copies the strand to the right of the dimer bridge. This creates a new left terminal palindrome in the original flip orientation and displaces a single-stranded monomer equivalent, which is still linked to a duplex, unit length component. This proposed synthesis involves two template strand switches. The duplex molecule created is cross-linked at one end by the right palindrome and could go through multiple rounds of displacement synthesis to produce minus strands with the original flip orientation of the left palindrome for packaging into the virion, as seen for MVM.[97] In this model, NS1 cannot cleave oriL when the left end palindrome is in the hairpin conformation but can in the extended duplex form of the dimer bridge in the RF. However, NS1 can nick oriR when the right end palindrome is hairpinned. The genomic ssDNA is generated and packaged only when capsids are present.[96,97]

Adeno-Associated Virus DNA Replication

The AAV genomes vary in size (between 4,500 and 5,000 nucleotides long) and have palindromic terminal sequences that serve as the primers for DNA replication of AAV (see Fig. 6.5). AAVs have several forms of the NS1 equivalent protein (called Rep) with multiple functions in DNA replication, while DNA polymerase, ssDNA-binding protein, and additional factors are supplied by either the helper virus or the cell. Because of the AAV ITR and the evidence for inversion of the palindromic sequences at both termini, replication can occur by single-strand displacement (Fig. 6.8). The 3′ terminal repeats fold over to form hairpin structures[233] that serve as primers for DNA synthesis[350] (see Fig. 6.8). Complementary strand synthesis forms a linear duplex molecule cross-linked at one end by the terminal hairpin, or the growing end of the complementary strand may become covalently linked to the hairpinned form of the ITR at the 5′ end of the parental strand template to form a linear duplex cross-linked at both ends. Resolution is achieved by Rep 68 or 78 binding to the hairpin via a Rep binding sequence [RBS], as well as a secondary binding site on one of the cross-arms, (see Fig. 6.5) and nicking the original parental strand at the terminal resolution site (TRS), which is opposite the phosphodiester bond between the 3′OH of the primer and the 5′PO_4 of the first nucleotide inserted into the progeny strand.[45,77,241,317] Rep covalently binds to the 5′ end released by the nick, while the 3′ end serves as a primer for synthesis, filling in the resultant gap at the 5′ end of the parental strand using the displaced hairpin sequence as the template.[171,337] Thus, the original 3′ end of the parental strand is transferred to become the 5′ end of the new strand, and the terminal palindromic sequence is inverted. The 3′ end of the newly synthesized strand may now fold over to prime synthesis of another new strand to produce a linear, duplex dimer-length molecule.[262] The structure of the initial primer strand may be either a linear single strand with a hairpinned 3′ end or a single-stranded circle held together by H-bonding between the ITRs (see Fig. 6.8).

FIGURE 6.8 The replication cycle of the adeno-associated viral DNA. The single-stranded DNA released from the virion after uncoating (top two possible forms) is extended from the 3′ end of the hairpin to form a full-length hairpin. The hairpin is nicked at the terminal recognition site by Rep68 or rep78, leaving the Rep protein attached to the end of the DNA. The hairpinned end is unwound, and the 3′ end formed by Rep cleavage is extended to the end of the template strand. The ends of each strand refold into their alternative self-base pairing hairpin structures, and full-length DNA synthesis from the 3′ primer on the left end of the genome produces one single-stranded genome and one duplex structure, which can each serve as a substrate for additional round of replication. mT, monomer turnaround; dT, dimer turnaround replicative form; ss, single-strand viral DNA; mE, monomer extended replicative form, TRS, terminal recognition site.

The functional complex of Rep is a pentamer.[160] The large Rep proteins introduce site-specific nicks at the TRS, and their helicases cause hairpin unwinding during resolution of the termini, while the two smaller Rep 52/40 proteins can bind ATP, have helicase activity, and may be involved in packaging of ssDNA strands into preformed capsids.[172,337,340] Rep 40 does not bind specifically to RBS but does bind ssDNA.[399] The site-specific DNA binding and endonuclease activities are functions of the N-terminal domain of the larger Rep 68/78 proteins.[338] The RBS is a tandem repeat of four copies of GAGC, but only two of the GAGC are required to bind Rep.[77,241,317] Rep 68/78 functions as a multimeric complex that binds to the RBS in the stem of the T-shaped structure of the folded ITR and also to a second site (RBS′, GTTTC) at the tip of the cross arm farthest removed from the TRS[46,317] (see Fig. 6.5). The TRS consists of a seven-base sequence (3′CCGGT/TG5′) recognized only on the correct strand.[46] Once bound to the hairpin, Rep unwinds the stem of the ITR in a reaction that requires ATP hydrolysis to generate a single-stranded TRS,[105,339] and then tyrosine 156 of Rep is linked to the 5′ phosphate end of the nick.[172,338] Rep remains covalently bound until after packaging occurs.[296]

AAV DNA replication requires both cellular and helper virus components. Although adenovirus encodes a DNA polymerase, AAV replication primarily uses cellular DNA polymerase δ. Other cellular factors required included replication factor 3, proliferating cell nuclear antigen (PCNA), and the so-called minichromosome maintenance complex. The herpes simplex virus (HSV) DNA polymerase may be used for AAV replication.[252,381] Several other helper virus gene products are required for AAV DNA replication. Adenovirus ssDNA-binding protein enhances AAV DNA replication.[66,177] HSV gene products include UL30/UL42 HSV DNA polymerase; the helicase–primase complex of UL5, UL8, and UL52; and the UL29 product ICP8, the HSV ssDNA-binding protein[252,381] AAV DNA replication colocalizes with helper viral ssDNA-binding proteins and with replication protein A (RPA), the cellular ssDNA-binding protein, and proteins associated with the DNA damage response.[327] In adenovirus coinfected cells, AAV replication can be associated with PML bodies, but those are not seen with the HSV helper.[125] Cellular proteins associated with AAV DNA replication include replication factor C (RFC), PCNA, RPA, Mre 11/rad50/Nbs1 complex, Ku70 and -86, and other mismatch repair proteins.[262,263] Nuclear high mobility group protein 1 (HMG1) binds to cruciform DNA[90] and binds to AAV hairpins and Rep to stimulate Rep nicking, ATPase activity, and repression of

AAV gene expression from the P5 promoter. The 52 kDa FK 506 binding protein FKBP52 binds to the single-stranded form of the D region of the ITR, the 20 nucleotide of the ITR beyond the palindrome.[238,299] The phosphorylated form of the protein binds and inhibits DNA replication, whereas when the nonphosphorylated form binds, synthesis can occur. Phosphorylation is controlled by the epidermal growth factor receptor tyrosine kinase and correlates with the ability of AAV vectors to transduce cells in the absence of a helper virus.

Transcription

Autonomous Parvovirus Transcription

The transcriptional schemes of the autonomous parvoviruses are both complex and variable (Figs. 6.9 and 6.10). Many use promoters around map positions 4 and 38 to generate two primary transcripts, along with one polyadenylation signal near the right end of the genome, and most have multiple additional messages generated primarily by alternative splicing.[181,254] A small intron is generally found between map positions 44 and 46, and a large intron between map positions 10 and 39. For MVM, all messengers have the small intron spliced, although alternative splice donor and acceptor sites are used. Half of the P4 transcripts also have the larger intron spliced at alternative splice donor and splice acceptor sites, producing at least nine mRNAs.[181,254] Where the P38 transcript uses the upstream splice donor site, the mRNA is translated to VP1, while the downstream donor site gives VP2. The erythroparvoviruses have one promoter at map position 6 but produce at least 12 different messages.[133] Those include two polyadenylation signals—near the middle of the genome and at the right end[147,272] (see Fig. 6.10). Read-through of the internal polyA site occurs only with genome replication, and the large transcript is translated into the capsid protein.[148] The Amdoparvoviruses have promoters at map positions 3 and 36, and the mRNAs have complex splicing patterns.[300,347] The Bocaparvoviruses have promoters at map positions 4.5, 13, and 39; NS proteins and VPs are encoded in large ORFs in the left and right sides of the genome, and a small ORF that overlaps the 3′ terminus of the NS ORF encodes NP1.[74,112(p1)]

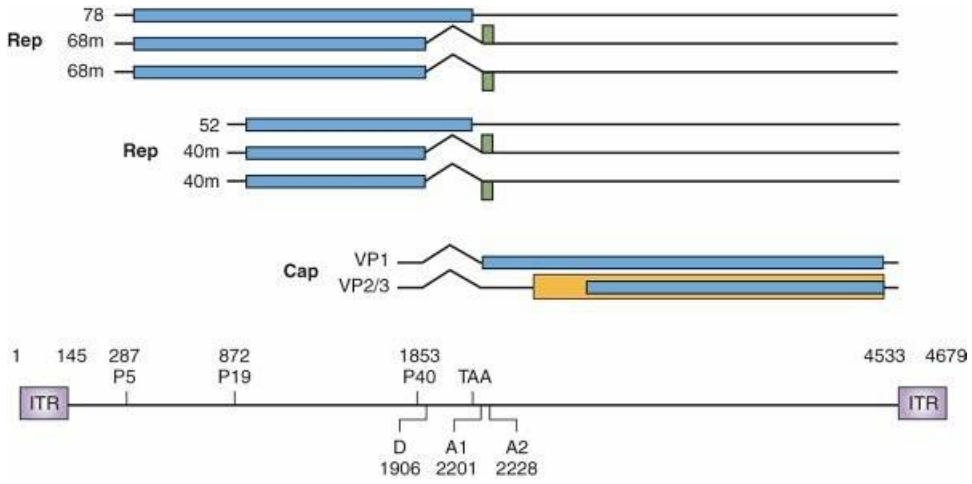

FIGURE 6.9 Transcriptional maps of the autonomous parvovirus minute virus of

mice. The three major transcript classes (R1, R2, and R3) are shown relative to the viral genome, and the P4 and P38 promoters are indicated. The proteins encoded are shown as NS1, NS2, VP1/2, and the SAT proteins. The alternative open reading frames used are shown as different shading patterns. (Adapted from Pintel DJ, Gersappe A, Haut D, et al. Determinants that govern alternative splicing of parvovirus pre-mRNAs. *Semin Virol* 1995;6(5):283–290. Copyright © 1995 Elsevier. FIGURE 6.10 Transcription map of the B19 genome, showing the level of complexity of the RNAs produced by alternative splicing and polyadenylation. The main features shown include the viral promoter (P6), the various splice donors (D1 and D2) and acceptors (A1-1, A1-2, A2-1, A2-2), and the polyadenylation sites (pA). Other features shown are the open reading frames (*open* or *closed boxes*) and the products likely generated from each transcript. (Adapted from Guan W, Cheng F, Huang Q, et al. Inclusion of the central exon of parvovirus B19 precursor mRNA is determined by multiple splicing enhancers in both the exon and the downstream intron. *J Virol* 2011;85(5):2463–2468. Copyright © 2011 American Society for Microbiology. Amended with permission from American Society for Microbiology.)

Regulation of transcription and posttranscriptional modification is complex. For MVM, splicing of the large intron (map units 10 to 39) depends on splicing of the small intron (44 to 46), and NS1 transactivates P39 transcription.[111,405] Three *cis*-active genomic sequences near P39 are required for transactivation—the tar (transactivation response element) to which NS1 binds in a reaction that is ATP dependent, an Sp1 site, and the TATA box.[6,82,230,231] NS1 can also interact with CBP, Sp1, TBP (TATA-binding protein), and TFIIA in the absence of DNA.[201,231] The promoter contains binding sites for Sp1, CREB/ATF, E2F, and NF-Y, and several regulatory mechanisms link MVM expression and replication to the cell cycle.[106,130,285] The viral NS2 interacts with the nuclear export protein Crm-1 and mutations altering MVMi NS2 binding to Crm-1 influence replication in different cells.[78,250]

AAV Transcription

The AAV genome contains three transcription units with promoters at map positions 5, 19, and 40 (Fig. 6.11), and one polyadenylation signal is at map position 96, so that all three transcripts cover the 3′ half of the plus strand.[301,352] A single intron lies just beyond mp 40, and the ratio of spliced to unspliced mRNA species depends on binding of Rep 78/68 to the transcription template.[301,302] Four mRNAs cover all or part of the ORF in the left half of the genome, two of which initiate at the P5 (mp5) promoter; one is spliced and produces Rep 68, and the other is not spliced and forms Rep 78. The P19 promoter also produces two mRNAs producing Rep 52 and Rep 40. The P40 produces two major mRNAs splice variants; one encodes VP1, and when the VP1 initiator codon is spliced out, an ACG initiator codon is used to translate VP2, and the first AUG in phase is used as the initiator codon for VP3.[256] An additional protein encoded by an alternative ORF within the *cap* gene has the initiator codon CTG, and the 23-kd protein promotes capsid formation.[261,345] In AAV5, most transcripts originating from P7 and P19 are polyadenylated at a site in the intron.[301,397]

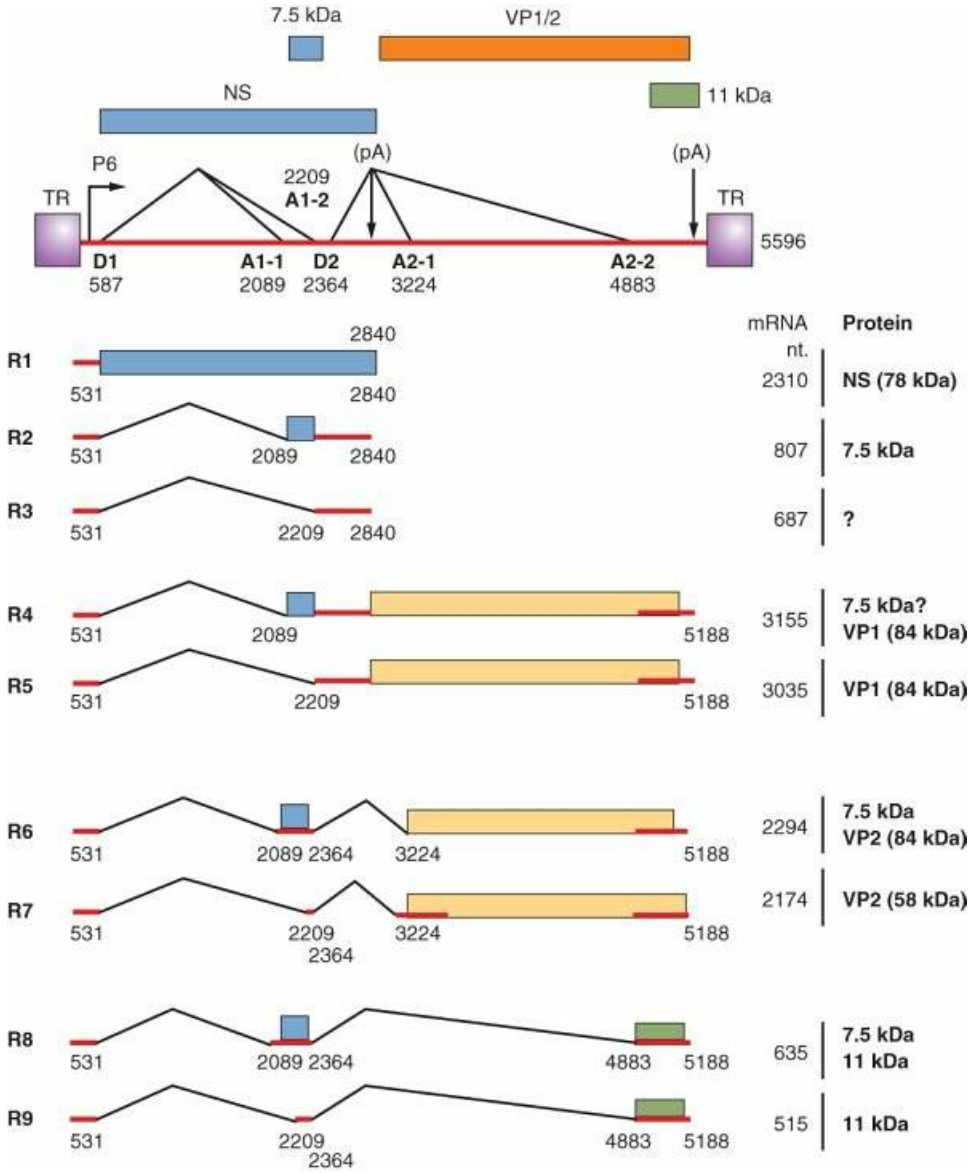

FIGURE 6.11 Transcriptional map of the adeno-associated virus type 2 (AAV2) genome, which includes three promoters (P5, P19, P40), the small intron donor (D), and acceptors (A1 and A2), the termination sites of the Rep and Cap messages. The major transcripts and the proteins they encode are shown, and the different open reading frames used are shown with different shading. (Adapted from Qiu J, Yoto Y, Tullis G, et al. Parvovirus RNA processing strategies. In: Kerr JR, Cotmore SF, Bloom ME, et al., eds. *Parvoviruses*. London: Hodder Arnold; 2006:253–274. Copyright © 2005 by Taylor & Francis Group, LLC. AAV represses its own transcription and DNA replication in the absence of a helper virus, but limited Rep expression results in establishment of latent infection. Adenovirus helper factors include early regions (E) 1A, 1B, 2A, and 4 (ORF 6).[7,307] The ICP0 gene product of HSV-1 turns

on AAV transcription and can activate transcription from an integrated latent viral genome.[137] Cellular transcriptional regulatory elements control AAV RNA synthesis, and the P5 promoter sequence contains binding sites for cellular, helper, and AAV transcriptional factors.[208,284]

Protein Synthesis

Autonomous Parvovirus Proteins

Protein synthesis depends on transcription, and NS protein transcripts appear earliest in the course of infection, and NS proteins regulate gene expression.[86,110,218] NS1 dimerizes prior to nuclear localization,[268,297] MVM NS2 is required for efficient virus growth in a host-dependent manner and is essential for growth in mouse cell lines and in animals.[104,228,259,316]

Adeno-Associated Virus Proteins

AAV protein amounts correspond to the levels of their transcripts. Rep78 and 68 are predominantly found in the nucleus, while Rep52 and 40 are also found in the cytoplasm.[244] Rep78 represses the p5 promoter, while Rep68 and Rep52 are less repressive, while either Rep78 or 68 may transactivate the p40 promoter.[166] VP1 to VP3 are translated from alternatively spliced p40 mRNAs, with VP2 starting from an ACG codon and VP3 from a downstream AUG, and VP1 is translated from the low-abundance spliced p40 message [256](see Fig. 6.11).

Virion Assembly

Capsid proteins translated in the cytoplasm are transported to the nucleus, where they assemble[309] (see Fig. 6.4). The major capsid proteins can assemble alone into capsids that are structurally similar to normal capsids, which can package DNA,[315,367,402] but the other capsid proteins (VP1 and VP3) are required for infectivity, likely due to the PLA_2 and nuclear localization functions of the VP1.[123,141,315,321,371] VP2 assembly requires nuclear transport, and multiple NLS appear to be present, and it is enhanced by the expression of an assembly activating protein.[165,261,390]

Viral ssDNA is inserted into the preassembled capsid and requires the helicase activity of the NS1 to translocate the ssDNA into the capsid[96,116,291,406] (Fig. 6.12). The polarity of DNA packaging of some viruses results from differences in the use of sequences at each end of the genome for initiating replication.[97] Capsids may be retained within the nucleus, translocated into the cytoplasm, or transported out of the cell in a process regulated at least in part by the phosphorylation state of the capsid proteins and the activity of gelsolin in the cytoplasm[28,120,224,385,402] (see Fig. 6.4).

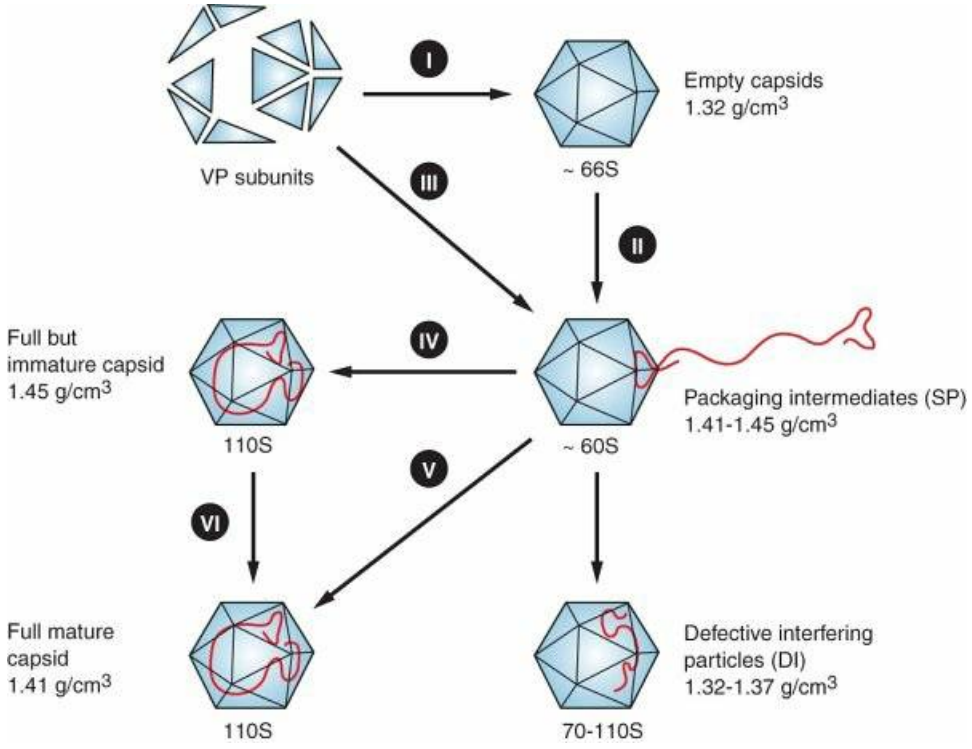

FIGURE 6.12 Possible pathways for parvovirus assembly and DNA incorporation, based on various studies of adeno-associated and autonomous viruses. Several mechanisms are possible; however, the current data propose the assembly of capsids from viral protein subunits, possibly trimers (see Fig.6.4), some of which remain as empty particles. The single-strand DNA is packaged during replication into the more or less intact capsids through the activity of the nonstructural or Rep protein. A final step involves the "maturation" of the capsids, which is seen as a small change in the buoyant density of the particle from 1.45 to 1.41 g/cm^3. (Adapted from Kleinschmidt JA, King JA. Molecular interactions involved in assembling the viral particle and packaging the genome. In: Kerr JR, Cotmore SF, Bloom ME, et al., eds. *Parvoviruses*. London: Hodder Arnold; 2006:305–319. Copyright © 2005 by Taylor & Francis Group, LLC. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.)

Adeno-Associated Virus Latent Infection

AAV can establish a latent infection, apparently allowing the genome to persist until conditions allow replication. In cell culture AAV latent infection requires inoculation of a high multiplicity of infection in the absence of helper, but the genomes may persist for many cell passages.[286] The AAV genome can integrate into the cell genome: wild-type AAV2 integrated to a higher level at a specific site (AAVS1) on the q arm of human chromosome 19 (q13.4), which included a 33-nucleotide sequence containing the RBS and the TRS separated by an 11-nucleotide spacer.[168,219,245,320] (Fig. 6.13). Expression of Rep 78/68 was required in *trans*, and viral DNA was mostly integrated as a concatemer.[76,140,168,175,286] Integration occurs approximately randomly without Rep expression.[243] The AAV genome may also survive for prolonged periods

as an extrachromosomal element and be expressed in the absence of a Rep gene. The unusual ends of the genome allow it to resist intracellular exonucleases and may prevent DNA modification, which would turn off expression. The extrachromosomal forms of AAV DNA are concatemers that are thought to be circular.[344] Many people likely harbor viral DNA sequences that can be reactivated.[129] No negative consequences of AAV DNA persistence have been demonstrated.

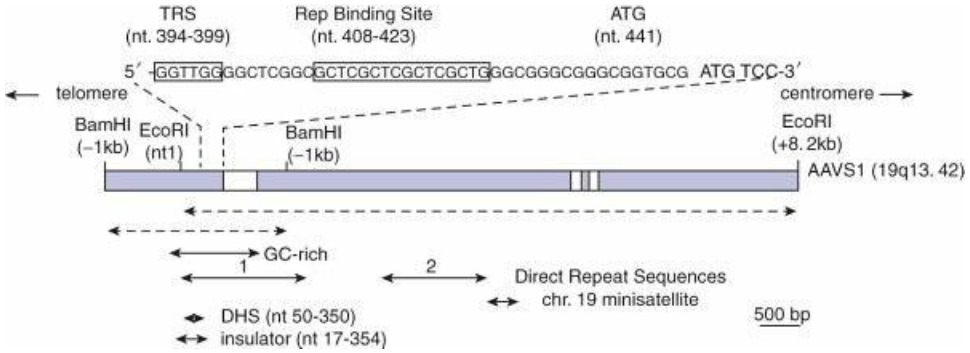

FIGURE 6.13 Schematic representation of the adeno-associated virus S1 region, the favored site of integration into the human chromosome position 19q13.42 chromosome, within the BamHI and EcoRI fragments as mapped by (REF and REF), where the EcoRI site is indicated as position 1. The sequence and position of the Rep-binding site (RBS), terminal resolution site (TRS), and the *MBS85* gene translation start sequence (ATG) are indicated, which allow Rep recognition and nicking. Locations of the GC-rich region, direct repeat sequence, chromosome 19 minisatellite sequence, DNAse I hypersensitive site (DHS), and insulator element as indicated by *arrows*. (Adapted from Dutheil N, Linden RM. Site-specific integration by adeno-associated virus. In: Kerr JR, Cotmore SF, Bloom ME, et al., eds. *Parvoviruses*. London: Hodder Arnold; 2006:213–236. PATHOGENESIS AND CONTROL OF TISSUE TROPISM

Parvoviruses likely infect most vertebrates and invertebrates, and many appear not to be commonly associated with disease.[126,180,341] Some major vertebrate pathogens are listed in Table 6.2. Autonomous parvoviruses mostly require S phase of the cell cycle for their replication, so there is an age dependence to many diseases. However, only some tissues containing dividing cells are targeted for high levels of infection, and there are additional controls of tropism.[278] Viral genes, including the capsid and NS2 sequences, govern the host range or pathogenicity of parvoviruses.[26(p),42,56,104,227]

TABLE 6.2 Major parvovirus pathogens of vertebrates

Virus	Disease
Human parvovirus B19 and primate erythroviruses	Erythema in children, polyarthritis and arthralgia, transient aplastic crisis, fetal hydrops
Feline parvovirus (canine parvovirus and feline panleukopenia virus, mink enteritis virus)	Enteritis; generalized neonatal disease, myocarditis, ataxia following cerebellar hypoplasia
Porcine parvovirus	Fetal infection and death, abortion, infertility
Aleutian mink disease virus	Chronic immune complexes
Canine minute virus	Mild diarrhea, fetal or neonatal death
Minute virus of mice, rat virus, H1 virus of rats	Congenital fetal malformations, persistent subclinical infections
Goose parvovirus and duck parvovirus	Hepatitis and myocarditis

Fetal and Neonatal Infections

Fetal and newborn animals are highly susceptible to infection owing to the large number of dividing cells, and several parvoviruses cause fetal death or abortion. However, maternal immunity completely protects the fetus, and maternal antibodies generally also protect the newborn for some weeks after birth. Fetal or neonatal infections in animals lacking maternal immunity can be caused by PPV,[102,351] bovine parvovirus,[348] goose and duck parvovirus,[265] parvovirus B19,[70,270] and AMDV.[8] Some infections are fatal, or the surviving fetus may suffer severe sequelae, such as congenital cerebellar ataxia by infecting cells in the developing cerebellum.[195,305] Neonatal dogs infected with CPV may develop myocarditis.[216] MVM and other parvoviruses may infect renal vascular endothelial cells and lymphocytes in mice.[53,215] Newborn mink infected with AMDV develop severe respiratory distress due to infection of type 2 alveolar pneumocytes, which proliferate in the neonatal period.[10,374]

Older Animals

Parvoviral diseases in older animals result from the direct effects of virus infection on target tissues, and sometimes from the subsequent immune responses. Direct infections of the target organs includes enteritis in CPV-infected dogs or FPV-infected cats, hepatitis in hamsters and geese, and erythrocyte aplasia in humans (B19 and related viruses) (reviewed in

Refs.[43,47,99,278,401]). Several disorders result from the host response to infection, including the chronic immune complex disease caused by persistent infection with AMDV.[1] Certain PPV isolates induce immunologically mediated vesicular skin lesions in late-gestation swine fetuses,[202] and immune responses likely cause the erythema seen in fifth disease and the polyarthropathy caused by B19 infection.[24,401]

Human Parvoviruses

There are several human parvoviruses. The B19 and the related erythroviruses are associated with primary diseases, whereas the human parvovirus 4 (Parv4) and human bocavirus appear to be associated with diseases primarily in mixed infections with other pathogens. Many parvovirus B19 infections are subclinical, and when disease occurs that is generally an acute, biphasic illness with a high viremia that peaks at days 8 and 9[17,80,295] (Fig. 6.14). Viremia is accompanied by nonspecific, influenza-like symptoms, including fever, malaise, and myalgia. Red cell aplasia coincides with viremia, leading to a drop in hemoglobin, reticulocytopenia, and modest lymphopenia and neutropenia. Specific immunoglobulin M (IgM) and IgG antibodies 10 to 14 days after inoculation results in immune complex formation and the symptoms of fifth disease (erythema infectiosum)[17,18,52,80,135] likely due to the host immune response to infection. Adults with acute B19 infection may suffer polyarthropathy that can persist for weeks or months,[387] also likely resulting from the host immune response and immune complex deposition.

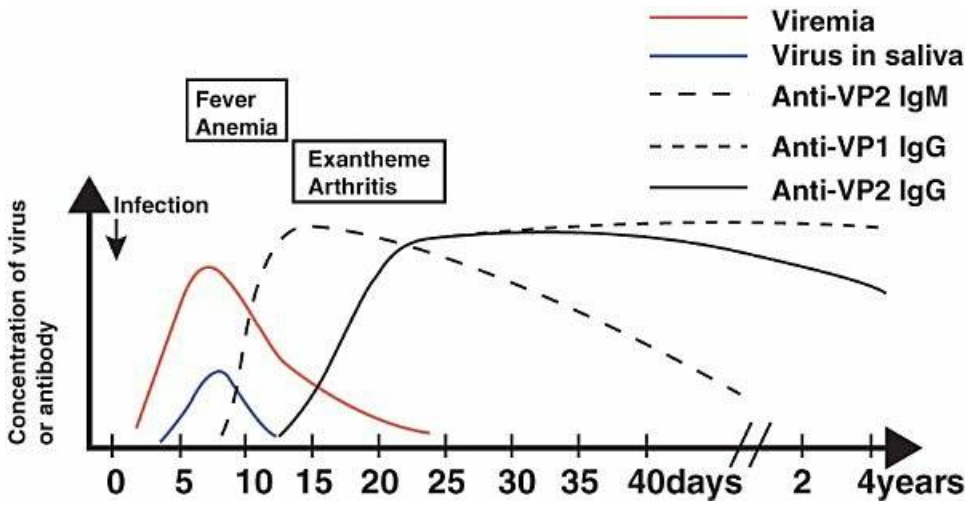

FIGURE 6.14 Pathogenesis of B19 in humans. The graph shows the changes in the amounts of the virus or the immune response to the various viral capsid components at different times in an acute human infection. (From Kerr JR, Modrow S. Human and primate erythrovirus infections and associated disease. In: Kerr JR, Cotmore SF, Bloom ME, et al., eds. *Parvoviruses*. London: Hodder Arnold; 2006:385–416. Copyright © 2005 by Taylor & Francis Group, LLC. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.)

Parvovirus B19 is found in the nasopharynx, and transmission is probably through the upper airway, as well as by transfer of contaminated blood products or tissues.[16,17,183,184] The major

sites of viral replication are the adult bone marrow and the fetal liver.[51(p19),207] Changes in the hematopoietic tissues include giant pronormoblasts in bone marrow aspirates and fetal liver tissue, along with depletion of later erythroid precursor cells.[15,70,207,273] Temporary depression of erythropoiesis results but is not significant in most healthy people. In people with a shortened red cell life span and reduced erythropoiesis, acute B19 infection causes transient aplastic crisis (TAC) and a precipitous worsening of anemia.[16,17,51,401] Predisposing conditions include sickle cell anemia, hereditary spherocytosis, enzymopathies, thalassemias, and acquired hemolytic anemias. Resolution of the crisis begins about 7 to 10 days after onset due to antiviral antibody and viral clearance.

Fetal infection may cause nonimmune hydrops fetalis characterized by severe anemia, high-output cardiac failure, and often fetal death.[361,388,392] Erythroblasts in the fetal liver are infected, and fetal myocarditis may contribute to the pathogenesis.[70,294] The risk for a fatal outcome is greatest during the first two trimesters, and fetal infection may persist after birth as pure red cell aplasia (PRCA).[33,124,388] About 30% of maternal infections are vertically transmitted, and fetal death occurs in 2% to 10% of maternal infections.[270]

B19-related parvoviruses may be common in various primates, including rhesus monkeys, pig-tailed macaques, chimpanzees, and gorillas, but likely cause severe disease only when animals are immunosuppressed.[271,332] Acute diseases range from inapparent to very mild, and appear to lack the arthropathy seen in humans. An erythroparvovirus-like virus has been found in Manchurian chipmunks.[398]

Canine and Feline Parvoviruses

CPV and FPV are very closely related strains and cause disease primarily in young animals, with a lessening of severity as the animals age.[278] The FPV-like viruses have long been found in cats, raccoons and many related hosts, while CPV is a dog-specific variant that emerged only in 1978.[12,378] CPV has since undergone variation in both antigenicity and in host range for cats and other carnivores.[14,364,375] The viruses infect through the oral–nasal route, replicate in the pharyngeal lymphoid tissues, then spread as a free or cell-associated viremia to the other lymphoid tissues.[61,62,100,235,236,248] Lymphocytes are lost from many tissues; then the virus spreads to the small intestine, infecting the rapidly dividing stem cells in the crypts of Lieberkühn, resulting in a loss of epithelial cells from the small intestine, shortened and nonabsorptive villi, and subsequent diarrhea.[60,237] Animals that survive recover normally and are protected against reinfection by the immunity they develop.

Porcine Parvovirus

A number of genotypes of PPV are now described, but fetal disease is mostly associated with the PPV type 1, while other diseases are associated with the type 2 strain.[211,247,351] Infection of older pigs by PPV-1 is mild or subclinical, but in pregnant pigs the virus takes approximately 15 days to reach the fetus, and can result in fetal death and resorption or mummification; fetuses infected prior to reaching immune competence (55 to 70 days of gestation) have an extensive infection and die.[102,182,246] After approximately 70 days of gestation, the fetuses are generally less severely infected, and the virus replicates in the lymphoid tissues.[53] PPV has also been

associated with a skin vesicular disease.[202] Combined infections of PPV and porcine circovirus type 2 may cause a severe disease termed *porcine circovirus disease*.[149,155]

Aleutian Mink Disease Virus

AMDV is widespread in mink and related carnivores (skunks, ferrets, and foxes) without much associated disease. The virus mostly causes disease in farmed mink of susceptible genotypes.[43,178] In neonatal mink without maternal immunity, infection of type II pneumocytes results in pneumonitis, while older animals, or young animals with antiviral antibodies, develop a chronic infection and disease characterized by plasmocytosis, hypergammaglobulinemia, glomerulonephritis, arteritis, focal hepatitis, and death.[8–10] Lesions in chronically infected mink result from chronic viral antigen production and antibody complexes that are not efficiently cleared.[158] The Aleutian coat color mutation is linked to more severe disease because of a lysosomal storage disease similar to the human Chédiak-Higashi disease.[150] Vaccination may enhance the disease; however, control can be achieved by testing and culling of infected animals, as transmission appears relatively inefficient.

Rodent Parvovirus Diseases

Many different parvoviruses infect rodents, including experimental and wild mice and rats, as well as other rodents.[37,38,174,310,394] Rodent parvoviruses can develop persistent infections but are not usually associated with overt clinical disease.[131] They can also infect and persist in rodent and other cells in tissue culture and be introduced into animals by transfer of those cells.[37,242,394] The viruses may cause fetal abnormalities or death owing to their tropism for dividing cells. Control is most effectively by physical isolation and barriers, by serologic or DNA testing, and by culling of the infected animals or populations, followed by cesarean derivation of the young into a clean environment.[176,379]

Other Pathogenic Parvoviruses

Several goose parvoviruses have been described, and those can infect goslings, resulting in focal or diffuse hepatitis and widespread degeneration of striated, cardiac, and smooth muscles.[142,343] Duck parvovirus causes a similar disease in ducks. Bovine and rabbit parvoviruses are common, but not generally associated with clinical disease. Minute virus of canines (canine minute virus; canine bocaparvovirus) is widespread in dogs, but the infection is generally subclinical or there may be disease in association with infections by other pathogens.[64,287,326]

Dependoviruses

Natural AAV infections are assumed to occur via respiratory or gastrointestinal routes. It is not clear which tissues are the preferred sites of latency or infection in humans. The virus has not been detected in human lung samples but is recovered from a small percentage of hematopoietic cells and from the female genital tract.[129,146] AAV has been found in muscle biopsies.[360] The chromosome 19 integration site is associated with the *MBS85* gene, and integration alters that gene expression.[118] Skeletal muscle normally is not infected by adenovirus or herpesviruses, so the association with viral replication is unknown.

IMMUNE RESPONSE, KEY ANTIGENS, AND VACCINATIONS

Immunity to parvovirus infection includes both antibody and T-cell responses. Antibodies protect animals against infection by most parvoviruses and aid in recovery, as antibody therapy can resolve chronic human infections with B19 and clear canine infections by CPV.[127,206,248] The immune responses in hosts that recover protect for many years. The major antigens recognized by antibodies are the conformational epitopes of the capsids.[121,151,225,366] Antibodies to the capsids of AAV can interfere with gene therapy.[251,264,369] Other structures recognized by neutralizing antibodies include the VP1 unique region of the B19 virus[257,313] and an exposed peptide of the VP2 N-terminus of CPV.[213] Less is known about the T-cell responses to parvoviruses; however, these are likely important in recovery from infection.[173,188,308,333]

Vaccines

Modified live and inactivated or subunit vaccines have been developed against parvoviruses, and in many cases they protect against infection. A candidate recombinant vaccine has been developed against B19.[35] Modified live vaccines protect dogs and cats against CPV and FPV,[32,63] and vaccines against PPV are also successfully used.[279,280]

EPIDEMIOLOGY

Prevalence and Incidence

Many parvoviruses appear to be widespread, and most circulate readily among susceptible individuals. Parvovirus B19 infects almost all humans, and IgG antibody generally persists for life; 50% of children have anti-B19 antibodies by 15 years of age, as do more than 90% of elderly people.[50,87,136] Viremia is relatively short-lived, and although virus may be transmitted by blood, few donated blood units contain high titers of B19.[59,183] Between 10% and 60% of susceptible schoolchildren and 20% to 30% of susceptible or adult school and day care personnel can develop fifth disease in school outbreaks,[50,80,139,199] Because of the resistance of parvoviruses to heat and solvents, virus may survive the inactivation treatments employed for blood products and pass through filters; thus, the virus can be spread through pooled blood products, although infections appear uncommon.[162,197,389]

Virus is shed at very high titers in feces during CPV or FPV infections and persists in the environment.[278] Maternal antibodies protect animals against infection by CPV and FPV, but after maternal antibodies wane pups or kittens are highly susceptible.[292] Vaccination with modified live vaccines provides strong protection; however, that is also blocked when maternal antibody is present.[63,71]

Adeno-Associated Virus Infections

AAV productive infections occur in the presence of adenovirus or herpesvirus infections, and respiratory, fecal–oral, direct conjunctival, and sexual transmission have all been suggested.[40,41,138,153,325] AAVs infect a wide variety of mammals; however, cross-species transmission is not known. AAV2, AAV3, and AAV5 have been obtained from humans in the presence of numerous adenovirus serotypes.[27] AAV3 was isolated during an outbreak of adenovirus type 3 conjunctivitis among children and adults, and was found in conjunctival, throat, and fecal specimens.[325] AAV5 was isolated from a male with a flat condylomatous genital lesion.[27] AAV DNA (primarily AAV2) has been detected in peripheral blood cells, cervical biopsy samples, and tissues from spontaneous abortions, as well as tissue culture cells and adenovirus isolates.[134,146,153,324] Many humans have antibodies to various AAV serotypes, which reduce the efficiency of gene transduction.

Treatments

Few specific treatments are used for most parvovirus infections. Chronic or persistent B19 infections of naturally or therapeutically immunosuppressed individuals can be treated with immunoglobulin preparations containing antiB19 antibodies.[127,205]

ADENO-ASSOCIATED VIRUS AS A VECTOR FOR GENE THERAPY

Several AAV types has been developed as vectors for human gene therapy, and a number of treatments are now being licensed. Different AAV serotypes have varying cell receptors, tissue tropisms, and host ranges, and differ in binding to antibodies against specific serotypes.[79,144,258] Most AAV vector genomes contain the transgene(s) and regulatory sequences between two copies of the AAV ITR, and little of the AAV genome sequence remains, and their greatest capacity is approximately 4.5 kb.[143] Some approaches to expanding the capacity include packaging of different parts of a transgene in two vectors to produce a larger spliced message and a functional protein product.[115,212]

Production of AAV vectors involves helper functions, such as the adenovirus or the HSV genes required for transcription and DNA replication. Most vectors lack both Rep proteins and Rep-binding sites in the DNA and hence do not integrate into specific integration sites,[200,320] so the transduced DNA remains within the cell primarily as extrachromosomal elements, and loss by dilution occurs during cell division. Targeting site-specific integration may overcome the challenges of cell division, and providing Rep in *trans* may allow more site-specific integration.[304] Vectors may be administered to isolated cells *ex vivo* as well as after *in vivo* administration via intramuscular, intravenous, bronchial, or upper respiratory routes, and by injection into the eye, and minimal toxicity has been observed. Transgene expression may be maintained for years in experimental tests.

The list of conditions that are treated or that may be treated with AAV gene therapy is now

extensive, as reviewed by[19,193,217,377]. Some conditions include hemophilia, acute macular degeneration, diabetes, parkinsonism, α1 antitrypsin deficiency, Leber congenital amaurosis, and hemophilia B. Different AAV serotypes and engineered variants show dramatically variant rates of transduction in various tissues, so that clinical trials may involve different serotypes and alternative routes of administration.

SUMMARY AND CONCLUSIONS

Parvoviruses include a wide variety of viruses that likely infect most (or even all) animals, from mammals to crustaceans. Although the long-known parvoviruses often cause various acute or chronic diseases, most of these viruses likely cause little or no disease, and those are being revealed by DNA detection or sequencing methods. The small genomes encode two large genes that are expressed in various spliced versions, as well as several small transcripts and proteins that are often less well characterized. The viral capsids are robust and survive in the environment and are assembled from 60 total copies of two or three forms of the same protein, and the overall topology and capsid forms are all similar, even when the viral sequences are very divergent. The capsids control DNA packaging, receptor binding, and cell infection. The viruses are highly dependent on host cell functions for their replication and generally complete their replication cycles in cells undergoing mitosis or that are coinfected with a helper virus. The lack of pathogenicity and efficient transduction capabilities of the AAVs has made them favored gene therapy vectors for use in humans.

- Genome structure and organization
- Stages of replication
- Pathogenesis and pathology
- Epidemiology and clinical features
- Diagnosis, prevention, and control
- Perspective

The *Circoviridae* and *Anelloviridae* are two families of small, circular, single-stranded DNA viruses with nonenveloped icosahedral viruses. They are similar in that both have capsids with *T = 1* icosahedral symmetry, exhibit a high degree of genetic diversity, replicate in nucleus of mitotically active cells, infect a large number of animal species including humans, and are ubiquitous in environments. They are distinguished by their morphology and coding strategy. The virions of anelloviruses, as revealed in chicken anemia virus (CAV), are larger with protruding pentagonal units compared to those with flat pentameric units in circoviruses. The circovirus genomes use an ambisense strategy for rolling circle replication (RCR) of the genome, whereas the anellovirus genomes employ a negative-sense strategy for replication. They are being considered in this chapter together because of their similar genome structure and ubiquity in nature.

CIRCOVIRIDAE

History

The prototype circovirus, porcine circovirus (PCV), was first reported in 1974 as papovavirus- and picornavirus-like particles in a contaminated porcine kidney cell line PK-15.[165] The name circovirus was proposed in 1982 when the viral genome was determined to be a circular single-stranded DNA molecule.[163] PCV was not known to be pathogenic[164] until 1997 when a variant strain, PCV type 2 (PCV2), was isolated from pigs with a wasting disease.[2] The PK-15 cell–derived virus was designated PCV1 to distinguish it from the pathogenic PCV2. In 2016, PCV3 was identified from pigs in the United States and subsequently from a number of other animal species.[130,135] PCV3 has been incriminated in several clinical conditions,[4] although its definitive association with a disease remains highly debatable. The avian circovirus, psittacine beak and feather disease virus (BFDV), was isolated in 1989 as a novel virus with a single-stranded circular DNA genome from cockatoos with beak and feather disease.[144]

Definitive evidence of human infections by circoviruses is lacking. Antibodies to PCV1 were reportedly detected in humans,[164] although subsequent studies could not confirm the initial report.[3,33] Evidence of productive PCV1 infection was demonstrated in human hepatocellular carcinoma cell line Huh-7,[8] and human cell lines were also reportedly infected by PCV2.[81] Contamination of PCV1 and PCV2 in live-attenuated human rotavirus vaccines prompted the FDA to temporarily suspend the use of the vaccines.[7,169]

Classification

Viruses in the family *Circoviridae* infect mainly mammalian and avian species. The genomic organization and replication strategy of circoviruses are similar to those of plant geminiviruses and nanoviruses. In fact, animal circoviruses may have evolved from a plant nanovirus through host switch followed by a recombination event with a picorna-like virus in a mammalian host.[49] Two genera of circoviruses, *Circovirus* and *Cyclovirus*, have now been recognized by the ICTV. The genus *Circovirus* consists of at least 39 species infecting a broad range of hosts such as pig, bat, bird, dog, chimpanzee, human, mink, rodent, and fish.[178] The genus *Cyclovirus*, originally discovered from stool samples of humans and chimpanzees,[76] contains at least 47 species identified from a large number of hosts including human, bat, cattle, chicken, chimpanzee, duck, cat, goat, horse, rodent, and insect.

Virion Structure

Circoviruses contain a single-strand circular DNA genome enclosed within a capsid, which is the only known structural protein in the virion. Morphologically, members of the genus *Circovirus* appear as small, nonenveloped, icosahedral particles of approximately 15 to 20 nm in size[28,104] (Fig. 7.1). Members of *Circoviridae* all have a $T = 1$ structure containing 60 copies of the capsid protein.[28] The capsids of genus *Circovirus* consist of 12 flat pentameric morphological units[28] (Fig. 7.2). The virion structure of genus *Cyclovirus* is currently unknown.

Genome Structure and Organization

The genome of *Circoviridae* is a single-stranded circular DNA molecule of 1.7 to 2.0 kb in size.[178] These are the smallest DNA viruses known to infect mammals and birds, and the genome size is reduced to the absolute necessities for the two basic functions of a virus, copying and packaging of viral genome.

For the genus *Circovirus*, the genome contains two major ORFs coding for the replicase protein (Rep) and capsid protein (Cap), respectively. The *rep* and *cap* genes are oriented in the opposite direction resulting in an ambisense genome organization. The Rep and Rep′ are produced from alternatively spliced RNA transcripts and contain endonuclease and helicase domains involved in rolling circle replication. An intergenic region between the 5′ ends of *rep* and *cap* genes contains the origin of viral genome replication (*Ori*), which is characterized by a stem-loop structure with a nonamer motif in its apex (Fig. 7.3). Three or four hexamer repeat motifs adjacent to the stem-loop serve as the binding sites for Rep and Rep′ to initiate rolling circle replication of viral genome.[40,94] The *rep* or *Ori* between PCV1 and PCV2 are fully exchangeable,[9–11,36–38] indicating conserved functionality of these regions among members of

the genus *Circovirus*.

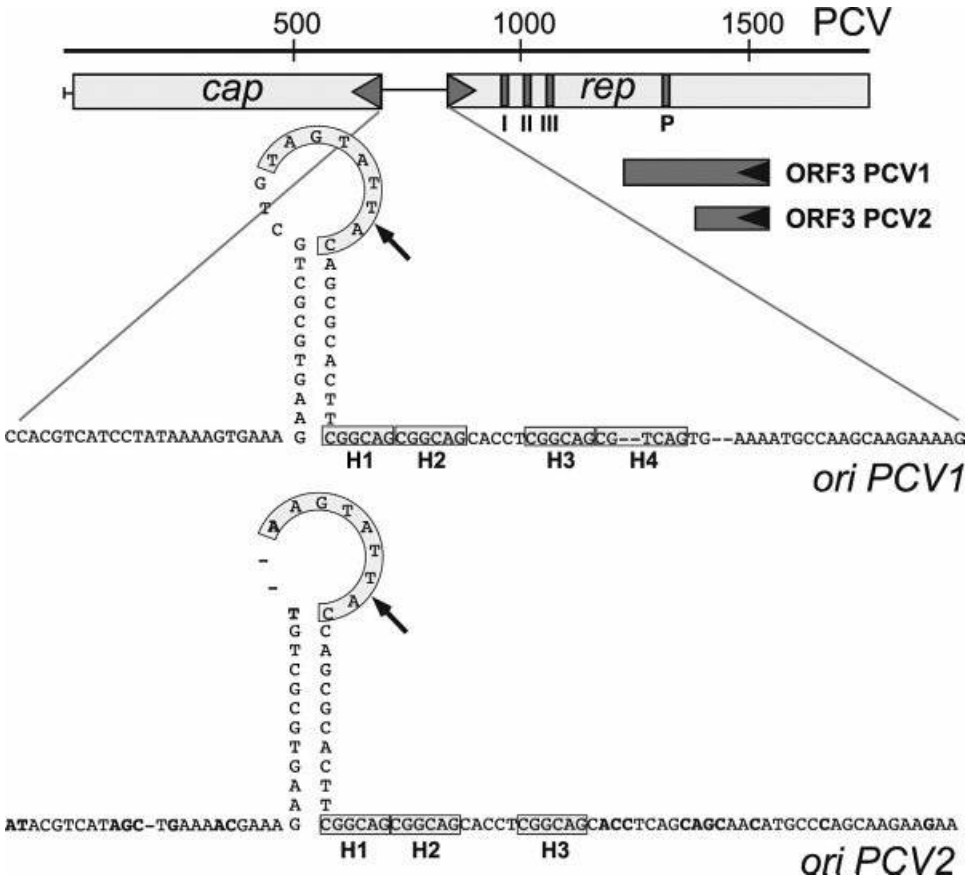

FIGURE 7.3 A linear map of the PCV genome indicates the two major ORF encoding *rep* and *cap*. Three motifs conserved in RCR enzymes (I–III) and a dNTP-binding domain (*P*) indicated within the rep gene. The ORF3 differing in length in PCV1 and PCV2 is indicated in *gray boxes*. The lower part shows a comparison of the two *Ori*s of PCV1 and PCV2. Sequences have been aligned, and the hexamer repeats 1 to 4 are marked by *open boxes*. The conserved nonamer sequence within the single-stranded loop of the hairpin is indicated by a *gray box*, the nicking site by an *arrow*. (Reprinted from Finsterbusch T, Mankertz A. Porcine circoviruses—small but powerful. *Virus Res* 2009;143(2):177–183. Copyright © 2009 Elsevier. With permission.)

Like genus *Circovirus*, members of the genus *Cyclovirus* also consist of two major ORFs encoding the Cap and Rep.[76] Unlike circoviruses in which the Rep is encoded on the virion sense strand and the Cap on the complementary sense strand, the gene orientation is opposite for cycloviruses. The genes encoding the Rep and Cap of most cycloviruses overlap at their 3′ ends. The intergenic region at the 3′ end of the ORFs is relatively smaller in cyclovirus genomes than that in circovirus genomes.

Stages of Replication

Among the 39 species in the genus *Circovirus*, only PCV1 and PCV2 can be propagated *in vitro*. Currently, there is no cell culture system for members of the genus *Cyclovirus*. Thus, the knowledge of circovirus replication is derived mostly from the studies of PCV1 and PCV2.

Attachment, Entry, and Uncoating

Glycosaminoglycans (GAG), heparin, heparan sulfate, and chondroitin sulfate B are attachment receptors for PCV2.[101,177] However, the interaction between PCV2 and heparin does not follow the icosahedral symmetry of the PCV2 Cap.[31] It is not surprising that PCV2 utilizes GAG as the general attachment receptors[40] (Fig. 7.4), since the virus targets multiple organs and tissues in infected pigs.[156] The target cells for PCV2 shift from cardiomyocytes, hepatocytes, and macrophages during fetal life to only macrophages postnatally.[146] A yet to be identified specific receptor may be needed for more efficient binding and entry of PCV2 into cells.[40]

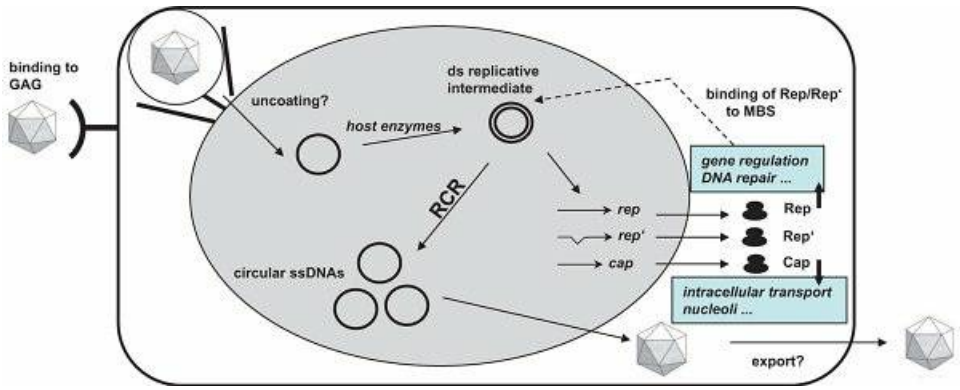

FIGURE 7.4 Life cycle of PCV. PCV uses glycosaminoglycans (GAG) as attachment receptors. After uncoating, the ssDNA genome is transported into the nucleus and converted by host enzymes into a dsDNA intermediate. The rep and cap mRNAs are transcribed, and the proteins are synthesized and imported from the cytoplasm. Rep and Rep′ bind to the dsDNA and initiate RCR by introduction of a nick that serves as primer. Elongation of the primer by host enzymes leads to replication. The Rep is covalently bound to the DNA and terminates the reaction by introduction of a second cleavage reaction via Tyr-93. Events leading to assembly and release of virions are unknown. (Reprinted from Finsterbusch T, Mankertz A. Porcine circoviruses—small but powerful. *Virus Res* 2009;143(2):177–183. Copyright © 2009 Elsevier. With permission.)

PCV2 is internalized by dendritic cells (DCs), and the internalization was observed with both mature and immature cells including blood DCs, plasmacytoid DCs, and DC precursors, and thus suggestive of a nonmacropinocytic uptake of the virus.[171,172] PCV2 virus-like particles (VLPs) quickly bound to porcine monocytic cells 3D4/31 and enter cells predominantly via clathrin-mediated endocytosis and require an acidic environment for infection.[102] PCV2 targets lymphoblasts *in vivo*, and infected pigs developed lymphocyte depletion in lymphoid tissues.

PCV2 reportedly attached to 11% to 26% of the T lymphoblasts *in vitro*, and 2.6% to 12.7% of the cells showed virus internalization.[177] It is believed that PCV2 binds to T lymphoblasts via chondroitin sulfate and enters the cells via clathrin-mediated endocytosis.[177] The epithelial cells are also major targets for PCV2 *in vivo*. Although PCV2 quickly attaches to epithelial cells, virus entry is slow.[100] It appears that a dynamin- and cholesterol-independent, but actin- and small GTPase-dependent, pathway allows PCV2 entry and internalization leading to full replication in epithelial cells.[100] A nuclear localization signal (NLS) with rich positively charged residues was identified in the N terminus of the PCV2 Cap and reportedly functions as a cell-penetrating peptide (CPP), similar to the classical CPP derived from HIV TAT. In addition to entering cells via endocytic pathways, the first 17 residues of the PCV2 Cap NLS play an important role in cellular uptake of cargo molecules.[182] After entry, PCV2 is localized in the endosomes[40] (Fig. 7.4). As the endosomal vesicles move toward the nuclear membrane and become acidic, a serine protease appears to be required for PCV2 release from the endosome, suggesting that a proteolytic cleavage of Cap may be a part of the uncoating process.[99,101,102] It has been shown that the ubiquitin– proteasome system is important for early stages of PCV2 replication and that protein ubiquitination may play a role in PCV2 replication.[17] PCV2 infection of untreated and chloroquine diphosphate–treated porcine kidney PK-15 cells was blocked by a serine protease inhibitor, suggesting that serine protease–mediated PCV2 disassembly is enhanced in porcine epithelial cells but inhibited in monocytic cells after inhibition of endosome–lysosome system acidification.[99]

Transcription

A total of nine RNA transcripts were synthesized during productive PCV2 infection in PK-15 cells: Cap protein RNA (CR), five Rep-associated RNAs (Rep, Rep′, Rep3a, Rep3b, and Rep3c), and three NS-associated RNAs (NS515, NS672, and NS0)[18] (Fig. 7.5). Rep′, Rep3a, Rep3b, and Rep3c are produced from Rep by alternate splicing. The three NS-associated RNAs are transcribed from three different promoters inside ORF1 and share only the 3′ sequence with Rep.[18] A stop codon introduced at the 5′ end of CR did not affect Rep-associated viral antigen or DNA synthesis.[19] Altering the consensus dinucleotides at the splice junctions of the minor Rep- and NS-associated RNAs or introducing a stop codon in the abundant NS0 RNA also had no effect on viral protein or DNA synthesis. However, mutations resulting in truncated Rep or Rep′ reduced viral protein synthesis by more than 99% and abolished viral DNA replication, indicating that both Rep and Rep′ are essential for PCV2 replication.[20] In contrast to the pathogenic PCV2, a total of 12 RNAs were synthesized in PCV1-infected porcine kidney PK-15 cells[19] including the viral CR RNA, eight Rep-associated RNAs, and three NS-associated RNAs.[19] The promoter for *cap* is mapped within the ORF1 (nt 1328–1252), and the promoter for *rep* is located in the intergenic region (nt 640–796) and overlaps the *Ori* of PCV1.[91]

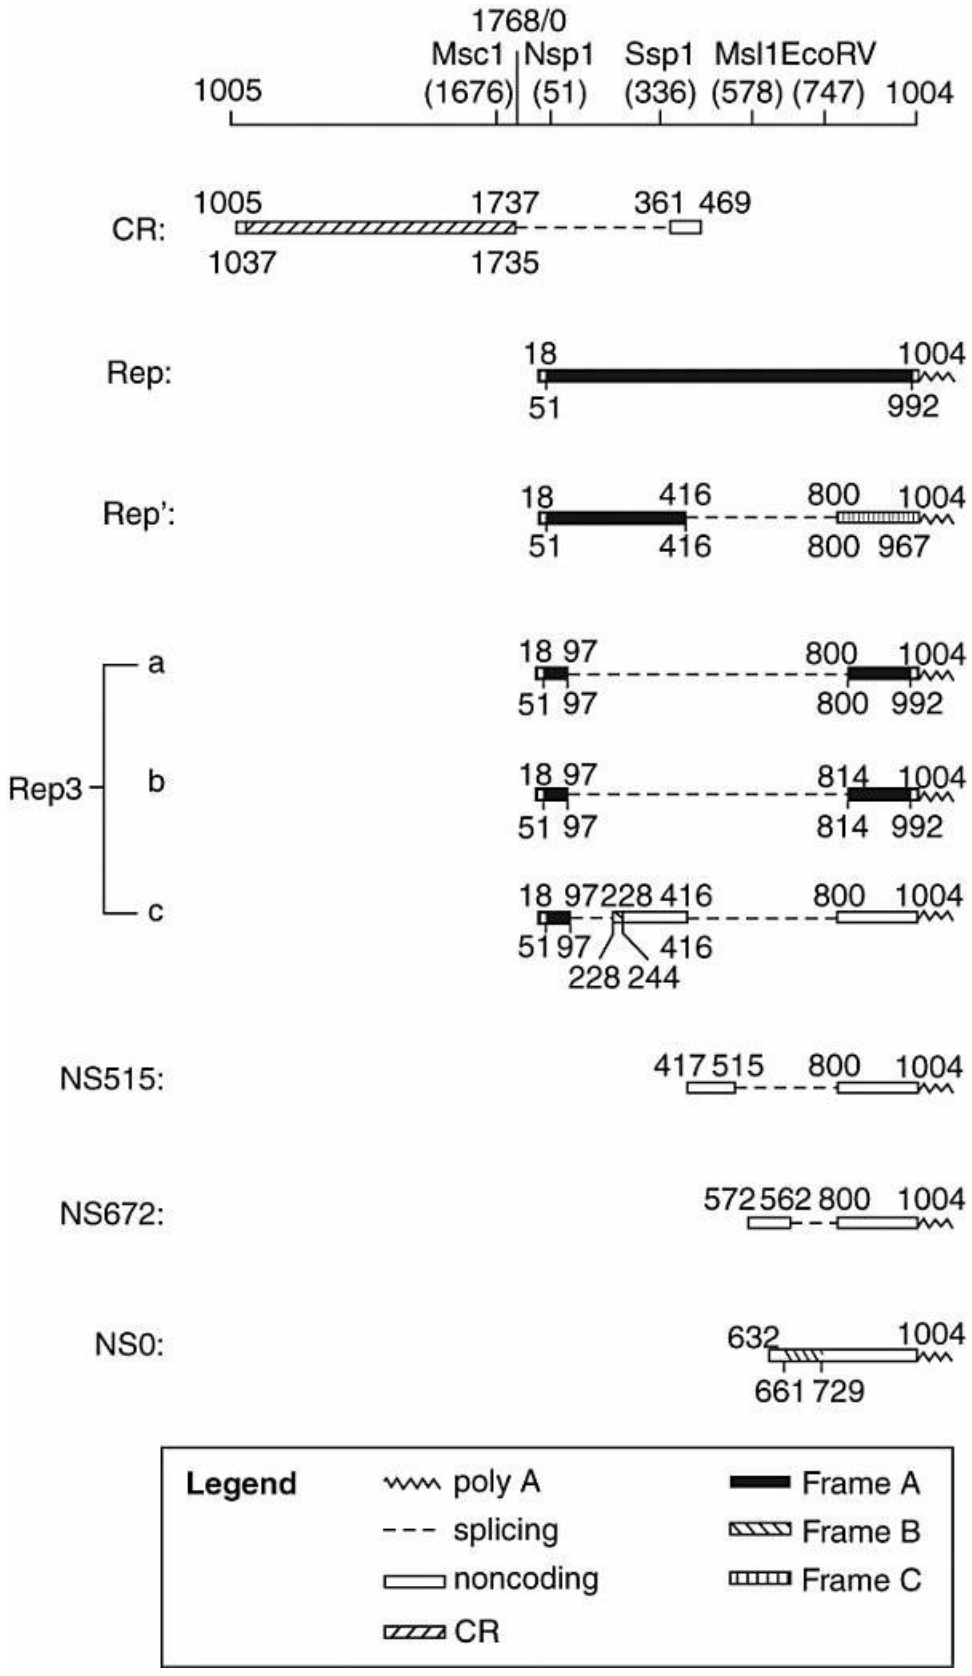

FIGURE 7.5 Summary of the PCV2 RNA transcripts. The schematic representation

of the PCV2 genome with relevant restriction enzyme sites is shown on *top*. The RNA is annotated on *top* with nt coordinates that indicates the last nucleotide of each respective exon. The coding sequence of each transcript was shaded and their nt coordinates are indicated below each RNA. (Reprinted from Cheung AK. Transcriptional analysis of porcine circovirus type 2. *Virology* 2003;305(1):168-180. Copyright © 2003 Elsevier. With permission.)

Several cellular gene transcripts were up-regulated in both PCV2-infected PK-15 cells and affected tissues including two transcripts with homology to an RNA splicing factor (SPF30) and a hyaluronan-mediated motility receptor. Microarray analyses of the genes in lymph nodes of PCV2-infected pigs revealed altered expression levels in genes that are involved in innate immune defense (TLR1, CD14, and CD180), immunosuppressed responses (FGL2 and GPNMB), proinflammatory signals (galectin-3), and fasting processes (ANGPTL-4), suggesting that PCV2 has developed an intricate mechanism to induce immunosuppression, inflammatory cell infiltration, and weight loss in pigs.[74] PCV2, but not PCV1, induces IL-10 secretion by monocytic cells, which led to repression of IL-12 in PBMCs.[69] The PCV2 ORF3 protein binds to a regulator of G protein signaling (RGS) and is colocalized with poRGS16 in LPS-activated porcine PBMC. The poRGS16 appeared to participate in the translocation of ORF3 protein into the nucleus.[162] NF-kB was activated concomitantly with PCV2 replication, and treatment of cells with an NF-kB inhibitor reduced virus protein expression and virion production, suggesting that NF-kB activation is important for PCV2 replication.[176]

Translation

The genome of genus *Circovirus* consists of two major ORFs: ORF1 encodes the Rep and Rep′, and the ORF2 encodes Cap. Rep is translated from the full-length *rep* transcript, while Rep′ is produced from a spliced transcript.[40] Both Rep and Rep′ are essential for the initiation of virus replication.[24,92,93] Mutation within motifs I-III and the GKS box of the Rep and Rep′ interfered with viral replication. Motifs I to III are essential for PCV1 *Ori* cleavage.[158] The repression of *rep* promoter is mediated by binding of Rep to H1 and H2 hexamers in the *Ori* of PCV1; however, transcription of *cap* promoter is not influenced by viral proteins.[41,93] Both Rep and Rep ′ colocalize in the nucleus of infected cells and form homo- and heteromeric complexes.[41,92] Three putative NLSs are present in the N termini of Rep/Rep′: NLS1 and NSL2 mediate nuclear accumulation, whereas NSL3 enhances the nuclear transport of Rep and Rep′.[41] PCV2 Rep interacted with an intermediate filament protein, similar to human syncoilin, and with the transcriptional regulator c-myc.[161] The PCV Rep also binds three porcine cellular proteins[1,42]: ZNF265 is an alternative component of the spliceosome, whereas VG5Q and TDG were linked to transcriptional regulation.

The Cap of the genus *Circovirus* can self-assemble into VLPs[14,104] and elicits neutralizing antibodies in vaccinated animals.[13,75] At least five different but overlapping conformational epitopes were identified within residues 47 to 63 and 165 to 200 and the last four amino acids at the C terminus of PCV2 Cap.[75,90] Two amino acid mutations in the Cap, P110A and R191S, enhance the growth ability of PCV2 *in vitro* but attenuate PCV2 *in vivo*.[39] The Cap localized in the nucleoli of PCV2-infected cells[82] and in the nucleoli of cells at an early stage of PCV1

infection.[41] The PCV Cap interacts with numerous cellular proteins[42,161] including complement factor C1qB, E3 ubiquitin ligase family member MKRN1, and proapoptotic gene product Par-4.[40] The exact function of these cellular factors in PCV replication remains to be elucidated.

An ORF3 has been identified in PCV1 but is truncated in PCV2. The *in vitro*–expressed ORF3 protein of PCV2 induced apoptosis through the activation of caspase 8 and caspase 3 pathways.[80] The ORF3 protein interacts with pPirh2 and competes with p53 in binding to pPirh2 and mediates the deregulation of p53 homeostasis, leading to increased p53 levels and apoptosis of the infected cells.[66,84] It was reported that abrogation of the ORF3 function attenuated PCV2 in pigs,[65] although other studies showed that PCV2 pathogenicity is not solely determined by ORF3.[15,60] In fact, whether or not PCV2 infection causes apoptosis remains controversial.[72,142,172] It has been reported that PCV2 induces ORF3-independent apoptosis, due to activation of PERK pathway, via increased cytosolic and mitochondrial Ca^{2+} levels and cellular reactive oxygen species levels.[185]

A small ORF4, which overlaps ORF3 in the same direction, was also identified in PCV2, but its function in virus replication, if any, is controversial. The ORF4 was shown to be dispensable for PCV2 replication but may play a role in inhibiting the caspase activity and regulating CD4+ and CD8+ T cells during virus infection.[51] It was suggested that ORF4 protein may play a role by restricting ORF3 transcription to prevent virus-induced apoptosis.[46] The ORF4 reportedly binds ferritin heavy chain to antagonize apoptosis by stabilizing its concentration.[85,86] By contrast, Lin et al. reported that the ORF4 actually induces apoptosis by interacting with adenine nucleotide translocase 3 (ANT3) through the mitochondrial pathway.[79]

Replication of Genomic DNA, Assembly, and Release

After uncoating, the single-strand circular viral DNA genome is converted to dsDNA intermediate by host enzymes in the nucleus. Binding of Rep and Rep′ to *Ori* unwinds the dsDNA intermediate to initiate genome replication.[21–25,40] Viral genomes with mutations on either or both arms of the inverted repeats (IR, palindrome) were still capable of synthesizing viral proteins and producing infectious viruses with restored or new palindromes, indicating that a flanking palindrome at *Ori* is not essential for initiation of viral DNA replication. A rolling circle “melting-pot” model for circovirus DNA replication was proposed[22,23] (Fig. 7.6). The Rep and Rep′ complex binds, destabilizes, and nicks the *Ori* sequence to initiate leading-strand DNA synthesis.[22] The four strands of the destabilized IRs exist in a “melted” configuration, and the minus-strand viral DNA and a palindromic strand serve as templates simultaneously during initiation or termination of viral DNA replication. The palindromic sequences flanking the *Ori* can potentially form single-stranded stem-loop cruciform structures that are essential for circovirus replication.[23] Three conserved rolling circle replication motifs (RCR-I, RCR-II, and RCR-III) and a dNTP-binding motif were identified within PCV Rep and Rep′.[40,157,168] Mutations of the conserved motifs negatively affect PCV replication.[93,158] The RCR-II motif is involved in the nicking of the viral DNA, and the Tyr-93 residue within the RCR-III motif cleaves the phosphodiester bond to produce a 3′-hydroxyl group that serves as a primer for viral genome replication and a 5′-phosphate of the cleavage product that covalently attaches to Rep and Rep′.[157,168] After a round of replication, the newly synthesized viral genome DNA is cleaved again, and the 5′-phosphate is ligated to the 3′-hydroxyl group, resulting in the release of unit-

length single-strand monomer genomes.[40]

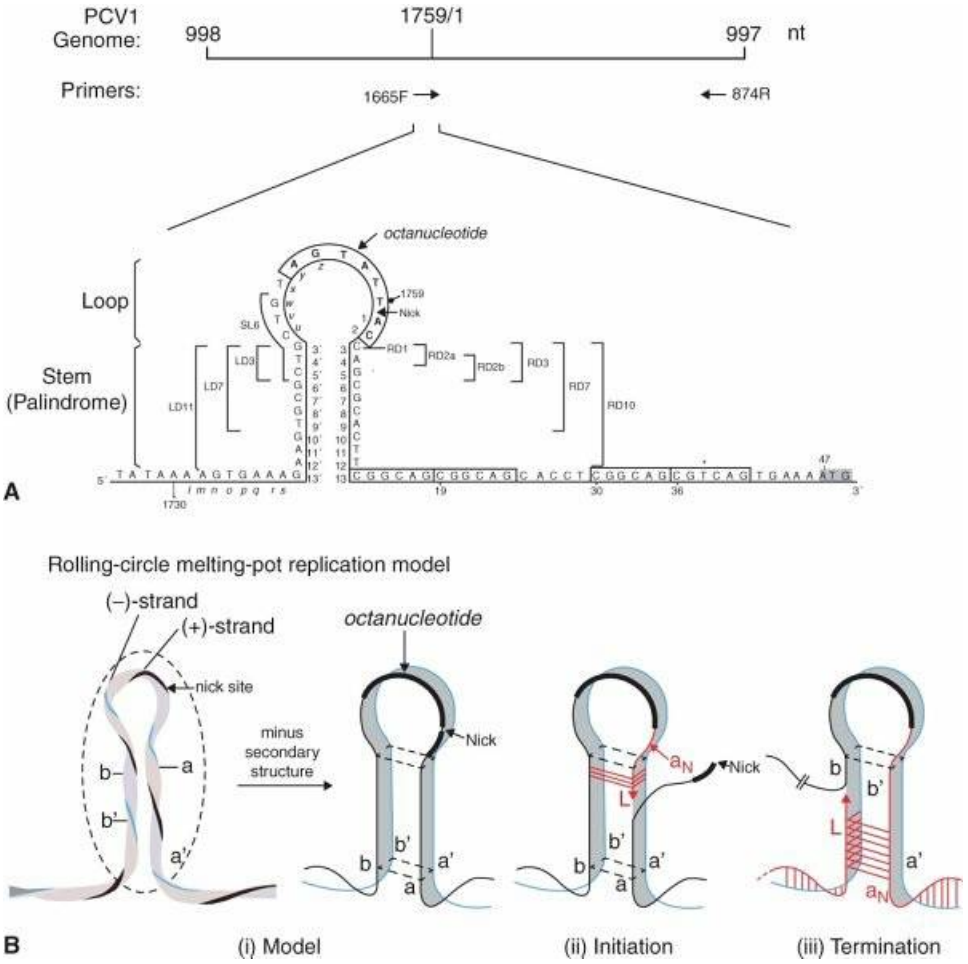

FIGURE 7.6 A: Schematic representation of the PCV1 *Ori*, indicating potential base pairing of the flanking inverted repeats. The genome sequence (1,759 nucleotides) and coordinates (1, 2, 3, etc.) are based on GenBank accession number AY184287. The nucleotide coordinates (3′, 4′, 5′, etc.) are arbitrarily assigned to show the nucleotide complementarity of the palindromic sequences. The octanucleotide containing the presumed nick site (AGTATT↓AC) is *boxed* and indicated in bold. The palindrome is divided into six regions (right arm, RD3, RD7, and RD10; left arm, LD3, LD7, and LD11). The six-nucleotide tandem repeats located at nucleotides 13, 19, 30, and 36 (not perfect at nucleotide 38 and indicated by an *asterisk*) are in *boxes*. Relevant nucleotide sequences are assigned arbitrary positions (l-m-n-o-p-q-r-s and u-v-w-x-y-z) to assist in retracing the templates used during replication. **B:** The rolling circle melting-pot replication model. (i) PCV1 *Ori* after Rep binding to the octanucleotide (prior to nicking) with the plus- and minus-strand genomes in close proximity to each other. The destabilized environment (i.e., the melting pot) is enclosed by a *dotted circle*. (ii) Schematic representation of the DNA templates available during initiation of DNA replication after removal of the secondary structure in the model. The leading strand (*L*) displaces strand a and uses strand a′ or strand b as the template. (iii)

Schematic representation of the DNA templates available during termination of DNA replication after removal of the secondary structure in the model. The leading strand (*L*) displaces strand b and uses the newly synthesized strand a_N or strand b′ as the template. The plus-strand genome is indicated in *black*, the minus-strand genome is indicated in *blue*, and the potential base-pairing opportunities available for the current round of DNA replication are indicated in *red*. (From Cheung AK. Palindrome regeneration by template strand-switching mechanism at the origin of DNA replication of porcine circovirus via the rolling-circle melting-pot replication model. *J Virol* 2004;78(17):9016–9029. The mechanism of PCV2 assembly and release remains largely unknown. It was reported that the p32 (gC1qR) is a key regulator for PCV2 nuclear egress.[173] PCV2 Cap recruits P32 to the nucleus as an adaptor to recruit phosphorylated PKC-δ and PCV2 Cap to the nuclear membrane to phosphorylate lamin A/C, leading to the rearrangement of nuclear lamina and facilitation of PCV2 nuclear egress. It was also demonstrated that nuclear targeting of PCV2 Cap involved conformational changes, and the viral genome was released from the assembled Cap.[175]

Pathogenesis and Pathology

Porcine Circovirus–Associated Diseases

PCV2 is associated with various disease conditions in pigs including postweaning multisystemic wasting syndrome (PMWS), reproductive failures, and porcine dermatitis and nephropathy syndrome (PDNS) collectively known as porcine circovirus–associated diseases (PCVAD).[127,147] The oronasal exposure is likely the natural route of PCV2 transmission, although pigs can be experimentally infected via intramuscular, oral, oronasal, and intrauterine routes of inoculation.[88,128,129] Lymphoid depletion and histiocytic replacement are characteristic lesions in lymphoid tissues[127] (Fig. 7.7). PCV2 is likely shed through respiratory and oral secretions, urine, and feces of infected pigs.[127] The interaction of PCV2 with the host immune system is a critical factor in PCV2 pathogenesis. Immunostimulations by coinfecting agents such as porcine reproductive and respiratory syndrome virus (PRRSV) or by adjuvants such as keyhole limpet hemocyanin exacerbate PCVAD.[127] An increase in IL-10 and proinflammatory cytokines such as IL-1 and TNF-α and a decrease in IL-2, IL-4 expression were observed in PCV2-infected pigs with PCVAD. An interferon-stimulated response element (ISRE) sequence was identified in the Ori of PCV2 genome. When present in the context of intact virus but not in isolation, the ISRE influences the interferon-mediated enhancement of PCV2 replication *in vitro* and plays a potential role in viral pathogenesis *in vivo*.[140,141]

The pathogenicity of PCV3 remains debatable. PCV3 was initially identified from pigs with cardiac and multisystemic inflammation,[135] PDNS, and reproductive failure.[130] PCV3 was detected from pigs with porcine respiratory disease complex (PRDC) in Thailand,[68] and PCV3 DNA was detected by *in situ* hybridization within lesions with myocarditis, encephalitis, and PDNS.[4] PDNS-like disease, but without mortality, was reportedly reproduced in pigs experimentally inoculated with PCV3 stock derived from a PCV3 infectious DNA clone,[58] although independent confirmation of this causal relationship is still lacking. The fact that PCV3 is highly prevalent in apparently healthy pigs[48,83] suggests that the mechanism of PCV3 pathogenesis is complicated and other cofactors may be involved. Little is known regarding the ability of cross-species infection by PCV3. Replication of PCV3 in baboons was reported following transplantation of a heart from a PCV3-positive donor pig, although an attempt to infect human 293 cells with PCV3 failed.[73]

Psittacine Beak and Feather Disease

Psittacine beak and feather disease (PBFD), caused by BFDV of genus *Circovirus*, is one of the most frequently diagnosed viral diseases in psittacine birds.[144,178] BFDV is now known to infect more than 60 different species of psittacine birds, and circovirus infections are common in many other avian species. The natural routes of exposures are thought to be via aerosolized virus particles or direct ingestion of contaminated materials. BFDV has tropism for rapidly dividing cells in mitosis stage such as basal follicular epithelium, lymphoid tissues, and intestinal epithelium. Virus transmission is through virus shedding in feather dander followed by fecal shedding and feeding of chicks with regurgitated crop contents. Gross pathological lesions include feather loss and dystrophy, and beak deformities. Microscopically, necrosis and inflammation are seen in dystrophic feathers. Lymphofollicular hyperplasia with necrosis and lymphoid depletion are commonly seen in lymphoid tissues of BFDV-infected birds.[178]

Epidemiology and Clinical Features

PCVAD affects grower pigs of 5 to 18 weeks of age and rarely occurs in 1- to 3-week-old pigs presumably due to maternal antibody protection.[96] PCV2 infection is widespread worldwide with 100% seropositivity in some herds; however, the morbidity is low and only a small proportion of infected animals (5% to 30%) actually develop clinical PCVAD.[127] Currently, there exist at least five different PCV2 genotypes (PCV2a, 2b, 2c, 2d, 2e), and PCV2a and PCV2b differ by as much as 10% at nucleotide sequence level.[10] PCV2 continues to evolve, as evidenced by continuous genotype shifts. Since 2003, PCV2b replaced PCV2a as the predominant genotype in swine populations. Since 2012, a second major genotype shift occurred when the PCV2d genotype has essentially replaced the previously predominant PCV2b genotype worldwide.[67,126] Currently, PCV2a, 2b, and 2d are all globally prevalent and are considered of major clinical importance.[126] The main clinical signs of PCVAD include progressive weight loss or decreased rate of weight gain, paleness or icterus, and gauntness and ill thrift[127] (Fig. 7.8A). The infected pigs may also experience labored respiration with coughing and diarrhea (Fig. 7.9). PCV2 is associated with a number of diseases including pneumonia, enteritis, reproductive failure, and PDNS (Fig. 7.8B).[127]

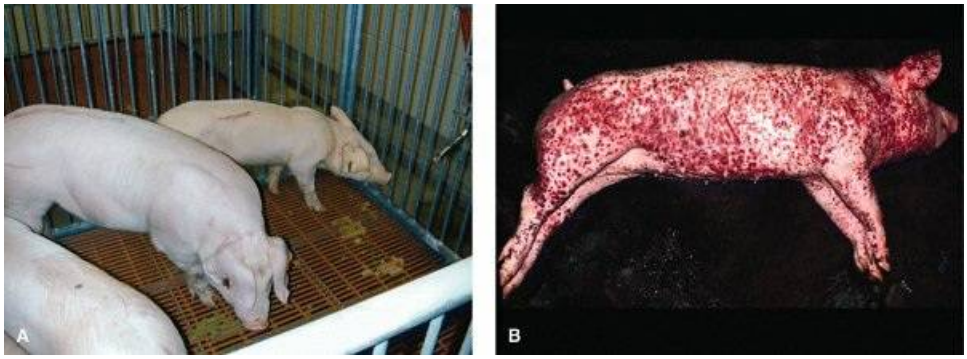

FIGURE 7.8 A: An 8-week-old pig experimentally coinfected with porcine circovirus type 2 (PCV2) and porcine parvovirus (PPV) showing icterus and a poor body condition typical of systemic PCVAD. **B:** A 12-week-old pig suffering from porcine dermatitis and nephropathy syndrome (PDNS). PCV3 apparently has a broader host range than do PCV1 and PCV2. In addition to pigs, PCV3 was reportedly detected in cattle[174] and dog,[159] although the biological and clinical significance of PCV3 in nonswine species are unclear. PCV3 was thought to have originated from a bat-associated circovirus, and at least two main clades (PCV3a, 3b) have been identified thus far.[16]

BFDV infection is usually seen in young psittacine birds of less than 3 years of age and young pigeons of less than 1 year of age, although older birds can also be infected. In general, circovirus infection in birds is associated with high morbidity but low mortality. The prevalence of BFDV infection varied in wild and captive bird populations. For example, approximately 41%

to 95% of the free-ranging psittacine birds in New South Wales are seropositive, whereas 5% of the captive birds in the United States are positive for BFDV.[178] Mortality and clinical signs in BFDV-infected birds varied depending on the age, species, and concurrent infection status. The most common signs in circovirus-infected pigeons include poor performance, diarrhea, and ill-thrift, whereas loss of flight and tail feathers is the main clinical sign in turtle doves.[178] The majority of the infected birds are subclinical.

Diagnosis, Prevention, and Control

The diagnosis of clinical PCVAD requires the demonstration of characteristic pathological lesions associated with the detection of PCV2 antigen or DNA in the affected tissues.[127] Prior to the availability of vaccines, good herd management practices, coinfection control, and disinfection of animal facilities can minimize the impact of PCV2 infection. Several commercial vaccines are available against PCV2 infection and PCVAD,[10,11,37,38,70] and these vaccines are highly effective. Definitive diagnosis of circovirus infections in birds requires the detection of viral antigen or DNA in affected birds. Virus isolation is not possible for most circoviruses. Currently, there is no commercial vaccine against BFDV, and thus control of circovirus infection in free-ranging birds is difficult.

Perspective

Members of the *Circoviridae* are associated with important animal diseases including PCVAD in pigs and PBFD in avian species. The biological significance and pathogenic potential for members of the genus *Cyclovirus* remain unknown. Contamination of live-attenuated human rotavirus vaccines with porcine circoviruses raised a concern of vaccine safety, although definitive evidence of zoonotic human infections by animal circoviruses is still lacking. Only porcine circoviruses can be propagated *in vitro*, and a specific cellular receptor for circoviruses has not yet been identified. Many steps in the circovirus life cycle are poorly understood. Future studies are warranted to elucidate the molecular mechanism of circovirus pathogenesis, identify cellular and viral factors that determine species tropisms, assess the zoonotic potential of animal circoviruses, and determine the clinical significance of cycloviruses.

ANELLOVIRIDAE

History

Anelloviruses are single-stranded, small circular DNA viruses infecting humans and a broad range of other animal species.[120,121] The first anellovirus, torque teno virus (TTV), was discovered from a Japanese patient with posttransfusion hepatitis of unknown etiology in 1997.[109] The virus was named “TTV” after the patient’s initials “T.T.” but was later adopted as torque teno virus in order to preserve the original abbreviation while also implying the circular nature of the virus genome: torque (from Latin *torques*, “necklace”) and teno (from Latin *tenuis*, “thin”).[12]

Other related viruses such as torque teno mini virus (TTMV) and torque teno midi virus (TTMDV), with smaller genomes than TTV, were subsequently identified in humans.[63,108,160] Studies have documented anelloviruses as the most abundant component of human virome, causing lifelong viremia.[43,44] Anelloviruses have also been identified in a large number of animal species with a high degree of genetic diversity.[59,121] The porcine anelloviruses, torque teno sus viruses (TTSuV), are highly prevalent in pig population worldwide and have been studied in more detail than other TTVs.[52–55,125] Human anelloviruses are epidemiologically incriminated in a number of diseases including liver diseases, respiratory disorders, hematological disorders, and cancer; however, there is no established direct causal relationship between TTV and a disease.[43,120]

CAV was first isolated in 1979,[183] although its complete genomic sequence was not determined until 1991.[27,113,119] The virus causes bone marrow atrophy, anemia, and immunosuppression in chickens.

Classification

In the absence of a disease association or lack of knowledge on anellovirus replication, the host species and genome size are utilized as the main criteria for taxonomic classification into different genera and species within the family *Anelloviridae*. According to the ICTV 9th Report, the *Anelloviridae* family consists of at least 14 genera (*Alpha-*, *Beta-*, *Delta-*, *Epsilon-*, *Eta-*, *Gamma-*, *Iota-*, *Kappa-*, *Lambda-*, *Mu-*, *Nu-*, *Theta-*, *Zetatorquevirus,* and *Gyrovirus*) and 76 species.

The genus *Gyrovirus*, previously classified within the family *Circoviridae*, has now been reclassified into the *Anelloviridae* family.[145] CAV is the prototype species within the genus *Gyrovirus*. At least 9 other gyrovirus species have now been identified from a number of animal species including chickens, birds, humans, ferret, mice, and domestic cats.[26,34,35,77,110,143,148,180] Avian gyrovirus 2, first reported in 2011 as a distant relative of CAV,[143,148] was identified in chickens and healthy humans.[181] GyV3 and GyV4 were identified from human feces,[26,136] and GyV3 has also been identified from commercial broiler chickens with transmissible viral proventriculitis.[78] GyV5 and GyV6 were detected in diarrheic samples from Tunisian children,[137] and GyV7 was detected in chicken meats.[184] The genome of a highly divergent GyV8 was characterized in the spleen and uropygial gland tissues of a sea bird in San Francisco.[77] GyV9 was found in the feces of an adult with diarrhea,[134] and GyV10 was discovered from birds with neurologic disease and chick mortality.[50] Unfortunately, little is known regarding the biology and pathogenicity of these novel gyroviruses; no direct association with a disease has been established. The ever-expanding host range with frequent identification of novel animal anelloviruses from diverse animal species suggests that the classification of *Anelloviridae* family will continue to evolve in the future.[44,152]

Virion Structure

The virions are nonenveloped spherical particles of approximately 30 to 35 nm in size for TTVs[56] and less than 30 nm for TTMVs.[160] The virion particles of CAV in the genus *Gyrovirus* have a diameter of 25 to 26.5 nm[28,47,97] (Fig. 7.2). The capsid of CAV, encoded by ORF1,

contains 12 pentagonal trumpet-shaped capsomers with a $T = 1$ icosahedral symmetry, which is different from that of *Circoviridae* that has 12 flat pentameric morphological units. Therefore, under EM, the circovirus virions have a smoother and more featureless surface than that of *Gyrovirus* CAV within the family *Anelloviridae*[28] (Fig. 7.2). Using viruses purified from sera, the virion buoyant density is 1.31 to 1.33 g cm^{-3} for TTVs[122] and 1.27 to 1.28 g cm^{-3} for TTMVs.[160] Anellovirus virion particles form immune complex with serum immunoglobulin in circulation, as visualized by immunogold electron microscopy[56] as aggregates of different sizes, while particles in feces exist as free virions.

Genome Structure and Organization

The genomes of anelloviruses are single-stranded circular DNA molecules ranging from 2.0 to 3.9 kb in size.[120,121] Members of *Anelloviridae* family contain two partially overlapping ORFs (ORF1 and ORF2),[121,125] additional ORFs with variable sizes translated from the negative strand of circular ds replicative form of viral DNA[54,55,103,139] and a short stretch of untranslated region (UTR) with high GC content (~90%).[121,122,124,125]

The genome of *gyrovirus* CAV is a negative sense with approximately 2.3 kb and contains three partially overlapping ORFs, a promoter-enhancer region, and a polyadenylation signal.[114,138] The ORF1 codes for the VP1 capsid protein, and the ORF2 and ORF3 code for VP2 and VP3 nonstructural proteins. The ORF3 completely overlaps ORF2, while ORF2 partially overlaps ORF1. The promoter-enhancer region in the 5′ NCR of CAV genome contains four or five 21-bp direct repeats (DR) and a 12-bp insert between the second and third DRs.[98,114] Host cell transcription factors bind to the DRs and the 12-bp insert, and at least two DRs and the 12-bp insert are required for efficient transcription and replication.[113_115,119]

Stages of Replication

Although CAV in the genus *Gyrovirus* can be propagated in cell cultures, other genera of the *Anelloviridae* could not be efficiently cultured *in vitro*. Therefore, knowledge of anellovirus replication especially regarding attachment, entry, and uncoating steps is very limited and derived mostly from the studies of gyrovirus CAV.

Transcription

The genome of human anelloviruses expresses at least three spliced mRNAs encoding at least six proteins: ORF1, ORF2, ORF1/1, ORF2/2, ORF1/2, and ORF2/3.[62,63,103,139] The porcine anellovirus, torque teno sus virus (TTSuV), also expresses at least three putative mRNAs encoding six proteins.[55] The transcriptional profile of human anellovirus genome has been studied by transfecting the plasmid containing the full-length viral genome in cultured cell lines.[103,139,170] Three species of TTV mRNAs (2.8 to 3.0, 1.2, and 1.0 kb) are transcribed from a single promoter located in the region −154/−76 (RNA initiation site is denoted as position +1) and are polyadenylated at the same nucleotide (nt) 2978 position.[63] Therefore, all TTV RNAs are cleaved at the same site at approximately nt 3000 and have common 5′ and 3′ ends. A small intron (~100 nt), located in approximately 70 nt from the RNA initiation site, is spliced out from all three transcripts. Among the three species of TTV mRNAs, the two short 1.2-kb and 1.0-kb

mRNAs are further spliced approximately 400 nt downstream of the small intron, excising another larger intron with alternative 3′ splice sites at nt 2315 and nt 2505. The 2.8-, 1.2-, and 1.0-kb mRNAs comprise approximately 60%, 5%, and 35% of the total TTV RNAs, respectively.[103] All the splice sites utilize the conserved GT-AG donor and acceptor sequences.[63,103,139]

For CAV in the genus *Gyrovirus*, three viral proteins are derived from a single 2.0-kb mRNA species.[116,132] Several minor mRNA species of 1.6, 1.3, and 1.2 kb in size are also identified[64] (Fig. 7.10). The 1.3-kb RNA had a splice site joining nt 1222 to nt 1814 and encoded head-to-tail VP1. The 1.2-kb RNA possessed a splice site joining nt 994 to nt 1095 and encoded several putative proteins with frame-shift mutations. CAV contains a single promoter-enhancer region with 4 consensus cyclic AMP response element sequences that are similar to the estrogen response element consensus half-sites. These sequences are arranged as direct repeats, an arrangement that can be recognized by members of the nuclear receptor superfamily and may provide a mechanism to regulate CAV activity in situations of low virus copy number.[98]

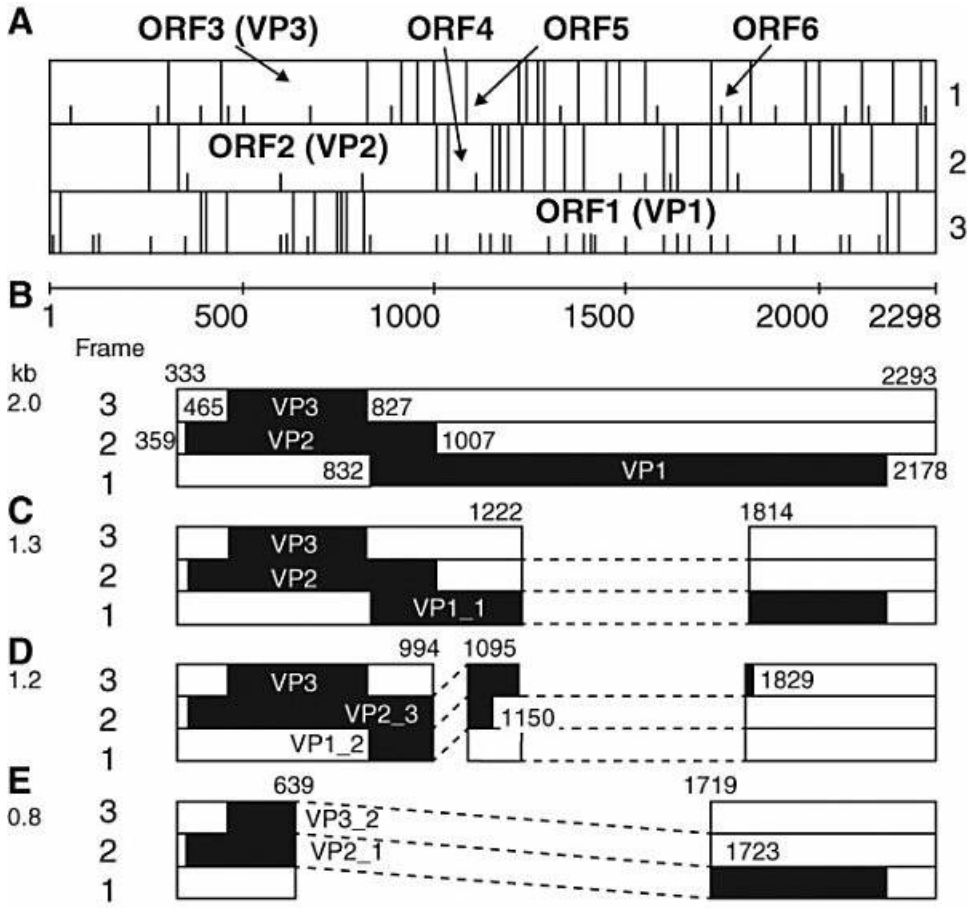

FIGURE 7.10 Schematic representation of the *Gyrovirus* CAV RNA transcripts and their candidate ORFs. A: Six ORFs of the CAV genome. *Short and long vertical lines* indicate ATG start and stop codons, respectively. Putative ORFs encoded by the RNA transcripts are indicated by *arrows*. ORFs evident in the 2.0-, 1.3-, 1.2-, and 0.8-kb transcripts are shown in panels **(B–E)**, respectively. *Dotted lines* indicate introns or

deleted regions. *Black boxes* represent putative coding regions. Nucleotide numbers indicate the positions of ORF junctions or boundaries of ORFs. Spliced mRNAs detected during the life cycle of Chicken anemia virus. *J Gen Virol* 2006;87(Pt 8):2227-2233; permission conveyed through Copyright Clearance Center, Inc.)

Translation

For human anelloviruses, the largest and most abundant 2.8-kb mRNA species expresses the ORF1 and ORF2 proteins, respectively. The smaller 1.2-kb mRNA species expresses the ORF2/2 and ORF1/1 proteins, whereas the smallest 1.0-kb mRNA species expresses the ORF2/3 and ORF1/2 proteins.[61,103,139] The ORF1, ORF1/1, and ORF1/2 expression products of human anelloviruses were localized in the nucleoli, ORF3 and ORF4 in the nucleoplasm, ORF2/2 in the nucleoli or whole nucleus, and ORF2 in the cytoplasm.[103] Similar to human TTVs, proteins encoded from ORF1 and ORF3 of TTSuV1 and TTSuV2 were also localized in the nucleoli, and ORF2 in the cytoplasm and nucleus excluding the nucleoli.[95]

The ORF1 of anelloviruses encodes a putative capsid protein containing arginine-rich, hydrophilic N-terminal sequences and replication-associated protein with the largest size relative to the other predicted viral proteins.[52,61,103] The ORF2 of TTMVs contains a highly conserved motif ($WX_7HX_3CXCX_5H$) in its N-terminal region[160] and may encode a protein with phosphatase activity. The ORF2 reportedly suppressed NF-κB pathways via interaction with IκB kinases and may involve in regulating the innate and adaptive immune responses.[186] The ORF3 of TTVs contains a serine-rich domain at the C terminus that may produce different phosphorylation sites,[5] possibly involving in maintaining persistent viral infection. The function of the other putative anellovirus proteins has not yet been demonstrated.

The gyrovirus CAV genome encodes three proteins: the VP1 Cap and the VP2 and VP3 nonstructural proteins.[150,166] The amino acid residue 394 of VP1 is a determinant of virus pathogenicity.[179] The VP2 is a multifunctional protein that also serves as a scaffold protein during virion assembly.[71,116,150] The VP2 has dual serine and tyrosine protein phosphatase activities,[132,133] and mutations in VP2 attenuated CAV.[131] Both VP1 and VP2 are required to elicit neutralizing antibodies against CAV.[32,71,115,117] The VP3 of CAV, also known as apoptin, induces apoptosis in chicken thymocytes and lymphoblastoid cells.[118] VP3 triggers the intrinsic mitochondrial death pathway resulting in loss of mitochondrial membrane and release of cytochrome c and apoptosis-inducing factors in mitochondria.[30,87] The VP3-induced apoptosis is independent of tumor suppressor p53, and Bcl-2 does not inhibit the VP3-induced apoptosis in tumor cells.[29,151] Synthesis of VP3 alone induces apoptosis in human tumor cell lines, but not in normal human diploid cells,[29] and thus VP3 is considered as an anticancer agent.[111,112]

Replication of Genomic DNA, Assembly, and Release

The viral DNA replication, assembly, and release are essentially unknown due to the lack of an efficient cell culture system for anelloviruses; however, the extensive heterogeneity among the genomes of anelloviruses suggests a poor proofreading mechanism during the viral genome

replication. Anelloviruses do not encode viral polymerase and therefore rely on the host cellular DNA polymerase for its genome replication. The ORF1 possesses conserved amino acid sequence motifs, such as a RCR sequence motif, found in the Rep proteins of other circular ssDNA viruses including *Circoviridae* and *Nanoviridae*, suggesting that anelloviruses likely also use a rolling circle mechanism for virus replication.[61,62,103] A conserved sequence and structure in the UTR region are essential for the initiation of viral genome replication.[62,124] The replication-associated protein ORF1 containing the "Rep" motifs is necessary for anelloviruses to interact with host proteins during virus replication.[61–63]

The genome replication of the genus *Gyrovirus* CAV is also thought to be via a rolling circle replication mechanism.[150,167] Homologous recombination occurs in cloned head-to-tail repeat replicative form of CAV genomes.[167] The VP1 contains a 3-amino acid motif associated with rolling circle replication. The phosphatase activity of VP2 is important but not required for CAV replication.[132,133] The VP3 is essential for completion of CAV life cycle as truncated VP3 lacking the C-terminal 11 amino acid residues failed to induce apoptosis.[114,118]

Pathogenesis and Pathology

Other than CAV in the genus *Gyrovirus*, attempts to associate other anelloviruses with a specific disease have not been successful.[43,53,120] It is generally believed that anelloviruses are commensal viruses to the host, although infection of anelloviruses may play a role in the homeostatic balance of host immune system, thereby indirectly affecting the severity and outcome of diseases caused by other pathogens.[44,89,152] It has been reported that TTV DNA loads are elevated in donor lungs in allografts and that the plasma loads of TTV DNA can predict rejection in lung transplant recipients.[45,57]

Chicken Infectious Anemia (CIA)

CAV is the only known virus within the family *Anelloviridae* that causes a disease. The natural route of exposure for CAV is likely oral.[149] Feces from infected chickens are the main source of virus for horizontal transmission. Vertical transmission in commercial flocks through hatching eggs is an important means of virus dissemination. Under field condition, vertical transmission occurs for a period of 3 to 9 weeks after exposure to CAV. Gross lesions include thymic and bone marrow atrophy and less commonly bursal atrophy. Hemorrhagic-aplastic anemia syndrome characterized by intracutaneous, subcutaneous, and intramuscular hemorrhages is associated with severe anemia in CAV-infected chickens. Microscopically, CAV-infected chickens are characterized by generalized lymphoid atrophy and depletion and panmyelophthisis. Infection of hemocytoblasts in the bone marrow and lymphoblasts in the thymus cortex in the early infection stage (6 to 8 days postinfection) causes a rapid depletion of these cells by apoptosis with drastically reduced numbers of erythrocytes, white blood cells, and thrombocytes.[154]

Epidemiology and Clinical Features

Beside humans, genetically divergent anelloviruses have been identified from more than a dozen other animal species including pigs, sheep, dog, horse, elk, masked palm civet, fur seals, bats,

opossums, gorillas, chimpanzees, and rodent species.[121,125,155] Whether anelloviruses infect across species remains largely unknown,[106,153] although human TTV reportedly infects chimpanzees.[123] Multiple infections of human TTV with different genotypes, as well as dual or triple infections of TTV, TTMV, and TTMDV in a single individual, have been documented and are believed to be a common event in humans.[6,107] Similarly, TTSuV infection with different genotypes or subtypes in a single pig has also been reported.[54] Antigenic cross-reactivity between two TTSuV genotypes (TTSuV1a and TTSuV1b), but not between two species (TTSuV1 and TTSuV2), has been demonstrated.[53] There appears to be antigenically distinct between human TTV and TTSuV.[53] The TTSuVs are highly prevalent in pig population worldwide, but the infection in swine is subclinical.[52,53] Human anelloviruses spread through multiple routes including blood, saliva, air, water, and contaminated food.[43,120]

Within the genus *Gyrovirus* alone, in addition to CAV, at least 9 other species of animal gyroviruses have been genetically identified through metagenomic analyses from various animals such as chickens, birds, humans, ferret, mice, and domestic cats.[26,34,35,77,110,143,148,180] CAV infection is ubiquitous in chicken flocks worldwide. CAV infection of chickens of 2 to 4 weeks of age induced anemia, which is characterized by hematocrit values ranging from 6% to 27%. The mortality is about 10% to 20% but generally does not exceed 30%. Surviving chickens completely recover from anemia by 20 to 28 days postinfection, although secondary bacterial or viral infection may slow down the recovery process. Chickens develop age resistance to CAV-induced anemia by approximately 3 weeks of age.[149]

Diagnosis, Prevention, and Control

Clinical samples such as plasma, saliva, feces, hairs, and skin biopsies can be used to detect anelloviruses by PCR, which is the most commonly used method for identification of anellovirus infection.[107,108,120,121,125] Primers specific for the highly conserved UTR region allow for PCR detection of different genotypes.[107,120,121,125] Quantitative PCR is also used for quantification of viral loads. Reagents for serological assays are very limited. TTSuV1a or TTSuV1b ELISA assays based on the respective ORF1 capsid antigen were developed to detect TTSuV antibodies in pigs.[52,53,105] With the exception of CAV, there is no cell culture system to isolate other anelloviruses. Due to ubiquitous nature and the lack of a disease association, it is rather difficult to ascertain the anellovirus-specific morbidity.

CAV can be propagated in lymphoblastoid T-cell lines (MDCC-MSB1 and MDCC-JP2) and B-cell line (LSCC-1104B1). Virus isolation in susceptible cells and detection of CAV DNA and antigen in tissues are means of diagnosis of CAV infection. Commercial live-attenuated vaccines against CAV are used to immunize chickens of 9 to 15 weeks of ages. Complete elimination of CAV from chicken flocks is not realistic and thus good management and hygiene procedures are important to minimize the impact caused by CAV infection.

Perspective

Members of the *Anelloviridae* have a very broad host range. Only *Gyrovirus* CAV is known to cause a disease in chickens, and the other anelloviruses are considered to be a part of host microbiota and not associated with a specific disease.[43] Anellovirus replication may be enhanced in infected immune-compromised individuals, and the anelloviral DNA load may be considered

as a biomarker of immune suppression.[44,89] An efficient cell culture system is critically needed in order to understand the life cycle of anelloviruses. CAV can be propagated *in vitro*, although a specific cellular receptor has not been identified. TTSuV has been detected in numerous porcine tissue–derived commercial products such as meats, vaccines, enzymes for laboratory use, and human drugs, suggesting a need to better screen biomedical products for anelloviruses. The natural history, ecology, potential cross-species infection, and pathogenicity of a large number of genetically diverse anelloviruses require in-depth research.

The way forward

Learn the biology.
Bernard Roizman

Herpesviruses form a taxonomic order of double-stranded DNA (dsDNA) viruses that establish lifelong infections in their animal host and cause disease that can have significant adverse effects on individuals and on host populations (e-Table 8.1). These complex biological nanomachines employ diverse mechanisms to reprogram cells to produce infectious virions, sometimes after lying dormant in a latent state for decades. Discoveries of the mechanisms by which herpesviruses subvert cellular processes and adapt to evolving host defenses will continue to have significant impacts on our understanding of molecular and cellular biology, as well as immunology and pathologies such as cancer. Development of strategies for control and

prevention of societally important herpesvirus infections is dependent on appreciating and understanding the virion structure, genetic content, and biological properties of this ancient and evolving family of extraordinarily interesting pathogens.

The objectives of this chapter are to provide definitions and examples of many of the terms and concepts that define the field of herpesvirology; a glossary of terms associated with herpesvirology is provided in e-Table 8.2. Summarizing such a broad area of active research is accomplished at the cost of oversimplification and overgeneralization, with the understanding that subsequent chapters will provide deeper coverage for individual viruses. Importantly, the paradigms presented here offer opportunities for conceptual and experimental challenge.

THE FAMILY *HERPESVIRIDAE*

Herpesviruses are defined on the basis of their shared virion architecture (Fig. 8.1). A typical herpesvirion consists of a ***core*** containing a linear dsDNA genome (ranging from 109 to 241 kb among the *Herpesviridae*); an icosahedral ***capsid*** approximately 125 nm in diameter containing 161 capsomeres with a hole running down their long axis, plus one capsomeric structure that serves as the portal for packaging and release of the viral genome; the ***tegument***, which is a less-ordered and often asymmetric layer composed of proteins and RNA that surrounds the nucleocapsid; and an ***envelope*** containing viral glycoprotein spikes on its surface. Based on the morphologic criteria, highly divergent viruses with hosts that range from bivalves to humans have been identified as herpesviruses (Fig. 8.2). Originally classified as a single virus family, genome sequence data led to establishment of the order *Herpesvirales*,[110] which encompasses three virus families: the herpesviruses of mammals, birds, and reptiles (the *Herpesviridae*[111]), herpesviruses of fish and amphibians (the *Alloherpesviridae*[112]), and herpesviruses of bivalves (the *Malacoherpesviridae*[113]). This and subsequent chapters in this book are concerned primarily with viruses that have long been recognized as members of the family *Herpesviridae*, with a focus on herpesviruses of humans.

The schematic shows branching patterns, not evolutionary distances.

DISTRIBUTION IN NATURE

Herpesviruses are highly disseminated in nature. Most animal species examined are host to at least one, and frequently several distinct herpesviruses. Given that few herpesviruses are hosted by more than one species, their number in nature likely vastly exceeds the more than 300 identified to date. Nine herpesviruses have been identified that have humans as their primary host: herpes simplex viruses 1 and 2 (HSV-1 and HSV-2); human cytomegalovirus (HCMV); varicella–zoster virus (VZV); Epstein-Barr virus (EBV); human herpesviruses 6A, 6B, and 7 (HHV-6A, HHV-6B, and HHV-7); and Kaposi sarcoma herpesvirus (KSHV, also known as Kaposi's sarcoma-associated herpesvirus and HHV-8). Herpesviruses of humans and of

veterinary and scientific importance are listed in Table 8.1; a more comprehensive list is provided in e-Table 8.3. We have not tabulated the many herpesviruses identified on the basis of small PCR amplimers or metagenomic sequencing data.[61,66]

[a]The table was extracted and extended from information compiled by the *Herpesvirales* Study Group of ICTV and available at ictvonline.org as ICTV Master Species List 2019.v1., plus information from the exemplar virus list provided by the Virus Metadata Resource.

[b]Formally recognized HV species are italicized. Information about hosts is in bold.

[c]Retired formal names and alternate historical names are in brackets.

[d]Genus designations: *α*, *Alphaherpesvirinae*: S, *Simplexvirus*; V, *Varicellovirus*; M, *Mardivirus*; I, *Iltovirus*. *β*, *Betaherpesvirinae*: C, *Cytomegalovirus*; M, *Muromegalovirus*; R, *Roseolovirus*; P, *Probscivirus*. γ, *Gammaherpesvirinae*: L, *Lymphocryptovirus*; Rh, *Rhadinovirus*; M, *Macavirus*; P, *Percavirus*. *Alloherpesviridae*: Ba, *Batrachovirus*, Cy, *Cyprinivirus;* Ic, *Ictalurivirus;* Sa, *Salmonivirus. Malacoherpesviridae:* Os, *Ostreavirus.* Species and viruses are indicated by U and the subfamily (if known).

[e]Genome sequence information is sometimes limited in the vicinity of genomic termini.

[f]Accession numbers are provided for a widely studied strain of EBV types 1 (B95-8) and 2 (AG876), respectively.

[g]Accession numbers are provided for a low-passage clinical isolate of HCMV (Merlin) and a high-passage widely studied laboratory strain (AD169), respectively.

[h]Values obtained in different laboratories may reflect differences in strains.

BIOLOGICAL PROPERTIES

Members of family *Herpesviridae* share four significant biological properties:

1. Production of infectious progeny virus (lytic infection) is generally accompanied by destruction of the infected cell.
2. Herpesviruses examined to date employ cellular latency as a mechanism for lifelong persistence in their hosts (Fig. 8.3).
3. Virus gene transcription, replication of the dsDNA genome, and nucleocapsid assembly occur in the nucleus. Virions acquire most of their tegument and are enveloped in the cytoplasm.
4. Herpesvirus genomes encode many of the proteins needed for virus replication, as well as most of the proteins and RNAs that make up the virion; many of these genes are conserved across the family (Table 8.2). In addition, much of the genetic content of herpesvirus genomes is dedicated to production of gene products (proteins and noncoding RNAs) that play diverse roles in managing cell biology and immune responses. The array of virus genes and gene products involved in management of the host ranges widely across the family. This genetic diversity is the source of much of the biological diversity of herpesviruses—it drives and defines their pathogenesis and clinical manifestations.

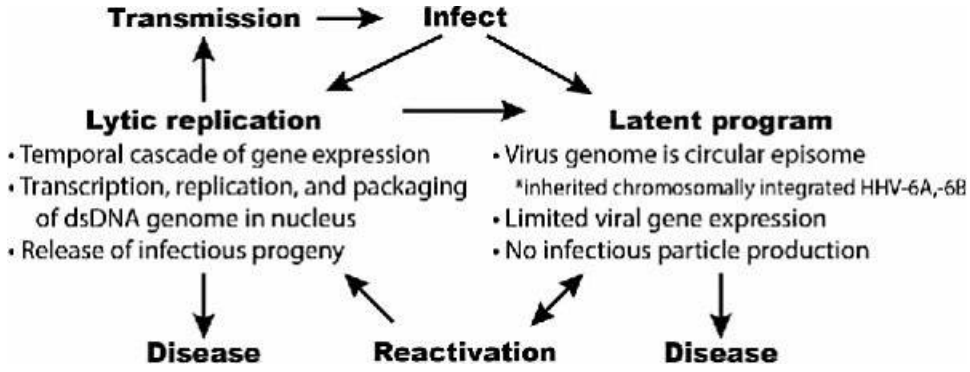

FIGURE 8.3 The complexity of herpesvirus infections. Persistence in the host organism via cellular latency is a defining property of herpesviruses. Cellular latency is different from clinical (or organismal) latency, which is the period between infection and disease, and during which extensive lytic replication might be occurring at the cellular level. Lytic replication, latent infections, and episodic reactivation at the cellular level lead to disease manifestations and transmission at the organismal level. Full-fledged reactivation from latency may be unsuccessful or may lead to productive replication, infectious particle production, and dissemination within and between hosts. Within an organism, a herpesvirus can be simultaneously latent in some cells and actively replicating in others due to periodic reactivation events. Reactivation likely plays a role in maintaining the viral load in the host and is key for transmission to new hosts upon shedding of infectious particles at mucosal tissues. (Copyright Laurie Krug and Philip Pellett.)

[a]Nomenclature and abbreviations are as described and proposed in (From Mocarski ES Jr. Comparative analysis of herpesvirus-common proteins. In: Arvin A, Campadelli-Fiume G, Mocarski E, et al., eds. *Human Herpesviruses: Biology, Therapy, and Immunoprophylaxis*. Cambridge: Cambridge University Press; 2007:44–58.).

[b]Gene blocks are as illustrated in Figure 8.4.

NOMENCLATURE AND CLASSIFICATION

Classification

Before their DNA and amino acid sequences were known, herpesviruses were classified into one family (the *Herpesviridae*) and three subfamilies (the *Alphaherpesvirinae*, the *Betaherpesvirinae*, and the *Gammaherpesvirinae*) on the basis of biological properties.[126] Remarkably, this framework stands and has withstood expansion. In the current formal taxonomy,[110] herpesviruses belong to Realm *Duplodna*, Phylum *Peploviricota*, Class *Herviviricetes*, and Order *Herpesvirales*. Order *Herpesvirales* is subdivided into three Families: *Alloherpesviridae* (viruses of bony fish and amphibians), *Herpesviridae* (viruses of reptiles, birds, and mammals), and *Malacoherpesviridae* (viruses of molluscs). Species within the *Herpesviridae* subfamilies and the *Alloherpesviridae* are further classified into genera.

Herpesvirus Species

A herpesvirus may be classified as a species if it “has distinct epidemiological or biological

characteristics and a distinct genome that represents an independent replicating lineage."[110] Two forms of nomenclature are employed for herpesviruses: an informal (also known as vernacular or colloquial) nomenclature that is often traced to the early days of virology, and a formal subfamily-based species nomenclature governed by the International Committee for Taxonomy of Viruses (ICTV). For example, *Human gammaherpesvirus 4* is the species name for the virus widely known as EBV. The species number enables differentiation of herpesviruses that share their host, but is not intended to imply anything about the relationship between a virus and other herpesviruses that infect the same host species (e.g., HHV-7 and HHV-8 are members of different subfamilies) or between similarly numbered viruses that infect different host species (e.g., EHV-2 and BoHV-2 are members of different subfamilies). Table 8.1 and e-Table 8.3 include informal and formal names for each virus.

Herpesvirus Phylogeny

The virus lineage that encompasses the present-day alpha-, beta-, and gammaherpesvirus subfamilies (the *Herpesviridae*) is rooted about 400 million years ago.[92] Within the major subdivisions of the three subfamilies, relationships among virus species generally mirror host phylogeny.

Alphaherpesvirinae

Alphaherpesviruses typically have relatively short reproductive cycles, spread rapidly in culture, efficiently destroy infected cells, and establish latency in sensory ganglia. Viruses of the *Simplexvirus* (HSV-1 and HSV-2), and *Varicellovirus* (VZV) genera have mammalian hosts, while *Mardiviruses* and *Iltoviruses* have avian hosts, and *Scutaviruses* have reptilian hosts.

Betaherpesvirinae

Betaherpesviruses typically have a restricted host range. The reproductive cycle can be protracted in cultured cells. Infected cells frequently become enlarged (cytomegalia), and carrier cultures are readily established. Betaherpesviruses can establish latency in secretory glands, lymphoreticular cells, kidneys, and other tissues. Betaherpesvirus genera include *Cytomegalovirus, Muromegalovirus, Proboscivirus, and Roseolovirus* (HHV-6A, HHV-6B, and HHV-7).

Gammaherpesvirinae

In vitro, all gammaherpesviruses replicate in lymphoblastoid cells, and some can lytically infect particular stromal cell types (epithelial and fibroblasts). They are usually specific for either T or B lymphocytes, and establish latency in lymphoid tissue. The subfamily contains four genera: *Lymphocryptovirus* (EBV), *Macavirus*, *Percavirus*, and *Rhadinovirus* (KSHV). Genus *Lymphocryptovirus* includes two major lineages that appear to have coevolved with their hosts: viruses of Old World (humans, chimpanzees) and New World (marmosets) primates.[46,93] Viruses of genus *Rhadinovirus* are mainly hosted by primates, *Macaviruses* are related to the malignant catarrhal fever viruses of ruminants, and *Percaviruses* include viruses of perissodactyls and carnivores.

VIRION ARCHITECTURE

The Virion

The virion is the vehicle for delivery of the virus genome and a set of accessory factors into newly infected cells. At the entry stage of infection, virion envelope glycoproteins bind to specific receptors on appropriate target cells to enable delivery of the cargo (nucleocapsid and tegument contents) into the cytoplasm. The tegument is an assortment, or toolbox, of proteins and RNAs that immediately upon entry begin to manage the host environment to meet the needs of the virus, for example, by shutting down host protein synthesis, inhibiting infection-triggered cell defenses, and stimulating viral gene expression. The nucleocapsid has signals that enable its transport via microtubules to a nuclear pore where it interacts with cellular machinery that facilitates injection of the genome into the nucleus. Individual herpesvirus virions are built from approximately 10,000 protein molecules, a collection of mRNAs, microRNAs, circular RNAs and other RNAs, and one molecule of the dsDNA genome. The virion thus represents the evolved solution to a significant design and manufacturing challenge: how to (a) efficiently build as many as thousands of virions in well-defended infected cells, (b) release the newly synthesized virions in a regulated manner, and (c) ensure that the mature virions are physically stable during transmission, yet able to disassemble in a regulated manner to start a new infection.

Mature herpesvirus virions vary in diameter from 120 to as much as 260 nm (reviewed in Ref.[127]). The range is due to variability in the thickness of tegument, the plane of sectioning, and the state of the envelope. The precise number of protein species contained in virions is not known and may vary from one virus to another, as well as from one virion to another of the same variety.[11] Estimates based on gel analyses of purified virions have generally been in the range of 35 to 45 major species. Proteomic analyses have identified from 24 to 71 virally encoded proteins in virions (4 to 7 in the nucleocapsid, 9 to >20 in the tegument, and 4 to 19 in the envelope, plus a number of proteins whose location within virions is unknown).[69,70,96,106,148] Numerous host proteins have been detected in virion preparations, including moderately abundant quantities of cellular structural proteins, enzymes, and chaperones; their roles and necessity are not known. The mean abundance of individual protein species varies widely, from less than one copy per virion to over 1,000.

Most of the virus-related particles released from infected cells are not independently infectious but are nonetheless bioactive. These include particles that appear by electron microscopy to be intact and complete virions. In addition, herpesvirus-infected cells can produce large numbers of nonvirion particles of uncertain biological significance, such as the dense bodies of HCMV, which are capsid-free enveloped collections of tegument proteins. HSV-1 induces production of extracellular vesicles (exosomes) that can activate antiviral defenses in uninfected cells.[36]

Virion Components

The Core

The core of mature virions contains a single molecule of the viral genome, in the form of nonchromatinized dsDNA that is packed in the form of a left-handed spool (evident in Fig. 8.1D), with shells of progressively tighter radii.[45,89] The tight packing and the repulsive forces generated by the negatively charged phosphates along the genome backbone necessitate the abundant presence in the core of the cation spermine.[48] Packaging of the viral genome into the capsid core requires ATP and results in a pressurized system that appears to be important for injection of virus genomes through the nuclear pore complex into nuclei of newly infected cells; the pressure and bending are sufficient to denature a portion of the dsDNA genome near the center of the core.[13,81]

The Capsid

The structural features of the capsid—its approximately 130 nm diameter, 161 capsomeres (150 hexons and 11 pentons), portal complex, and capsid triangulation number (T = 16)—are characteristic of all herpesviruses (Fig. 8.1), including the evolutionarily distant herpesviruses of fish and oysters.[59,121] Nonenveloped capsids are present in infected cells in three main forms, A-, B-, and C-capsids.[47] A-capsids have no core structure, B-capsids contain the assembly scaffold but no genome, and C-capsids are DNA-containing species that no longer house the scaffold. The four conserved capsid proteins that constitute the major structural features of the capsid include the major capsid protein (MCP), the monomer and dimer proteins of the triplex (TRI1 and TRI2, respectively), and the small capsomere-interacting protein (SCP) (Fig. 8.1; HSV homologs are listed in Table 8.2). MCP is present in six copies per hexon (6 × 150 = 900 copies per capsid) and five per penton (5 × 11 = 55 copies per capsid), for a total of 955 copies per capsid. The triplex proteins interact with $\alpha_2\beta$ stoichiometry and form complexes that are present at the 320 sites of threefold symmetry. Hexameric capsomeres are 9.5 × 12.5 nm in longitudinal section; a channel of 4 nm in diameter runs from the surface along their long axis.[155] Penton channels are generally somewhat narrower and are nearly closed at their midpoint in B-capsids.[161] The twelfth pentonal position is the portal for transit of genomic DNA into and out of the capsid; it is composed of 12 copies of the capsid portal protein (PORT) (Fig. 8.1D). The portal capping protein (PCP) is associated with mature, DNA-containing nucleocapsids. Cryoelectron microscopy has enabled determination of capsid structures for nearly all human herpesvirus to greater than 4 Å resolution.[24,50,80,82,160,162,163]

The Tegument

The tegument is the protein- and RNA-containing structure between the nucleocapsid and the envelope.[127] It has no distinctive features in thin section electron micrographs but may appear fibrous on negative staining. The tegument can be distributed asymmetrically within the virion.[11] Tegument thickness may vary, depending on the location of the virion within the infected cell, with it being thinner in virions accumulating in the perinuclear space following primary envelopment than in cytoplasmic vacuoles following secondary envelopment.[40] Teguments contain greater than 20 different virally encoded proteins, some of which are present at hundreds of copies per virion. Structural polarity across the tegument has been visualized by immunoelectron and fluorescence microscopy,[11,136] indicating that it is an ordered structure. This is further evidenced by the inner tegument proteins that associate with the capsid in the

nucleus to form the capsid-associated tegument complex[24,50,80,82,160,163] and the tail-like portal vertex–associated tegument.[89] Following nuclear egress, subsequent components of the tegument are likely added in a somewhat ordered manner during its cytoplasmic maturation.[22,95]

The Envelope

Envelopes of mature virions are derived from patches of altered cellular membrane that trace to the organelle where envelopment occurs.[83] A major constituent of virion envelopes is a collection of virally encoded glycoproteins (gPs), most of which are involved in virion entry. gPs form protrusions on virion envelopes that are more numerous and shorter than those present on the surface of many other enveloped viruses.[155] The number and relative abundances of virion gPs vary among herpesviruses. HSV specifies at least 11 different virion-associated gPs; copy numbers of individual gPs can exceed 1,000 per virion. All members of the *Herpesviridae* have homologs of glycoprotein B (gB) and gH and gL, which form the gH/gL complex. These gPs are involved in virion entry, in association or concert with other gPs and gP complexes that are specific to the various herpesvirus lineages.[103,139]

HERPESVIRUS GENOMES

Herpesvirus genomes serve two major purposes: they are the stable repository of genetic information that is transmitted via the virion to newly infected cells, and they provide the instructions needed for the viruses to carry out their evolved biological programs. A curated set of reference herpesvirus genome sequences is maintained at Genbank (https://www.ncbi.nlm.nih.gov/genomes/GenomesGroup.cgi?taxid=10292).

Genomic Architecture

Herpesvirus genomes extracted from virions are predominantly linear and double stranded, but circularize immediately on release from nucleocapsids into the nuclei of infected cells. Across Order *Herpesvirales*, genome lengths range from approximately 109 to 295 kbp (Fig. 8.4, Table 8.1, and e-Table 8.2). They contain terminal and internal repeated sequences that vary in copy number, and can be oriented in the same or reverse direction relative to each other (e-Fig. 8.1). Herpesvirus genomes range from 31% to 77% in total G+C content and vary in local G+C content across the genome, with generally higher G+C composition in the terminal repeats (Table 8.1 and e-Table 8.2).

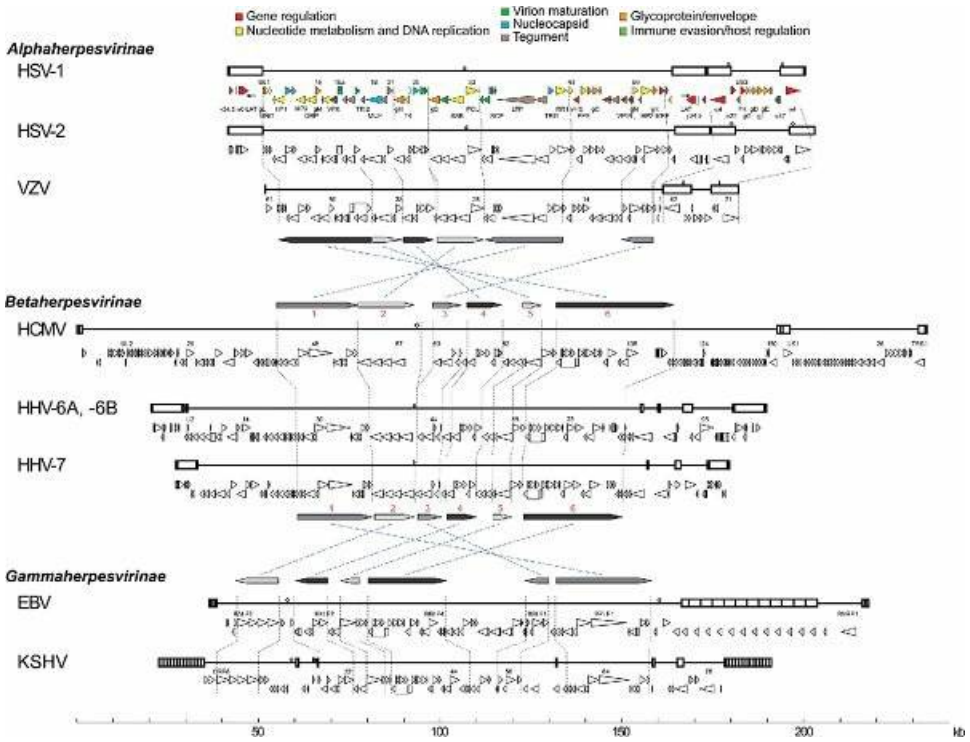

FIGURE 8.4 Genomic and genetic architectures of the human herpesviruses. Major repeat elements are indicated on each genomic schematic as boxes. Beneath each genome, open reading frames considered likely to encode expressed proteins are indicated as *triangles* that are oriented to show their direction of transcription. 5′ exons of spliced genes are indicated as boxes that are connected by bars to 3′ exons. The seven conserved herpesvirus sequence blocks (block 1 through block 6) are diagramed to show their relative locations and orientations in the three major lineages. Diagrams are based on annotations and coordinates in Genbank accession numbers X14112 (HSV-1 strain 17), Z86099 (HSV-2 strain HG52), X04370 (VZV strain Dumas), NC_006273 (HCMV strain Merlin), X83413 (HHV-6A strain U1102), AF157706 (HHV-6B strain Z29), U43400 and AF037218 (HHV-7 strains JI and RK), NC_007605 (EBV strain B95-8), and U75698 (HHV-8 BC-1). The diagram does not include details related to the complex array of RNAs expressed by the viruses (e-Fig. 8.2). Detailed descriptions are available in virus-specific chapters that follow. Abbreviations for conserved proteins are as listed in Table 8.2. (Copyright Laurie Krug and Philip Pellett.)

Herpesvirus genomes contain numerous *cis*-acting sequences that play critical roles in transcription regulation, function as origins of lytic (oriLyt) or latent replication, are involved in tethering latent genomes to host chromosomes during latency in dividing cells, and provide signals that direct packaging of nascent DNA into capsids and cleavage of concatemeric genomes to unit length (cleavage/packaging, or *pac* sequences).

The genetic requirements for efficient replication in cultured cells differ from *in vivo* requirements. Spontaneous deletions have been noted in HSV, EBV, and HCMV strains passaged outside the human host. A progression of changes in a small number of genes enables

clinical isolates of HCMV to begin replicating efficiently in cultured cells.[25] Highly passaged strains of HCMV lack a segment encoding at least 19 genes that are present in wild-type isolates.[17]

Genetic Architecture

Herpesvirus Genes

Over the past 40 years, studies of herpesvirus gene structure, expression, and regulation defined many properties of what can be termed "canonical" genes, which are often represented in diagrams such as Figure 8.4, where the diagrammatic emphasis is on major open reading frames (ORFs) from which many well-studied proteins are expressed. In recent years, application of systems biology methods such as deep DNA sequencing, RNAseq, ribosome profiling, and temporal and spatial proteomics have greatly expanded our understanding of the breadth and complexity of herpesvirus gene expression and gene function.[38,39,64,67,104,107,137,142,153] Here we summarize the new information in the context of the framework provided by our understanding of canonical genes and their expression.

Canonical herpesvirus genes have features indistinguishable from eukaryotic genes: (a) a collection of promoter/regulatory sequence elements that are located 50 to 200 bp upstream of a transcription initiation site, (b) express mRNAs with 5′-capped nontranslated leader sequences of 30 to 300 bp, (c) encode an ORF that can express a single protein of at least 100 amino acids that is initiated at a translation initiation codon that often meets the host requirements for efficient initiation, and (d) have 3' regions that include 10 to 30 bp of nontranslated sequence followed by a canonical polyadenylation signal with standard flanking sequences (e-Fig. 8.2, panel A). Because herpesvirus genomes are dsDNA, genes can be oriented in either direction along the genome.

The predominant form of transcript for most herpesvirus genes had long been thought to be unspliced; that is, the 5′-capped primary transcript needs only to be polyadenylated to form the mature mRNA. However, recent application of deep RNA sequencing and proteomic analyses have made it clear that RNA splicing (including alternative splicing) is much more common than previously recognized, and the functional coding capacity of the viruses is greatly expanded by alternative transcription initiation and termination sites, alternative splicing, and noncanonical translation initiation signals (e-Fig. 8.2).[5,35,42,107,154] Combined transcriptional, proteomics, and genetic analyses have made it clear that the newly recognized forms of gene expression enable production of functional products that play important biological roles during infection. Such studies have also demonstrated translation of functional proteins from RNAs long thought to be noncoding.[42,64]

Gene overlaps are common in herpesvirus genomes. For head-to-tail gene arrangements, the upstream gene can overlap with the promoter-regulatory sequences of the downstream gene (e-Fig. 8.2B). Independent transcriptional units can be embedded in a protein coding sequence to yield a shorter polypeptide that is initiated at an internal methionine within the same ORF as the larger protein (e.g., HSV UL26 and UL26.5) (e-Fig. 8.2C). The resulting proteins thus share a domain of identical amino acid sequence, yet differ markedly in their function. Protein-encoding ORFs can be expressed from mRNAs that are antisense to each other (e.g., HSV-1 $\gamma_1$34.5 and

ORF P and O (e-Fig. 8.2D). Common features of herpesvirus genomes are clusters of 3′ coterminal transcripts, each of which expresses a different ORF (e-Fig. 8.1B). Within these clusters, coding domains seldom overlap by more than a few codons.

Another strategy is to use splicing to enable differential regulation of a gene at different parts of the virus life cycle. In some cases, this means the same ORF is accessed from different promoters, or different ORFs can be expressed from the same primary transcript (e-Fig. 8.2E).

While they were largely ignored in many of the initial descriptions of herpesvirus genome sequences, short ORFs (sORFs) of less than 100 codons can direct translation of functional proteins.[43] Upstream open reading frames (uORFs) are sORFs that encode proteins of less than 100 amino acids, and are located in the 5′ leader sequences of mRNAs that direct translation of larger canonical proteins. Translation of uORFs is regulated via noncanonical translation initiation environments. The short translation products of uORFs can have regulatory activities, sometimes directed at the canonical ORF that is part of the same mRNA, enabling complex forms of regulation of protein expression[5,9,77] (e-Fig. 8.2, panel F).

Herpesviruses express a plethora of biologically important small noncoding RNAs (ncRNA), including microRNAs (miRNAs), long noncoding-RNAs (lncRNA; >170 nucleotides in length), and circular RNAs (circRNAs).[15,54] miRNAs are often clustered in intergenic regions and are not highly conserved across herpesvirus lineages. Highly stable circRNAs are formed via covalent linkage of a backspliced viral transcript, and can be incorporated into virions.[1,146] Although most genes are transcribed by RNA polymerase II, some small ncRNAs are transcribed by RNA polymerase III, including the EBV EBER transcripts[62] and the tRNA-miRNA molecules (TMERs) of MHV68 (MuHV-4).[15]

Naming of Genes and Their Products

There is no formalized system for naming herpesvirus genes or their products. The historical nomenclature can be particularly daunting to newcomers to the field. For example, the major HSV-1 transcriptional transactivator was first identified as a component of the virion and designated by its migration in denaturing gels relative to that of other virion proteins (VP16). Subsequently, it has been known on the basis of its migration in denaturing gels relative to other infected cell proteins (ICP25), its apparent molecular weight in denaturing polyacrylamide gels (vmw65), its best-known function (*α*-trans-inducing factor or *α*-TIF), and the gene encoding it (pUL48). EBV genes and their products are named after the restriction endonuclease-generated DNA fragment in which the gene maps; for instance, BZLF1 is BamHI, Z fragment, left frame 1. This nomenclature precludes all but the most dedicated from visualizing the position of the gene in the genome.

An additional hazard is the assumption that all functions of orthologous gene products are fully conserved from virus to virus. Most herpesvirus proteins studied in detail have multiple functions; proteins sharing a conserved block of amino acids may diverge in the functions encoded in their other domains.

Fortunately, gene name cross-references are often available in readily available compendia.[85,97,125] The nomenclature and abbreviation system proposed for genes conserved across the *Herpesviridae*[97] is used in this chapter.

Gene Functions

The cellular and organismal host ranges of herpesviruses differ enormously, from very wide (e.g., HSV) to very narrow (e.g., EBV, HHV-6B). The host range is determined only in part by the availability of receptors. Virally encoded proteins are required for entry into the cell, regulation of viral gene expression, nucleotide metabolism, synthesis of viral DNA, structural proteins, and virion assembly, as well as for management of host defenses, metabolism, and macromolecular biosynthesis and transport. Standing apart are genes expressed during latency; in the case of EBV there are multiple forms of latency differing with respect to the genes that are expressed.

Regulatory genes are specifically adapted to the requirements of the cell types inhabited by the virus *in vivo*. Some subsets of herpesviruses (e.g., the alphaherpesviruses) share clear homologs of regulatory genes such as α4, α0, and α27. Other groups of herpesviruses have important regulatory genes that have little obvious sequence similarity, although they may occupy similar genomic locations and even share splicing patterns (e.g., the immediate-early genes of the betaherpesviruses).

Viral non-coding RNAs (ncRNAs) represent a treasure trove of novel strategies evolved to promote infection and impair immune responses.[15,54,115,146] ncRNAs are highly variable in their sequence, structure, biogenesis, and the molecules with which they interact. Herpesvirus miRNAs posttrancriptionally silence mRNAs of both the virus and host; their roles in latency versus lytic infection often reflect their pattern of expression.[115] The highly expressed EBERs of EBV latency bind host proteins to protect the cell from apoptosis. The HSV latency-associated transcript (LAT) is a lncRNA that protects latently infected neurons from apoptosis. Like the lncRNAs of HCMV and KSHV, HSV LAT interacts with chromatin modifiers to regulate α/IE gene expression. Small circular RNAs bind miRNAs, functioning as molecular sponges for miRNAs to regulate viral gene expression.[146]

The functionality of herpesvirus gene products is defined by three key characteristics. ***First***, they often have multiple functions that may or may not be related. For instance, the ribonucleotide reductase, large subunit (RR1) is a key enzyme for nucleotide metabolism with additional roles in the impairment of apoptosis and necroptosis (e.g. HSV1, HSV2,) and relocalization of the host mutator APOBEC3B (e.g., HSV1, KSHV, EBV).[20,53] The decision as to which function is performed by a particular protein may be determined by the nature of posttranslational modifications, protein interactions that occur only in the context of infection, or the local environment of individual protein molecules. Full assessment of the multifunctional nature of viral proteins requires their study in the context of infection. A variety of approaches have been applied to the study of herpesvirus gene function, including cloning complete herpesvirus genomes into plasmids that can replicate in *E. coli* as bacterial artificial chromosomes. This enables rapid and precise mutagenesis of herpesvirus genomes, which can then be transfected into susceptible mammalian cells to generate virus stocks for functional studies.

The ***second*** key characteristic relates to their role(s) in virus replication. Genes necessary for replication in cultured cells are sometimes referred to as “essential,” while dispensable genes can be described as “nonessential” or “accessory.”[28] For HSV, more than 50% of the ORFs are dispensable for growth in cells in culture. However, most of these seemingly nonessential genes are not dispensable for virus replication or for reactivation from the latent state in experimental

animal systems. Assays involving the establishment or maintenance of latency require conditional loss of function approaches to most accurately assess whether a virus gene is dispensable.

The ***third*** key characteristic is that virus proteins and RNAs mediate their activities via self-interactions or via interactions with other proteins and biomolecules of the virus or host. A conserved central intraviral protein interactome has been defined for members of the *Herpesviridae*,[60] in which clusters of protein–protein interactions enable identification of sets of viral proteins involved in critical processes such as entry, genome replication, capsid assembly, nuclear egress, cytoplasmic maturation, and egress. In addition, the interactions help to define roles of many conserved proteins in processes other than their primary function. This form of analysis has been extended to the full set of interactions between and among virus and cellular proteins during the course of infection,[105] as well to the influence of virus gene products on the properties of cellular organelles during the course of infections,[67] greatly broadening our understanding of the complex set of interactions that take place during infection.

Gene Relatedness and Arrangement

Complete genomic sequences have been determined for greater than 80 herpesviruses, and smaller segments have been obtained for many others (Table 8.1 and e-Table 8.2). From this and other information, several fundamental principles of herpesvirus genetic architecture have been deduced.

Herpesvirus gene sequences are related to each other in ways that reflect the long-standing, biology-based classification of herpesviruses into subfamilies and their respective genera. These relationships are substantial and easily detected. For viruses of the *Herpesviridae*, the nucleotide sequence of a 400-bp PCR product amplified from the viral DNA polymerase gene by the use of degenerate consensus primers is sufficient to establish the identity of a herpesvirus and place it into the appropriate subfamily. Higher resolution and more robust classification can be obtained by expanding the size of the comparison sequence and by analyzing more than one gene. A representation of herpesvirus taxonomic and phylogenetic relationships is shown in Figure 8.2.

Forty-one genes, referred to as the herpesvirus core genes, have been identified as conserved across the alpha-, beta-, and gammaherpesviruses (Table 8.2). Each gene belongs to one of six core gene blocks. Within each gene block, gene order and polarity are conserved (Fig. 8.4). Across the family, the core gene blocks are found in various permutations of order and orientation.[19,30] Block arrangement, and thus gene order, is conserved at the subfamily level. Conserved genes do not share identical sequences (e-Fig. 8.3). In some instances, homologs have readily detected sequence identity or similarity across their full lengths, while for others only a small portion is identifiably conserved. The implication is that the resulting proteins are an amalgam of conserved and diverged functions.

Some genes are conserved at the subfamily level. Thus, genes unique to alphaherpesviruses include their latency-associated genes, glycoprotein D, a tegument-associated protein that induces transcription from *α*-genes, and a transcriptional regulatory protein related to HSV *α*4 (e-Fig. 8.3). To the left of conserved gene block 1, betaherpesviruses encode a block of 14 genes that have no counterparts elsewhere in the family (Fig. 8.4). Gammaherpesviruses uniquely encode conserved proteins needed to maintain latent genomes in dividing cells.

An interesting variation on the linkage of gene sets to subfamilies is offered by the origin-

binding protein (OBP) and its binding site. OBP binds to its cognate sites in origins of lytic replication and serves to nucleate the DNA replication machinery and play a role in initiating DNA replication. Only alphaherpesviruses and members of the *Roseolovirus* genus of the betaherpesviruses encode OBP homologs and OBP binding sites[65] (e-Fig. 8.3). Other betaherpesviruses and the gammaherpesviruses initiate DNA replication by another mechanism.

Herpesviruses generally encode at least one gene of obvious host origin (reviewed in Refs.[63,118]); KSHV has acquired at least 12.[131] Examples include thymidylate synthase and *bcl-2*. These genes appear to have been acquired by retrotransposition events from cDNAs, given that they are most often encoded on the viral genome as continuous ORFs that do not require splicing. Some of these genes appear to have been acquired independently by different herpesvirus lineages (again, thymidylate synthetase and bcl-2). Host-acquired genes tend to be located toward the viral genomic termini and between core gene blocks. In some cases, the host-acquired genes retain a function similar to its cellular counterpart; expression from the viral genome allows the desired product to be produced when needed by the virus. In other cases, the host-acquired gene has been modified to alter its function. For example, the KSHV homolog of the cellular D-type cyclin is resistant to cyclin-dependent kinase inhibitors, rendering the viral version constitutively active and capable of transforming cells.[6]

BIOLOGICAL CYCLE OF HERPESVIRUSES

The herpesvirus biological cycle can be divided into four major components: initiation of infection, lytic replication, latency, and reactivation (Fig. 8.3). These components are linked by a biological decision in the infected cell to follow either the lytic or latent pathway, as well as by the ability of latently infected cells to be reactivated to a lytic state. Here we provide a general outline of the herpesvirus biological cycle; detailed descriptions of the diverse mechanisms employed by the various viruses to accomplish this are provided in subsequent chapters. It is important to bear in mind that essentially every step and stage of the herpesvirus biological cycle is dependent on the virus making use of, or adapting for its purposes, cellular systems, structures, and materials. Host interactions include modification of cellular systems for regulating gene expression, modulation of the cell cycle, reprogramming metabolic pathways for energy production and generation of biosynthetic precursors, remodeling of the secretory apparatus, using intracellular transportation systems throughout the infectious cycle, and managing host defenses.

Initiation of Infection

Initiation of infection spans the events that begin with receptor binding through the initial interactions of the virus genome with the host transcriptional machinery in the nucleus (Fig. 8.5, **Steps A1** to **A4**). The general features of this stage occur in cells destined for immediate entry into the lytic state, as well as in cells that will become latently infected.

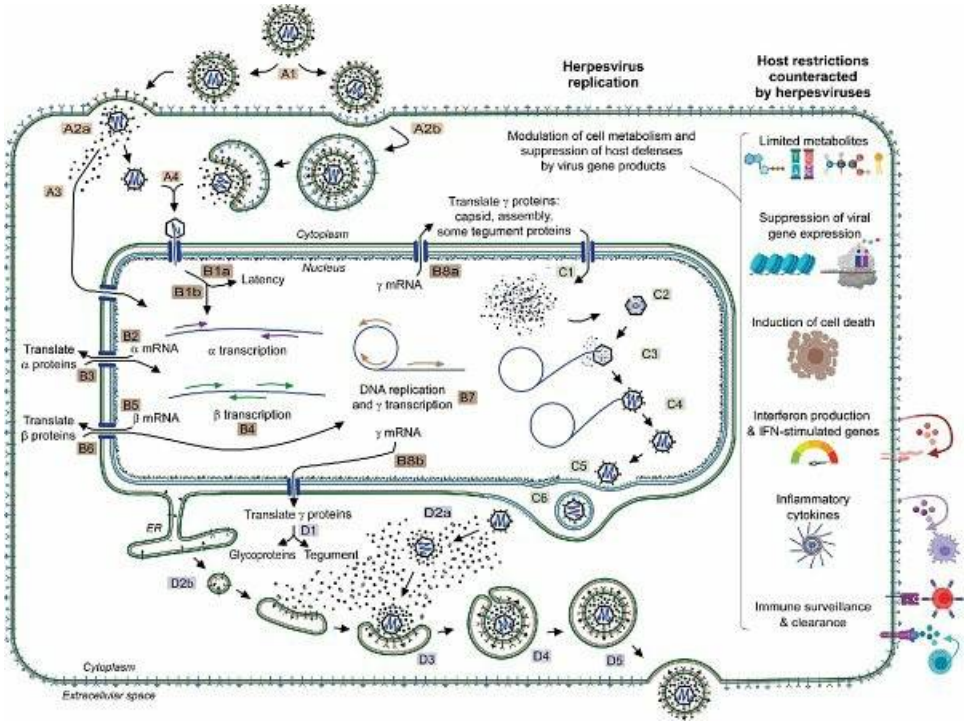

FIGURE 8.5 Herpesvirus replication in the context of host restrictions. Stages of lytic replication (left side). *Initiation of infection* (Steps **A1** to **A4**). Incoming virions engage cell surface receptors (**A1**) and then enter cells by fusion at the plasma membrane (**A2a**) or after endocytosis (**A2b**). Tegument proteins are routed to their various destinations, including the nucleus to activate α gene transcription (**A3**). Nucleocapsids are transported to nuclear pores via microtubules, and the virus genome is injected into the nucleus through a nuclear pore (**A4**). *Gene expression* (Steps **B1** to **B8**). Depending on the virus, cell type, and cell state, the virus can follow either the latent (**B1a**, details not illustrated) or lytic gene expression program, which is quickly dominated by transcription of α genes (**B1b**). α mRNAs are transported to the cytoplasm for translation (**B2**). Some α proteins are transported to the nucleus (**B3**) to initiate β gene transcription (**B4**). β mRNAs are transported to the cytoplasm (**B4**), translated, and then transported to the nucleus (**B6**) where they play various roles in replication of the virus genome (**B7**). γ genes are transcribed from replicating genomes, and the transcripts are then transported to the cytoplasm for translation (**B8a** and **B8b**). Nucleocapsid assembly and nuclear egress (Steps **C1** to **C6**). Capsid proteins and proteins required for capsid assembly and nuclear egress are transported to the nucleus (**C1**). Capsids form on a scaffold (**C2**) that is digested by a viral protease as the capsid is filled with newly replicated DNA (**C3**). Unit length virus genomes are cleaved from replicating genomes at specific sequences and the filled capsid is capped, thus forming a nucleocapsid (C4). Nuclear nucleocapsids associate with inner tegument proteins (**C4**). Nuclear egress involves modification of the nuclear lamina by viral and cellular kinases (**C5**), followed by nuclear egress complex-driven acquisition of the primary envelope by budding into the lumen of the nuclear membrane (**C6**), and then delivery into the cytoplasm after de-envelopment at the outer nuclear membrane. *Cytoplasmic virion assembly* (Steps **D1** to **D5**). The cytoplasmic steps of virion assembly begin with translation of tegument proteins and virion envelope glycoproteins (**D1**).

Nonenveloped, partially tegumented nucleocapsids acquire most of their tegument during transport via microtubules (not illustrated) to their exit vesicle (**D2a**). Exit vesicles are populated with viral glycoproteins that were synthesized at the ER and then transported and processed via the Golgi apparatus and the trans-Golgi network (**D2b**). A small subset of tegument proteins associates with exit vesicles prior to nucleocapsid arrival. Nucleocapsids acquire their envelope by a budding/wrapping process (**D3**) that culminates in fully enveloped virions being contained within cytoplasmic vesicles that can be transported to the cell surface (**D4**). Virions are released to the extracellular space after fusion of the exit vesicle membrane with the plasma membrane (**D5**). While the general features of this scheme are shared by all herpesviruses, details vary from virus to virus. *Host restrictions counteracted by herpesviruses (right side)*. Over half of the genetic content of herpesviruses is involved in counteracting the formidable array of host defenses to successfully drive a productive lytic infection. As detailed in Table 8.3 and in the text, these interactions may take place in the cytoplasm or nucleus, in subcompartments and organelles therein, or at the cell surface via receptors for extracellular factors. (Copyright Laurie Krug and Philip Pellett.)

Because they infect wide varieties of cell types, individual herpesviruses employ multiple cell surface receptors for virion entry. These interactions are mediated by individual, or combinations of, virion surface virus glycoproteins. For most, if not all herpesviruses, the initial binding of the virion to the host cell involves interactions of gB with cell surface heparan sulfate proteoglycans. After receptors are fully engaged, herpesviruses enter cells by two major pathways: fusion of the virion envelope with the plasma membrane at the cell surface (**Step A2a**), or membrane fusion after virion uptake by endocytosis (**Step A2b**). Fusion of virion and cellular membranes is mediated by gB and the gH/gL complex. gB is a class III fusion protein that has structural features in common with membrane fusion proteins encoded by viruses as diverse as vesicular stomatitis virus and baculoviruses.[57] In addition to their roles in virion entry, virion–receptor interactions activate cellular signaling pathways, some of which the virus takes advantage of, while others need to be redirected or blunted (Fig. 8.5, right side).

As part of entry, virus particles must interact with and ultimately penetrate the cytoplasm. Because of the macromolecular density and highly structured nature of the cytoplasm, objects the size of nucleocapsids are unable to migrate from the cell surface to the nucleus by diffusion alone. By way of interactions that ultimately link to microtubule motors, nucleocapsids hitch rides on microtubules for active transport to nuclear pores (**Step A3**). Next, tegument and capsid proteins mediate the docking of the nucleocapsid with the nuclear pore complex. The DNA is translocated from the capsid portal across the nuclear pore into the nucleus. Injection of the genome is powered in part by internal pressurization of the capsid during DNA packaging.[13] Almost immediately upon entry into the nucleus, the virus genome associates with histones. The organization and modification of the chromatinized genomes impacts the availability and state of particular viral and cellular transcription regulators. Thus, the epigenetic landscape is a major determinant of the biological decision to either establish a latent infection or enter the lytic replication cycle (**Steps B1a** and **B1b**).[76] Tegument proteins that are released into the cytoplasm during entry can have effector activities in the cytoplasm or nucleus. These include management of intrinsic defense responses and transcriptional activation of α genes (Fig. 8.5, right side).

Lytic Replication

The purpose of lytic replication is to manufacture infectious virions that can infect other cells and hosts. As illustrated in Figure 8.5, lytic replication includes regulated expression of virus genes, genome replication, virion assembly, egress, and transmission, all the while managing a wide range of host activities and defenses. As with any assembly line manufacturing process, virion assembly is dependent on production of appropriate levels of the various parts, plus mechanisms to ensure their presence in the proper locations when they are needed. Coordination of events during lytic infection is regulated as a function of the state of infection rather than by synchronization to a molecular clock. Lytic replication involves sophisticated use of preexisting cellular compartments such as the nucleus, cytoplasm, and cytoplasmic organelles, as well as their modification and sometimes subcompartmentalization.

As studied in detail for HSV, gene transcription, genome replication, and DNA packaging into capsids take place in subnuclear compartments. Several replication compartments, each nucleated by a single viral genome, constitute an infected cell nucleus. The compartments are dynamic, changing in size and composition as infection progresses.[73] Host chromatin is marginated to the nuclear periphery and host factors involved in gene transcription, DNA repair, and epigenetic silencing are relocalized; factors may be either recruited to, or excluded from, viral replication compartments.[18] Our understanding of the spatial–temporal changes that mediate transcription, replication, and genome packaging will continue to advance through use of super resolution microscopy and methods for purification of active transcription and replication complexes.

Expression and Activities of Lytic Genes

Herpesvirus gene expression during productive infection represents a classic regulatory cascade, the basic features of which are conserved across the family. In productively infected cells, viral genes form at least three kinetic classes that differ with respect to their order of gene expression. These are the α (immediate-early, IE) genes that require no new (cellular or viral) protein synthesis for their expression, β (early, E) genes whose transcription is totally independent of viral DNA synthesis, and γ (late, L) genes that typically follow viral DNA synthesis. In HSV, these γ genes are further categorized into γ1 (leaky-late) genes whose expression is augmented by the onset of viral DNA synthesis, and γ2 (true late) genes whose expression is absolutely dependent on viral DNA synthesis. The immediate-early, early, and late nomenclature is rooted in early phage studies; it has the virtue of instant recognition but does not fully describe the events occurring in the infected cell. Both systems are used widely and interchangeably.

Upon entry and circularization of the histone-free genome in the nucleus, the viral genome rapidly associates with nucleosomes. Epigenetic modifications of the chromatinized genome direct the availability of viral gene promoters. Regardless of whether the lytic pathway is entered directly as part of a new infection or via reactivation from latency, a key event is triggering α/IE gene transcription in a manner that drives the coordinated cascade of lytic gene infection. The activation of α/IE gene promoters is dependent on a transcriptional enhancer complex of viral and host factors. For example, host transcription factors recruit the virion protein VP16 of HSV and the host coactivator HCF-1 to promote active chromatin and drive transcription from α/IE promoters.[75]

Herpesviruses typically encode a small number of α/IE genes, whose products perform a

number of regulatory functions, including activation of β/E gene transcription, modulation of the cell cycle, chromatin structure, RNA transport and splicing, and blunting innate, intrinsic, and adaptive immune responses. Most β/E gene products are involved in virus genome replication. This includes enzymatic activities that ensure adequate pools of nucleotides, as well as the proteins and enzymes necessary for DNA synthesis at the replication fork. In the beta- and gammaherpesviruses, preinitiation complexes that are distinct from those that activate α/IE promoters drive transcription from γ/L promoters at a non-canonical TATT motif.[51,101] Most γ/L gene products are virion proteins.

Genome Replication

Replication of the virus genome is dependent on the presence of sufficient biosynthetic precursors, *cis*-acting signals in the virus genome that guide assembly of the replication complex and initiation of DNA replication, and *trans*-acting factors that replicate the virus genome in a manner that is sufficiently orderly to generate several thousand genomic copies from as few as one starting template and then efficiently encapsidate the nascent genomes.

Herpesvirus genomes have 1 to 3 *cis*-acting sites that can act as origins of lytic DNA replication (oriLyt). For alphaherpesviruses and a subset of betaherpesviruses (members of the *Roseolovirus* genus), assembly of the replication complex at these sites is dependent on the virally encoded OBP, which binds to specific oriLyt sequences and then triggers conformational changes in the virus genome that enable assembly of the replication complex and initiation of replication. Other herpesviruses employ virally encoded DNA-binding transcription factors for oriLyt activation. Regardless of how oriLyt is activated, a set of six proteins that are conserved across the *Herpesviridae* interact to form the enzymatic complex that replicates the genome. These proteins include the viral DNA polymerase (POL) and its associated processivity subunit (PPS), a single-stranded DNA binding protein (SSB), and the three components of the helicase–primase complex (HP1, HP2, and HP3). Some host proteins are involved, but their roles have not been fully defined. Other forms of replication might be involved, but rolling-circle replication (**Step B7**) appears to be the major source of new genomes. Because packaged genomes are not chromatinized, thus far undefined mechanisms are needed to either prevent chromatization during and after viral DNA replication or remove nucleosomes from newly replicated viral DNA prior to packaging.[102]

Virion Assembly and Egress

Biosynthesis and intracellular delivery of virion components

Dissection of the process of virion assembly needs to account for the structure of mature infectious virions and the topological constraints imposed by cellular compartmentalization. The major stages of virion assembly occur first in the nucleus and then in the cytoplasm. Extensive use is made of cellular systems for synthesis, processing, and trafficking of membrane proteins, plus nucleocytoplasmic, intracytoplasmic, and vesicular transport systems, as well as management of cellular metabolism to ensure manufacture of raw materials such as amino acids and nucleotides, in addition to lipids needed to form virion envelopes. The process is dependent on coordinated delivery of virion subcomponents to appropriate subcellular addresses at appropriate times.

Biosynthesis of most virion proteins begins with translation of mRNAs for structural genes. The mRNAs for virion glycoproteins need to be translated by ribosomes associated with the endoplasmic reticulum, to begin the trafficking through the ER, Golgi apparatus, and trans-Golgi network required for sequential maturation of nascent glycoproteins and their ultimate delivery to the organelle(s) where virions are enveloped (Fig. 8.5, **Steps D1** to **D3**). Proteins and multiprotein complexes formed in the cytoplasm are required for construction of capsids in the nucleus must associate with machinery that enables their transport to and through the nuclear pore complex. Tegument proteins that will be assembled onto nucleocapsids in the cytoplasm need to be routed to areas that will be traversed by nucleocapsids on their way to the cytoplasmic organelle where they will acquire their envelope.

Assembly and nuclear egress of the nucleocapsid

Capsids are assembled in the nucleus (**Steps C1** to **C4)**.[23,59,121] In addition to its structural proteins, capsid assembly is dependent on several other viral proteins expressed from a pair of overlapping genes (*UL26* and *UL26.5* in HSV). These include the assembly protein precursor (pAP), the mature assembly protein (AP), and the assembly protease (PR), which are self-excised by PR from a precursor polyprotein (prePR) that contains PR, pAP, and AP, and proteolytic products that form the temporary scaffold during capsid assembly. Capsid assembly nucleates on the dodecameric portal complex (**Step C2**). The scaffold enables assembly of pentonal and hexagonal capsomeres and their associated proteins into closed capsids, after which the scaffold is proteolytically digested (**Steps C3** and **C4**).

The genome is packaged into the capsid by the packaging motor and site-specific endonuclease that form the terminase complex (**Step C3**), which is built from six terminase monomers that are arranged as a ring just outside the capsid portal complex at its pentonal vertex.[121,157] Each of the terminase monomers consists of three conserved subunits: the terminase binding protein (TERbp; HSV pUL33), the terminase ATPase subunit (TER1; HSV pUL15), and the TER DNA recognition subunit (TER2; pUL28). To initiate packaging, the complex recognizes and then employs its endonuclease activity to cleave the nascent genome at its packaging and cleavage sequence. With one end now precisely defined, the genome is then translocated into the capsid by the packaging motor activity of the complex.

Rather than screwing the DNA into the capsid (rotation model for packaging), which would produce torsional forces that would twist and tangle the genome, DNA is packaged via a rotational mechanism. During translocation, the DNA is passed from one terminase subunit to the next, the double helix revolving around the center of the central channel of the hexameric complex, without rotation of either the DNA or terminase complex. The DNA is advanced into the capsid at an energy cost of one ATP per terminase monomer step. The bacteriophage phi29 packaging motor, which uses a related mechanism, advances its DNA 1.75 bp per step into the capsid.[132] As packaging approaches completion, and the capsid is nearly filled, a conformational change occurs that enables the complex to cleave the genome precisely at the next packaging and cleavage sequence it encounters. The portal capping protein (PCP; HSV pUL25) is involved in securing the DNA in the highly pressurized nucleocapsid.

Filled nucleocapsids are exported from the nucleus via a process that involves primary envelopment at the inner nuclear membrane followed by deenvelopment during entry into the cytoplasm.[58,128] The viral nuclear egress complex (NEC) is made from two conserved herpesvirus proteins, nuclear egress membrane protein (NEMP; HSV pUL34) and nuclear egress

lamina protein (NELP; HSV pUL31). NEC mediates a viral and cellular kinase-driven disassembly and rearrangement of the nuclear lamina that enables filled nucleocapsids to access the nuclear face of the inner nuclear membrane (**Step C5**). NEC enables generation of the inner nuclear membrane curvature needed for capsid envelopment, which is followed by NEC-driven scission of the nascent primary envelope, with no apparent requirement for ESCRT machinery. In the lumen of the nuclear membrane, nucleocapsids present in primary enveloped virions are surrounded by the NEC and a small set of capsid-associated tegument proteins (**Step C6**). The mechanism for the membrane fusion that enables primary enveloped virions to migrate from the lumen of the nuclear membrane to the cytoplasm is not well defined.

Cytoplasmic tegumentation, secondary envelopment, and egress

As delivered into the cytoplasm, nonenveloped nascent virions consist of nucleocapsids and a set of nucleocapsid-associated tegument proteins (the inner tegument) that were acquired in the nucleus (**Step D2a**). The next assembly steps involve addition of the final complement of tegument proteins and some RNAs, and then acquisition of the mature envelope while budding into a cytoplasmic organelle from which the virion can be transported to the cell surface for release[22,23,156] (**Steps D3** to **D5**). Few mechanistic details are known of the tegumentation process. Virion membrane proteins must possess trafficking signals appropriate for being routed to exit organelles (**Steps D2b** to **D3**), where they form concentrated patches. Nucleocapsids are transported from the site of nuclear egress to their exit vesicle through associations with microtubule motors. Some tegument proteins interact with each other to form subassemblies that associate with the developing virion during transport to the exit organelle. Electron micrographs make it clear that most of the tegument forms on the nucleocapsid, but some tegument proteins associate with cytoplasmic projections of virion membrane proteins. When the necessary associations and structures have formed, tegumented nucleocapsids bud into the exit organelle. The final step of envelopment is scission of the neck of the membrane that connects the tegument-containing compartment of the developing virion to liberate the mature virion into the lumen of the exit vesicle (**Steps D4** to **D5**). Topologically similar activities are important in cell biology and for other enveloped viruses (e.g., retroviruses and filoviruses), and are commonly carried out by ESCRT machinery.[8] Current evidence indicates that ESCRT machinery is employed for completion of secondary envelopment of HSV-1, but HCMV employs a different mechanism, one possibly mediated by viral proteins.[138]

Herpesviruses can differ with respect to the organelle where they acquire their mature envelope. The unifying concept is that the exit organelle is adapted from an organelle that is normally involved in vesicular transport and delivery of cargo for release at the plasma membrane. Thus, HSV uses the trans-Golgi network and early endosomes, HCMV appears to follow a secretory endosomal pathway, and HHV-6A follows a pathway used by CD63-positive multivesicular bodies.[23,156] Vesicles containing enveloped virions are transported to the plasma membrane, where vesicle membranes fuse with the plasma membrane; mature virions are then released to the extracellular space from which they can infect other cells, in the same or a different host.

Latency and Reactivation

Latency

Latency is a defining property that drives much of herpesvirus biology. Each herpesvirus establishes latency in a specific set of cells, with the cellular site of latency differing from one virus to another. In cells that harbor latent virus, viral genomes generally take the form of closed circular chromatin that is not integrated into a host chromosome (an episome), with epigenetic marks that silence transcription, enabling expression of only a small subset of viral genes (Fig. 8.3). Latently infected cells differ from chronically or persistently infected cells in that infectious progeny are not produced during latency. The limited gene expression of latency is a stealth mode that reduces potential exposure of viral antigens to the immune system. Importantly, latent genomes retain the capacity to reactivate to a lytic state during which new infectious virions are produced. The capacity to reactivate differentiates latent from abortive infections.

Epigenetic regulation to silence lytic gene expression from the viral genome is a broad strategy of latency. However, there appears to be no shared genetic component for establishment, maintenance, or termination of the latent state. Members of some genera of herpesviruses encode several proteins and ncRNAs that are expressed to facilitate latency in cells at particular states of differentiation (e.g., EBV), while others (e.g., HSV) might express ncRNAs derived from a single latency-associated transcript (LAT) to establish and maintain latency. Maintenance of the viral genome in nondividing cells, such as neurons infected by alphaherpesviruses, requires less viral activity than in cells infected by beta- and gammaherpesviruses, which typically establish latency in proliferating cells of the immune system. EBV and KSHV express latency nuclear antigens that tether the viral episome to the host chromosome and recruit the host replication machinery to the latent origin of virus replication upon host cell division.[32]

HHV-6A and HHV-6B readily integrate into the telomeres of host chromosomes in cell culture models of infection.[71] Chromosomal integration is hypothesized to provide a mechanism for maintenance and replication of the virus genome during latency. Approximately 1% of humans have germ-line integration of HHV-6A or HHV-6B, which leads to the intriguing phenomenon of inherited vertical transmission.

The molecular mechanisms that lead to establishment of, and reactivation from, the latent state are not fully understood. A central feature of latency is epigenetic regulation of transcription. Chromatin modifications of the viral genome ensure transcription of latency-specific transcription, as well as suppression of lytic gene transcription.[32]

During the establishment of latency, host factors such as histone deacetyltransferases promote heterochromatin with repressive histone modifications to suppress lytic gene expression.[75] The host chromatin remodelers and regulatory factors vary with the type and state of the cell. Virally encoded proteins and ncRNAs modulate the activities of the host factors and directly regulate latent gene programs.[32,54,124]

Reactivation

Reactivation from latency is the reversal of suppressed lytic gene expression. In a cell type–dependent manner, cellular stress conditions and particular states of activation and differentiation serve as cues to reverse the epigenetic modifications that silence latent viral genomes. Signaling pathways culminate in the activation of transcription factors that drive α/IE lytic promoters; these vary with cell type and stimulus. Reactivation events are held in check by antiviral cytokines and

the virus-specific adaptive immune response.

Defining the signals that coordinate a permissive chromatin state and the engagement of transcription enhancer complexes is a fascinating challenge. For HSV, both animal models and primary culture systems model reactivation using stress cues such as tissue explant or withdrawal of neuronal growth factors (NGFs). Molecular events during reactivation include the loss of the translational repressor 4E-BP1 that is regulated by NGF-dependent mTORC1, relocalization of host coactivator HCF-1 and its associated histone demethylases to the nucleus, and chromatin modifications that displace repressive factors.[21,72,75,76] A simple binary latent or lytic state of infection may not exist for all herpesviruses.[134] Gene expression patterns that do not fit the regulated, ordered lytic cascade is observed prior to the establishment of latency and in the early phase of reactivation. The collective molecular cues that regulate latency are likely in flux within the infected cell and its microenvironment. If the threshold to trigger the full lytic cascade is not met or if the immune system blocks this event, reactivation is aborted.

Reactivation from cellular latency can result in disease due to a combination of the cellular and tissue damage directly caused by lytic virus replication, plus the immunologic responses to the reactivated lytic replication. Within an organism, a herpesvirus can be simultaneously latent in some cells and actively replicating in others due to periodic reactivation events. Reactivation likely plays a role in maintaining the viral load in the host and is key for transmission to new hosts via infections virions shed via lesional fluid or mucosal tissues.

VIRUS–HOST INTERACTIONS

Across the herpesviruses, multiple mechanisms have evolved that accomplish the shared objective of thwarting host defenses at each step of infection, for example, the many ways they block the attempt of infected cells to undergo a form of death termed apoptosis or block the action of antiviral interferon cytokines. The diversity of approaches is a remarkable testimony both to the depth and complexity of host defenses and to the adaptive prowess of the virus (summarized in Table 8.3). That the virus wins in the infected cell but normally allows the host to survive attests to an evolutionary necessity.

TABLE 8.3 herpesvirus countermeasures for host restrictions

Host restriction	Virus Countermeasures	HSV-1 HSV-2	VZV	HCMV	HHV-6A HHV-6B HHV-7	EBV	KSHV
Limited metabolites	Induce nucleotide, lipid, and/or glucose metabolism	⊙	○	●	●	●	●
	Modulate host regulators of cell cycle	●	●	●	●	●	●
Suppression of viral gene expression	Impair epigenetic silencers and repressors that silence viral genomes	●	○	●	○	●	●
	Degrade host transcripts	●	○	○	○	●	●
	Alter transcription, splicing and export of transcripts to favor virus	●	○	●	⊙	●	●
	Promote translation initiation and downregulate stress responses	●	○	●	⊙	●	●
Induction of cell death	Block host sensors and signaling that activate death effectors	●	●	●	●	●	●
	Induce host survival factors or encode viral mimics	●	●	●	○	●	●
Antiviral cytokines	Block pathogen sensors and production of antiviral cytokines	●	○	●	●	●	●
	Prevent interferon signaling and interferon simulated gene expression	●	○	●	●	●	●
Immune response	Block induction of inflammatory cytokines	●	○	●	⊙	●	●
	Encode or induce immunosuppressive cytokines	○	⊙	●	●	●	●
	Pirating of chemokine, chemokine binding protein or receptor	●	●	●	●	●	●
	Alter cell surface receptors to prevent NK cell activation	●	⊙	●	●	●	●
	Interference with antigen presentation to T cells	●	●	●	●	●	●
	Latency program of restricted viral gene expression	●	●	●	●	●	●

Filled circle indicate that specific viral factors promote the indicated countermeasure.
Circles with center dot indicate viral infection impacts a particular host process, but the specific viral factor that is responsible remains undetermined.
Open circles indicate that the virus countermeasure has not been reported.

Conquering the Cell

Herpesviruses are exquisite cellular parasites that transform the infected cells into a production factory for virus particles. Infection typically ramps up the acquisition and usage of fuel, in addition to the production of molecular building blocks such as nucleotides, amino acids, and lipids. Glycolysis, glutaminolysis, and the synthesis of fatty acids are common pathways boosted by infection.[140] In addition to encoding enzymes involved in nucleotide metabolism, some herpesviruses (e.g., HSV) alter the flow through metabolic pathways that result in enhanced pyrimidine biosynthesis,[149] while others (e.g., HCMV) manipulate the tricarboxylic acid cycle to ensure adequate lipids for other stages of replication.[99,149,159] Herpesvirus subversion of the metabolic microenvironment may involve increased glucose uptake, up-regulation of metabolic enzymes, and interference with cellular signaling.[84,122,140] HCMV UL38 targets the host TSC tumor suppressor to increase glycolytic and amino acid flux that promotes virus production.[123] miRNAs and proteins encoded by gammaherpesviruses subvert metabolic processes that promote cell survival.[117] The EBV latency protein EBNA2 drives one carbon metabolism via MYC up-regulation to promote transformation of primary B cells.[152]

The molecular battle with the cell occurs on many fronts. During lytic production, cell cycle progression ramps up metabolism and host factors needed to produce infectious particles. Viral proteins perturb the cell cycle by direct interaction with cyclin-dependent kinases or by the phosphorylation, degradation, and redistribution of host regulators of the cell cycle.[41,135] On the gene expression front, herpesvirus mRNAs are indistinguishable from mature host mRNAs (5′7-methylguanosine cap and 3′ polyA tails) and they rely on the transcriptional and translational

machinery of the cell. How does the virus compete with the much larger host transcriptome to favor viral gene products and repress host antiviral responses? The ICP27 family of viral IE proteins exhibits a remarkable array of interactions with host factors and viral RNAs that promote the stability of viral RNAs in the nucleus. Most herpesvirus transcripts are not spliced. HSV-1 ICP27 dysregulates termination, splicing, and export of host transcripts.[145,151] KSHV ORF57 protects viral mRNAs from RNA decay in the nucleus,[130] and as reported for its HSV, HCMV, and EBV homologs, it promotes translation of intronless viral mRNAs in the cytoplasm.[49] Viral nucleases of the alphaherpesviruses (HSV-1 vhs) and gammaherpesviruses (KSHV vSox) cleave mRNAs of the host and virus to facilitate optimal viral gene expression.[49] Another broad feature of the battle at the translational front is virus-mediated stimulation of the assembly of translation initiation factor complexes. Down-regulation of stress responses to infection such as the unfolded protein response and protein kinase R activation prevents host shutdown of viral protein synthesis and cell death.[49]

Herpesvirus proteins interact with cytoskeleton components throughout the infectious cycle: retrograde virion transport to the nucleus, egress from the nucleus, and then final tegumentation and envelopment in the cytoplasm, with anterograde directional transport to release infectious particles.[100] Engagement of virion glycoproteins with surface receptors cues actin remodeling and signaling that stabilizes microtubules.[34] As exemplified by pseudorabies virus infection of neurons, the inner tegument proteins bind motor proteins to facilitate transport to and from the nucleus, and virion proteins including kinases modify and dissociate nuclear lamins.[87] HCMV-infected cells form a distinct virion assembly complex in which the nucleus is bent into a kidney shape around a cylindrical organelle structure composed of virus-modified Golgi, TGN, and secretory vesicles, all radiating from a microtubule organizing center.[4]

Modulation of Host Defenses

Intrinsic Defenses

The intrinsic defense of a cell to an incoming virion in the cytoplasm or a newly deposited viral genome in the nucleus initiates with sensing by preexisting host molecules. Promyelocytic-nuclear bodies (PML-NB), also referred to as nuclear domain 10 (ND10), are nuclear hubs of host factors including the PML, Sp100, and hDaxx transcriptional regulators that restrict virus replication.[144] PML has been observed to form a cage-like lattice around the HSV-1 genome early during infection.[3] PML-NB components recruit chromatin remodelers to transcriptionally silence the promoters of immediate early genes, and they facilitate innate interferon-stimulated gene expression. Viral proteins delivered via the virion tegument (gammaherpesvirus vFGARATs and HCMV pp71) or newly synthesized during the first hours of infection (HSV-1 ICP0) neutralize these host restriction factors by ubiquitin-mediated degradation, disruption of protein–protein interactions, or relocalization of the PML-NB components to inert subcompartments.[44,78,129] A fine balance is involved, since herpesviruses co-opt these restriction factors to facilitate their own latency. HSV-1 genomes localize to ND10 in the nuclei of neurons during latency.[37]

The interferon gamma–inducible protein IFI16 is a nuclear DNA sensor that activates host restriction factors that epigenetically silence viral genomes to prevent gene expression.

Repressive histone methylation marks on KSHV lytic gene promoters that are driven by IFI16 facilitate and maintain latency in endothelial cells and B lymphocytes.[129]

Apoptosis, necroptosis, and autophagy are distinct cell death responses invoked by virus infection. Caspase-dependent apoptosis is initiated from extrinsic death receptors such as the TNFα receptor or from intrinsic pathways via the mitochondria or ER following cell stress. Herpesviruses override these death cues with glycoproteins and tegument components of the virions, in addition to newly expressed genes during lytic infection.[143] Viral strategies of subversion encompass transcriptional up-regulation or molecular mimicry of prosurvival host factors, altering the phosphorylation of host signaling intermediates or impairing the function of signaling factors and caspases through direct interactions.[7,52,158] The latency-associated transcript of HSV-1 and numerous proteins expressed in the latency programs of EBV and KSHV employ similar strategies to protect the viability of cellular reservoirs of latent infection.[7,158] Necroptosis is a fallback host defense to counter viruses that impair caspase 8. RIP kinase 3 associates with RIP1 of death receptor activated complexes to phosphorylate a host factor that disrupts plasma membranes. RIP homotypic interaction motifs found in proteins of alpha and betaherpesviruses directly impair RIPK3 interactions and protect against necroptosis.[52] The cellular recycling process of autophagy is induced in response to cell stress and can destroy virions by fusion of virion-containing endosomes with autophagolysosomes. Inhibition of autophagy increases virus yield in many systems. However, autophagy also provides an opportunity to recycle vacuolar membranes to enhance egress, increase metabolites, drive host cell survival and proliferation, and reduce inflammatory responses.[86] With each type of cell death, herpesviruses may encode gene products or employ ncRNAs that engage upstream signaling events to drive beneficial outcomes while others intervene to circumvent execution of cell death processes.

Innate Defenses

The sheer physical complexity of the virion in addition to virus-driven subversion of cellular processes triggers numerous molecular tripwires in the host. Cytoplasmic sensors of virion DNA and stress-induced release of mitochondrial DNA drive cGAS/STING activation that signals to trigger type I IFN (IFN-I) production.[164] Engagement of toll-like receptor sensors and RIG-I with double-stranded RNA produced during infection leads to a series of phosphorylation events that activate transcription factors to induce IFN-I.[147] Interferons are a potent family of cytokines that induce hundreds of interferon-stimulated genes (ISGs) that function to blunt replication in the infected cell and warn neighboring uninfected cells to bolster defenses against the imminent herpesvirus intruder. The antiviral ISGs can impair multiple stages of infection such as an early block in the delivery of the viral genome to the nucleus, a shutoff of protein translation, or the induction of apoptosis. In response to this threat, each herpesvirus employs multiple strategies to thwart host induction of, and responses to, interferons. For example, HSV-1, HCMV, and KSHV each encode over a dozen distinct proteins that block upstream events to impair key host signaling molecules STING and TBK1, interfere with the function of host transcription factors NF-kappaB and IRF3 to dampen the expression of IFN-I, directly repress the expression of key players in the IFN pathway, and block signaling downstream of IFN receptor engagement to reduce ISG expression[2,10,143,147]

Innate immune cells express high levels of pathogen recognition receptors and are responsive

to chemokine-directed recruitment and cytokines produced by infected cells. As first-line responders, neutrophils and macrophage cells produce toxic moieties such as reactive oxygen species and nitric oxide. They produce soluble factors that amplify inflammation and recruit additional leukocytes of both the innate and adaptive host immune response. Herpesviruses have pirated numerous chemokine-related molecules to redirect immune cell communications. Paradoxically, some herpesviruses facilitate the recruitment of innate immune cells as a reservoir of latency or as a vehicle for dissemination. Every human herpesvirus encodes at least one chemokine homolog with distinct agonist or antagonistic relationships with host chemokine receptors.[116] Chemokine binding proteins of the alpha and beta subfamilies may enhance or inhibit their cognate chemokines while the chemokine receptors of the beta and gamma subfamilies usurp signaling pathways to drive proliferation, cell migration, and angiogenesis of the infected cell. These pirated immune modulators can profoundly influence pathogenesis. For example, the vGPCR of KSHV is a homolog of CXCR2 that constitutively drives the production of paracrine growth factors to promote endothelial cell proliferation and angiogenesis, a hallmark of the Kaposi sarcoma neoplasm.[116]

Natural killer (NK) cells survey the surface receptors of cells for signatures indicative of infection such as down-regulation of MHC I molecules or up-regulation of the activating ligand NKG2D. Potent antiviral effector functions include the production of cytokines IFNγ and TNFα, recognition of antibodies bound to infected cells, and the directed killing of target cells by perforin/granzyme B and FasL. Herpesviruses have evolved a multitude of molecular strategies to counter recognition by NK cells. Viral proteins facilitate ER retention and degradation of ligands for NK activating receptors, or they provide decoys and ligands for NK cells receptors that inhibit activation; viral miRNAs down-regulate NK activating ligands.[33] Viral glycoproteins may function as viral Fc receptors for antibodies that recognize viral antigens on a cell surface; this impairs antibody-dependent cytotoxity by NK cells.

In vivo investigations of nonhuman herpesviruses (BHV-1, MCMV, gpCMV, MHV68, RRV) in their natural hosts have proven invaluable to define critical host determinants of immune control and the role of viral genes that promote pathogenesis by evading host immune responses. For example, the biological importance of NK cell inhibition is quite apparent in mice infected with MCMV. Viral mutants that lack genes products or viral miRNAs that interfere with NK cell surveillance have reduced pathogenesis; these phenotypes are absolved when NK cells are depleted or inhibited in mice.[114]

Adaptive Defenses

B lymphocytes produce virus-reactive antibodies that either neutralize the virion particles directly or lead to the death of the infected cell when antibodies that bind viral surface antigen cue the complement cascade or innate immune cells recognition via Fc receptors. B lymphocytes also present antigen and provide help to T cells. Activation of CD4+ T cells leads to cytokine production that facilitates the expansion and activation of virus-specific CD8+ T cells. Virus-specific CD8+ T cells produce the antiviral cytokines IFNγ and TNFα, which inhibit herpesvirus replication and reactivation; most importantly, they kill infected cells via perforin/granzyme B– or Fas-mediated cytolysis.

Herpesviruses escape killing by virus-specific CD8+ T cells by preventing surface presentation of viral antigens on MHC I. Strategies to down-regulate viral antigen presentation

include cleavage of MHC I transcripts, increasing MHC I turnover by viral ubiquitin ligases, retention of MHC I molecules in the ER, and blocking transport of peptides into the ER and loading onto MHC I.[109,120] The EBNA1 latency antigen contains a glycine–alanine repeat that reduces its translation and MHC I antigen presentation.[120] Many herpesviruses have either independently pirated an IL-10 homolog (vIL-10) or induce cellular IL-10 expression to suppress proinflammatory cytokine production and inhibit CD4+ and CD8+ T-cell effector responses.[108] The remarkable set of immune modulators encoded by herpesviruses coupled with the molecular program of latency bestows an invisibility cloak that is a major contributor to lifelong persistence of herpesviruses, even in immunocompetent hosts.

Animal studies provide numerous examples whereby virus-specific cells of the adaptive immune system play a critical role in acute control, prevention of latency, or long-term control of reactivation. Neutralizing antibodies suffice for sterilizing immunity for many pathogens, but antigen-specific CD8+ T cells and CD4+ helper T cells are most critical for long-term control of herpesviruses. In humans, herpesvirus pathologies that manifest upon failure of immune defenses due to genetic immunodeficiency, young or advanced age, uncontrolled HIV or pharmaceutical suppression demonstrate that chronic cycles of reactivation and reinfection that transpire must be controlled by a vigilant, armed immune system.

The success of the human VZV vaccines demonstrates that sterilizing immunity is not required for protection against herpesvirus diseases. The Oka vaccine is a live attenuated form of VZV that establishes latency and has reduced the incidence of chickenpox worldwide. For persons already infected with VZV, a glycoprotein-based subunit vaccine that is administered with a potent adjuvant markedly reduces the occurrence of shingles and the debilitating development of postherpetic neuralgia. The challenge is to understand the spatial and temporal events of the immune response required for the control of each herpesvirus and prevention of their respective diseases, and then tailor a vaccine formulation that will generate the protective determinants of humoral and/or cellular immunity to reach that end.

Pathogenesis

Human Herpesvirus Transmission and Disease

Initial infections with herpesviruses might be asymptomatic or the newly infected individual may present with disease-defining clinical manifestations (e-Table 8.1). Herpesviruses are shed at mucosal sites including the oral and genital tissues. Shedding is often asymptomatic; the periodicity and level of infectious virus in secretions is not well-characterized for most herpesviruses. Primary infection typically occurs through asexual contact in childhood and adolescence, but some viruses may be acquired through sexual contact. HCMV may be acquired by vertical transmission from the mother to the fetus *in utero* and is also shed in the urine and breast milk. Mothers who undergo primary infection with HCMV during their pregnancy are most at risk for *in utero* transmission, but reactivation and reinfection events are also sources of placental infection that contribute to more total cases of congenital HCMV disease.

Herpes is forever. Once infected, the host will perpetually harbor the virus in multiple reservoirs of the body; most reservoirs are latent with some degree of lytic replication. Reactivation or low-level persistent replication can lead to mild, even asymptomatic shedding or more severe manifestations such as cold sores and genital lesions (HSV-1 and -2), shingles

(VZV), and retinitis (HCMV). As detailed below, gammaherpesviruses (EBV and KSHV) drive numerous types of cancers that manifest in the lymphoid and nonlymphoid cells in which they reside at much higher rates in individuals with weakened immune systems. Sporadic, low-level reactivation is difficult to measure. However, the increased incidence and severity of herpesvirus diseases that manifest in HIV+ patients with low CD4+ T cell counts and in individuals undergoing immunosuppressive chemotherapy are striking evidence that the immune system plays an essential role in controlling intermittent productive infection.

Oncogenesis

The gamma subfamily has a strong association with lymphomas, tumors, and neoplasms in the host, albeit most frequently in the context of immune suppression (e-Table 8.1). Rapid proliferation and a prolonged life span of newly infected lymphocytes is integral to the establishment of their latent repository. Bypass of normal checkpoints likely places the gammaherpesvirus-infected cell at risk for further genetic insults, such as the classic chromosomal translocation of the c-myc oncogene to the immunoglobulin heavy chain locus in EBV-positive Burkitt lymphoma. Few alpha- or betaherpesviruses are considered to be oncogenic. A notable exception is the alphaherpesvirus, Marek disease virus (MDV, GαAHV-2), a potent driver of T-cell lymphomas in chickens.

The exquisite and complex latency program of gammaherpesviruses in a newly infected lymphocyte contrasts sharply with the single latency-associated transcript of HSV-1/2 that is expressed in nondividing neurons. EBV latency initiates with the expression of at least ten viral proteins and dozens of ncRNAs with potent proliferative and antiapoptotic functions that drive several rounds of rapid B cell division.[68] Concomitant with the generation of an adaptive immune response that surveils and eliminates infected cells with active expression of latency antigens in the host, there is a progressive shutdown of the expression of latency genes as the cell is reprogrammed towards a more differentiated, longer-lived memory B cell. The latency program of the rhadinoviruses such as KSHV in lymphocytes appears less complex. Even so the multiple latency gene products and miRNAs expressed in newly infected cells coordinate the critical end-goal of promoting proliferation and survival while maintaining the viral genome.[16]

Kaposi sarcoma is a highly angiogenic neoplasm of endothelial cell origin that arises in the skin and numerous cutaneous sites of the body. A small population of cells in an active lytic phase of KSHV infection have paracrine effects on the majority latent population and other uninfected cell types of the tumor microenvironment. Low-level but consistent detection of KSHV lytic genes with functions that promote the hyperproliferative, inflammatory, and angiogenic characteristics of Kaposi sarcoma suggest that gammaherpesvirus pathologies are not driven solely by the latency program.[16]

Many gammaherpesvirus genes are considered to be oncogenes based on their consistent detection in cancer tissues and ability to drive transformation in cell culture and animal models. Gammaherpesviruses encode an array of proteins and noncoding RNAs with functions that can induce classical hallmarks of cancer.[15,68,94] A gammaherpesvirus arsenal may encompass surface receptors, cytokines, and chemokine receptors that engage numerous signaling pathways, potent regulators of host gene expression and epigenetic modifications to activate or silence host and viral genes of interest, and homologs of host cyclin to dysregulate the cell cycle and bcl-2 to block cell death.[68,94] Taken together, these accoutrements drive cellular proliferation while

impairing host DNA damage responses and tumor suppressors that risk genome instability and bona fide transformation. Viral proteins and ncRNAs place the cell at risk for transformation, but a combination of circumstances involving immune status, infections with other pathogens (notably HIV), genetic and environmental factors, and a conducive microenvironment likely serve as contributing factors to drive neoplasms and cancers. A major challenge in the gammaherpesvirus field is to understand the mechanism and order in which viral factors drive oncogenic processes in patients that transpire many years after primary infection.

HERPESVIRUS EVOLUTION

Virus Origins

Herpesviruses and their hosts have deeply shared coevolutionary histories. As elegantly summarized by Koonin et al.[74] herpesvirus origins connect to the caudoviruses (order *Caudovirales*) of prokaryotes. Early stages of herpesvirus evolution likely involved linkage of modules of genes involved in capsid structure and assembly and genome replication, plus other genes that facilitated survival in their hosts. Consistent with this, herpesviruses have discernable structural homologs of several caudovirus proteins, including the major capsid protein (MCP; HSV pUL19), which incorporates the unique caudovirus HK97 capsid protein fold, plus capsid maturation proteases and the terminase.[26] These distantly related viruses employ similar mechanisms for capsid assembly.

Prior to the mammalian radiation,[91] the ancestral herpesviruses diverged into at least three major lineages that encompass the virus families of Order *Herpesvirales*: the Alloherpesviruses of fish and amphibians, the Malacoviruses of molluscsm and molluscs, and the α, β, and γHV of birds, reptiles, and mammals that belong to family *Herpesviridae* (Fig. 8.2, Table 8.1, and e-Table 8.3). Although there is little obvious genetic similarity between viruses from the three families, their capsid structures and genomic architectures are well conserved.[31]

The evolutionary distances between closely related herpesviruses that infect different species —such as the rhadinoviruses KSHV (humans) and Herpesvirus saimiri (squirrel monkeys)— suggest that in most instances viral and host speciation occurred at approximately the same time. Herpesviruses thus have intimate shared evolutionary history with their hosts.

Mechanisms of Evolution

A number of rational mechanisms have been used to explain the development and divergence of herpesviruses; because of their timescale and net complexity, some are essentially impossible to prove directly. Mechanisms used to assemble primordial genomes likely included recombination-based acquisition and then subsequent evolution of segments of host DNA, as well as transposition or recombination of viral or cellular DNA or cDNA.

Herpesviruses have employed diverse methods for small-scale genetic changes that have collectively had profound effects on diversification of their biological activities at relatively low cost. These include shifts in base and dinucleotide composition that can be products of viral DNA polymerase mutation rates or occur in response to concentrations of intracellular nucleotide

precursors and pools. There can be positive selection for variations in sequences that regulate transcription, splicing, RNA stability, translation, and timing of signal peptidase cleavage.[98,119]

dsDNA viruses that replicate in the nucleus can take advantage of cellular recombination mechanisms to acquire new genes from the host, from unrelated viruses, or from other strains of the same virus. On an evolutionary timescale, many of the host-derived genes of herpesviruses were acquired relatively recently and are involved in modulation of host immune responses.[28] Some genes were recently introduced into limited lineages, including a glycosyltransferase (core *β*-1,6-*N*-acetylglucosaminyltransferase-mucin) acquired from an ancestor of the African buffalo that is present only in viral lineages closely related to Bovine γHV 4.[88]

Recombination between genomes of different virus strains or species is rare, because it requires their presence in the same cell at the same time.[119] Examples of intervirus gene transfers include the presence of homologs of the parvovirus *rep* gene in the genomes of some betaherpesviruses,[141,150] as well as the homolous glycoproteins encoded by members of the HCMV RL11 gene family and human adenovirus E3 genes.[27] Despite the expected rarity of the simultaneous infection step, there is abundant evidence for intraspecies recombination occurring in nature, with recombination being described as “pervasive” in HCMV genomes[133] and contributing to HSV-1 strain variability at a level comparable to mutation.[12] The frequent recombinations are dependent on coinfections of cells with dissimilar strains, which is more likely if the host is superinfected by additional strains. HCMV US2-US11 gene products encode immune suppressive genes that are not needed during primary infection, but might enable superinfections that promote emergence of recombinant strains with enhanced fitness.[79]

Recombination can lead to gene duplication and divergence that allows for neofunctionalization in one of the copies.[14] This strategy has been used across the herpesvirus family, as exemplified by the evolution of the dUTPase gene of the mammalian/avian/reptilian herpesviruses, which appears to have undergone a duplication and subsequent fusion that involved permuting the order of its subdomains.[29,90] Further duplication and divergence events led to the current family of genes that encode proteins with dUTPase function, as well as proteins that lack residues that are essential for dUTPase activity, and have diverse or unidentified functions. Some of these proteins are essential for viral replication, whereas others are not. The betaherpesviruses have exploited this duplication and divergence strategy extensively, with HCMV encoding five additional gene families that each have from 2 to 12 members.[19]

Modifying a protein that is already able to be incorporated into the virion to execute a new function is a much smaller evolutionary challenge than a *de novo* strategy that requires simultaneous or successive development of function and its incorporation into virions. Thus, the strategy of adapting functionally flexible structural scaffolds to new purposes can confer a significant selective advantage. Recent catalogs of conserved herpesvirus protein domains illuminate many of the critical steps during evolution of extant herpesviruses,[14,165] and make it clear that core replication and structural proteins are much more highly conserved than proteins involved in interactions with the host.

Some viruses have evolved to rapidly spread new genotypes through the host population, for instance, the reassortment of influenza viruses that leads to rapid global distribution of new strains by birds. This is in marked contrast to herpesviruses such as KSHV that have been relatively stable in their hosts over a time course that corresponds to the global radiation of humans from our African origins.[55] VZV is another genetically stable herpesviruses that has

geographically linked genotype distributions.

In summary, herpesviruses are well adapted to their hosts. In the natural immunocompetent host, fatal infections are rare. From the point of view of virus survival, fatal infections can be counterproductive because they limit opportunities for transmission of virus. This is not always the case when herpesviruses infect a heterologous host, such as the frequently fatal outcomes of infections of cattle with pseudorabies virus of pigs, of humans with simian B virus of macaque monkeys, and the severe malignant catarrhal fever caused by infection of cattle and bison with Ovine γHV 2, a virus that is a relatively benign inhabitant of sheep, its natural host. Thus, in addition to adaptation to specific cellular niches, core lytic replication genes and accessory genes undergo positive selection for temperance properties that enable them to strike a more optimal balance between virus growth in the host and avoidance and stimulation of host responses.[98] By doing so, herpesviruses have persisted in organismal populations of over a remarkable evolutionary timescale.

THE WAY FORWARD

This chapter is intended to introduce the reader to the fascinating world of herpesvirus biology. Coevolution of multiple herpesvirus species adapted to individual species within Kingdom *Animalia* (nine distinct human herpesviruses) demonstrates their evolved success as pathogens. The herpesvirus strategy that links latency and intermittent mild reactivations to enable infection of most members of their host population makes “herpes is forever” a reality for the foreseeable future. Nonetheless, the international community of herpesvirologists is active and engaged, and on the cusp of breakthroughs on many fronts. Decades of vigorous investigation have led to development of a robust data-driven conceptual foundation regarding virion structure and morphogenesis, viral gene functions, regulation of gene expression, and virus–host interactions. The work is not finished. Unbiased and progressively deeper “-omics” approaches will enable understanding of how viral gene products reprogram host metabolism, transcriptomes, and proteomes to meet the needs of the viruses. Single cell analyses suggest that the viruses likely evolved to embrace the stochastic nature of the biology that shapes infection outcomes. Whole genome sequencing of clinical isolates has illuminated responses of the viruses to transmission bottlenecks, antiviral therapy, and immune responses, and enabled identification of nucleotide polymorphisms that influence the functions of viral gene products and ultimately disease outcomes. Understanding the large and complex datasets produced by many newer technologies requires application of quantitative systems biology approaches to enable integration of the multidisciplinary advances in structural biology, molecular biology, cell biology, cancer biology, immunobiology, epidemiology, synthetic chemistry, and computational biology. Immortalized cell lines have long offered ease of manipulation, reproducibility and permissivity for infection, but increased use of primary cells, organoids, tissues from the infected host, and animal models will be needed to develop a more physiologically relevant understanding of virus biology. Together, these approaches will enable identification of key points in latent and lytic infection processes that can be targeted by small molecule inhibitors. Advances in our understanding of virus immunobiology will hopefully enable development of vaccines that can prevent herpesvirus-associated disease, including virus-associated cancers. Subsequent chapters explore

in much greater specificity and detail the unique features and strategies of the herpesviruses of humans and their close relatives that have enabled their success on an evolutionary timescale.

"It is important to go into work you would like to do. Then it doesn't seem like work. You sometimes feel it's almost too good to be true that someone will pay you for enjoying yourself. I've been very fortunate that my work led to useful drugs for a variety of serious illnesses. The thrill of seeing people get well who might otherwise have died of diseases like leukemia, kidney failure, and herpes virus encephalitis cannot be described in words."

Gertrude B. Elion

1988 Nobel Laureate in Physiology

Developed the first successful antiviral drug, acyclovir, to treat herpes simplex virus infection.

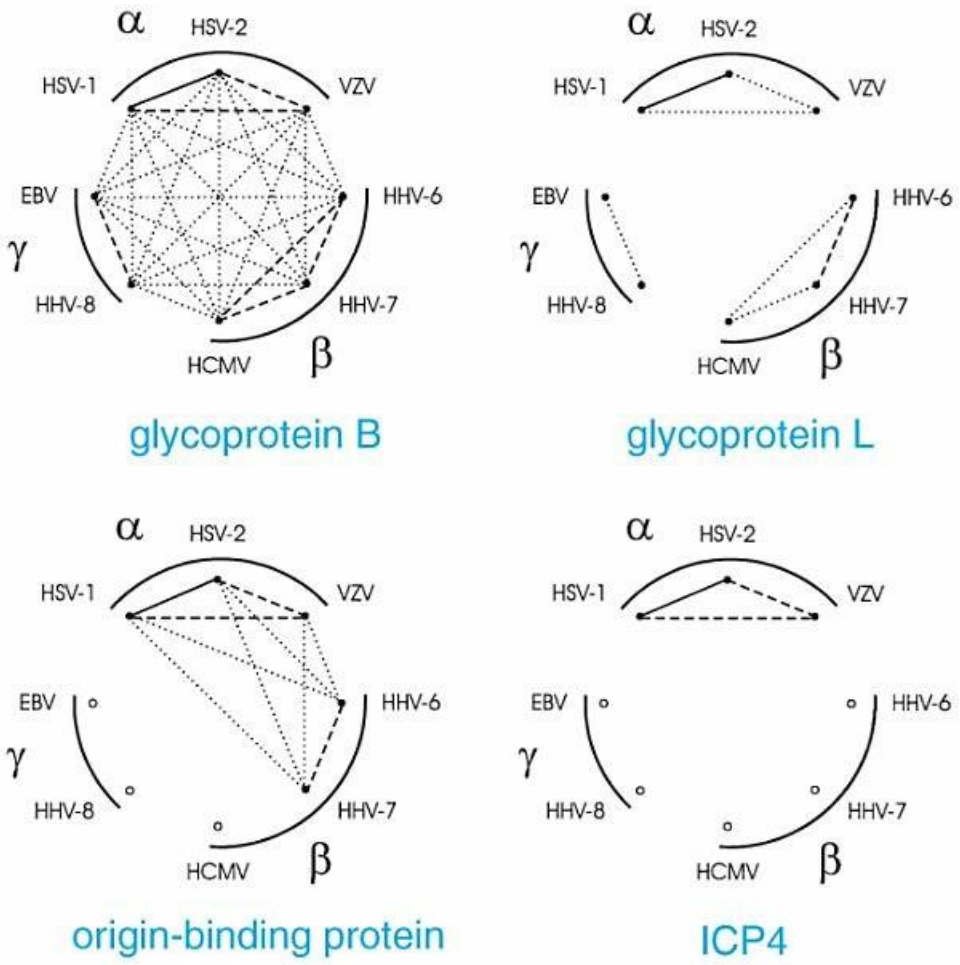
CHAPTER 8

The Family Herpesviridae: A Brief Introduction



e-FIGURE 8.1 Herpesvirus genome architecture. Schematic diagram of the sequence arrangements of the six classes of genomes of the viruses constituting the family *Herpesviridae*. The diagrams emphasize the presence and location of reiterations of terminal sequences greater than 100 bp. In this scheme, herpesvirus genomes are divided into six groups designated by the letters *A* to *F*. In the genomes of viruses constituting group *A* and exemplified by HHV-6, a large sequence from one terminus is directly repeated at the other terminus. In the group *B* genomes exemplified by herpesvirus saimiri (*Saimiriine γHV 2*), the terminal sequence is directly repeated numerous times at both termini, and furthermore, the number of reiterations at the termini may vary. In the group *C* genomes exemplified by EBV, the number of direct terminal reiterations is smaller. In addition, group *C* genomes can harbor other direct sequence arrays that subdivide the unique (or quasi-unique) sequences of the genome into several well-delineated stretches. In group *D* genomes exemplified by VZV, the sequence from one terminus is repeated in an inverted orientation internally. In these genomes, the domain consisting of the stretch of unique sequences flanked by inverted repeats (Small or S component) can invert relative to the remaining sequences (Large or L component) such that the DNA extracted from virions or infected cells consists of two equimolar populations differing solely in the orientation of the S component relative to the L component. The termini of group *E* (e.g., HSV and HCMV) consist of two elements. One terminus contains **n** copies of sequence **a** next to a larger sequence designated as **b**. The other terminus has one directly repeated **a** sequence next to a sequence designated as **c**. The terminal **ab** and **ca** sequences are present in an inverted orientation (denoted by primes) at the junction between the unique long (U_L) and unique short (U_S) domains. The long and short components can invert relative to each other, and DNA extracted from virions or infected cells consists of four equimolar populations of isomers that differ in the relative orientation of the two components.

Group *F* genomes are exemplified by *Tupaiid βHV 1*; the terminal sequences are not identical and are not repeated either directly or in an inverted orientation. Although the potential of inverted repeat sequences to cause inversions and gene expansion is well appreciated, their role and the advantage they confer to viral replication are not understood. Courtesy of Dr. Bernard Roizman.

e-FIGURE 8.2 Herpesvirus gene arrangements. The three possible reading frames in each direction are indicated as three *gray lines*; panels *A* and *D* show both strands, while panels *B, C, E, and F* show only one strand (similar events can take place from

both strands). R, regulatory element; T, TATA box. (Copyright Laurie Krug and Philip Pellett.)

e-FIGURE 8.3 Patterns of gene conservation among the human herpesviruses. Viruses encoding the protein are indicated by the *filled dots; empty dots* indicate viruses that do not encode the protein. Degrees of similarity are indicated by the lines connecting the viruses; *solid, dashed, and dotted lines* represent greater than 70%, 40% to 70%, and less than 40% identity, respectively. Glycoprotein B is highly conserved and is represented in all of the viruses; glycoprotein L is conserved within subfamilies; the origin-binding protein is conserved among the alphaherpesviruses and a subset of betaherpesviruses; ICP4 is found only in the alphaherpesviruses. The HHV-6A and HHV-6B counterparts of these proteins are highly related to each other and have similar distances to the other viruses; thus they are represented here as a single entity, HHV-6.

e-TABLE 8.1 Human herpesviruses: epidemiology, disease associations, and cell tropisms

Virus[a]	Age of Primary Infection	Prevalence in adults (%)	Disease Manifestations				Cell Associations	
			Acute Infection	Reactivation	Chronic Infection	Immunocompromised Patients	Primary Infection	Chronic Infection
Alphaherpesviruses								
HSV-1	50% by third decade	~75%–90% by fifth decade	Typical: subclinical or oral lesions; rare: neonatal infections, encephalitis, meningitis		Sporadic reactivation, increased with stress	Large, slow to heal lesions, disseminated infections	Skin, epithelial cells	Sensory neurons of trigeminal ganglia
HSV-2	after sexual activity	~15%–40%, generally females>males	Typical: subclinical or genital lesions; rare: neonatal infections, meningitis, encephalitis		Sporadic reactivation	Large, slow to heal lesions, disseminated infections	Skin, epithelial cells	Neurons of lumbosacral, dorsal root ganglia
VZV	6 mos to adolescence if not vaccinated	>95% in unvaccinated	Varicella (chicken pox)	Herpes zoster (shingles), postherpetic neuralgia	Sporadic reactivation in unvaccinated, increased with stress	Severe shingles	Skin, epithelial cells	Cells of trigeminal and dorsal root ganglia
Betaherpesviruses								
HCMV	~40%–50% by 12 years	>80% by sixth decade	Congenital disease, 5% of infectious mononucleosis		Increased risk for cardiovascular disease	CMV disease, gastrointestinal disease, retinitis	Endothelial cells, epithelial cells, fibroblasts, and smooth muscle cells	CD34+ progenitor cells monocytes, macrophage cells
HHV-6A	Subsequent to HHV-6B, germ-line chromosomal integration in ~1% population	<50%; perhaps more common in sub-Saharan Africa	Typical: asymptomatic; rare: subset of exanthema subitum	Excision of chromosomally integrated genome?		Cofactor for CMV disease and graft versus host disease (GVHD)	CD4+ T cells	CD4+ T cells, neurotropic
HHV-6B	50% by 2 years, germ-line chromosomal integration in ~1% population	~95%	Typical: exanthema subitum; rare: neurological sequelae	Excision of chromosomally integrated genome?		Most frequent cause of encephalitis following allogeneic transplants; cofactor for CMV disease and GHVD	CD4+ T cells	CD4+ T cells, neurotropic
HHV-7	By 3 years	>95%	Rare: subset of exanthema subitum, febrile status epilepticus			Cofactor for CMV disease	CD4+ T cells	CD4+ T cells, macrophages
Gammaherpesviruses								
EBV	Typically by 20 years	~90%–95%	~50% adolescents present as infectious mononucleosis		Burkitt lymphoma, Hodgkin lymphoma, nasopharyngeal carcinoma, ~10% of gastric carcinoma	HIV-associated B-cell lymphomas and oral hairy leukoplakia; posttransplant lymphoproliferative disorder; chronic active EBV	Oropharyngeal epithelium, B cells	Typical: B cells; less frequent: T cells and NK cells
KSHV	After sexual activity, childhood in endemic areas	Typically <5%, 10%–40% in endemic areas or HIV+ men who have sex with men populations	Children: fever and maculopapular rash; adults: lymphadenopathy		Classic and endemic Kaposi sarcoma	Kaposi sarcoma, primary effusion lymphoma, multicentric Castleman disease (variant), KSHV inflammatory cytokine syndrome	Oral epithelium, B cells	B cells, endothelial cells

[a]Herpes simplex virus 1 (HSV-1); herpes simplex virus 2 (HSV-2); varicella–zoster virus (VZV); human cytomegalovirus (HCMV); human herpesvirus 6A (HHV-6A), human herpesvirus 6B (HHV-6B); human herpesvirus 7 (HHV-7); Epstein-Barr virus (EBV); Kaposi sarcoma herpesvirus (KSHV).

e-TABLE 8.2 Herpesvirus glossary

alpha (α) gene (syn. immediate early [IE] gene): A herpesvirus gene that can be transcribed in the absence of *de novo* protein synthesis. Alpha genes are the first viral genes to be transcribed in newly infected cells and have regulatory functions.

Alphaherpesvirinae: The alphaherpesvirus subfamily of the *Herpesviridae*.

alphaherpesvirus: A member of the *Alphaherpesvirinae*.

beta (β) gene (syn. early gene): A herpesvirus gene whose transcription is dependent on prior expression of one or more alpha genes and can be transcribed in the absence of viral DNA synthesis. Many beta genes are involved in the process of viral DNA replication.

Betaherpesvirinae: The betaherpesvirus subfamily of the *Herpesviridae*.

betaherpesvirus: A member of the *Betaherpesvirinae*.

capsid: The virion substructure structure that houses the virus genome. Capsids consist of 162 capsomeric subunits that are interconnected by 320 capsid triplexes, each consisting of two copies of one triplex protein and one copy of the other.

capsomere: One of the major structural and morphological subunits of herpesvirus capsids. Capsids contain 161 capsomeres, 150 of which are hexameric complexes (hexons) in which each hexon consists of six copies each of the major and minor capsid proteins, and 11 of which are pentamers of the major capsid protein (pentons). The twelfth pentonal position is occupied by a capsomeric structure that includes six copies of the portal protein.

early gene: See beta gene.

envelope: Lipid bilayer studded with glycoproteins and integral membrane proteins that surrounds and encases other parts of the virion. Most of the envelope proteins are encoded by the virus, but a fraction of unknown significance are of host origin. The membrane of infectious virions is derived from the membrane of the cellular organelle where the virus is enveloped.

G+C content: The fraction of the genome, or subgenomic segment such as the terminal repeat, that is composed of G or C residues; generally expressed as a percentage.

glycoprotein B: An abundant viral glycoprotein that is conserved across the *Herpesviridae* and mediates fusion of the virion envelope with the cellular membrane during virus entry. gB has structural features in common with membrane fusion proteins specified by some other viruses.

gamma (γ) gene (syn. late (L) gene): A herpesvirus gene whose transcription is dependent on viral DNA replication. Genes that are transcribed at low levels in the absence of viral DNA synthesis and at high levels after initiation of viral DNA synthesis are referred to as beta-gamma (βγ) or early-late genes. Genes not transcribed in the absence of viral DNA replication are referred to as true gamma or true late genes.

Gammaherpesvirinae: The gammaherpesvirus subfamily of the *Herpesviridae*.

gammaherpesvirus: A member of the *Gammaherpesvirinae*.

hexon: Six-sided capsomere. Consists of six copies of the major capsid protein and six copies of the small capsid protein.

immediate early (IE) gene: See alpha gene.

inversion: A circumstance where a large segment of a herpesvirus genome has rearranged so that its genetic orientation is in the opposite orientation. In group D genomes, one genome segment can invert relative to the other, resulting in two genomic isomers. In group E genomes, the genome consists of two segments that can each invert relative to the other, resulting in four genomic isomers.

inverted repeats: Segments of herpesvirus genomes that are duplicated, with one copy being present as a reverse complement of the other. Inverted repeats are present at the termini of genomic segments that are capable of inversion.

LAT: Latency associated transcript.

late (L) gene: See gamma gene.

latency: At the cellular level, herpesvirus latency is a state where the virus genome is present but genes necessary for production of infectious virions are not expressed. In response to appropriate signals, the virus can be reactivated from latency to the lytic state. At the organismal level, latency can also refer to the period between infection and the appearance of disease (clinical latency).

latency associated transcript (LAT): A viral transcript that is expressed during latency.

major capsid protein (MCP): The major constituent of capsomeres; can form homo-pentamers and homo-hexamers.

non-coding RNA (ncRNA): A class of viral RNAs transcribed with no known protein-coding capacity. This includes long non-coding RNAs (lncRNAs), miRNAs, circular RNAs (cRNA), and tRNA-like molecules. Broadly, this class of transcripts has regulatory properties that can impact viral and host gene expression.

nucleocapsid: A capsid that has been filled with a unit-length virus genome and then capped.

PAC sequence: Packaging and cleavage sequence. PAC sequences provide the cis-acting signals that regulate packaging of nascent herpesvirus genomes into nuclear capsids, and guide the site-specific cleavage of concatemeric genomes into packaged monomers. Portions of incomplete PAC sequences are present at the termini of herpesvirus genomes. Genome circularization or concatemerization is required for formation of complete and functional PAC sequences.

penton: Five-sided capsomere. Consists of five copies of the major capsid protein.

portal: Specialized capsomere through which the virus genome is packaged following viral DNA replication. At the initiation of new infections, after docking at nuclear pores, the genome is ejected through the portal to deliver the genome to the interior of the nucleus.

primary infection: The initial infectious exposure of a host organism to the virus. Occurs in the absence of preexisting adaptive cellular immunity, but may occur in the presence of maternal antibody against the virus.

reactivation: Resumption of lytic infection from the latent state, sometimes resulting in symptomatic disease.

recurrent infection: Clinically apparent reactivations that occur over a period of time.

***T* = 16:** The capsid triangulation number shared by all herpesviruses.

tegument: The portion of herpesvirus virions that occupies the space between the envelope and the nucleocapsid. The major constituent of teguments is virally encoded proteins, but teguments also house some RNAs and some proteins of host origin. Tegument proteins are released into the cytoplasm immediately after fusion of the virion envelope with plasma or endocytic vesicle membranes. Many tegument proteins regulate host responses to infection, creating a stabilized environment that is conducive to lytic replication.

terminal repeat: A segment of DNA that is present in two copies, one at one end of the virus genome and the other elsewhere on the genome.

unique (U) segment: A segment of the virus genome that is uniquely represented on the viral genome. That is, it does not contain large repeats or numerous iterations of smaller repeat elements.

unique long (UL) segment: The longer unique genomic segment of Class D and Class E herpesvirus genomes.

unique short (US) segment: The shorter unique genomic segment of Class D and Class E herpesvirus genomes.

virion: The complete herpesvirus particle, consisting of one copy of the virus genome packaged into a nucleocapsid that is surrounded by tegument proteins, all contained in the envelope.

CHAPTER 9

Herpes Simplex Viruses: Mechanisms of Lytic and Latent Infection

David M. Knipe • Ekaterina E. Heldwein • Ian J. Mohr • Catherine N. Sodroski

Introduction
Virion structure
- Virion proteins
- Core
- Capsid
- Tegument
- Envelope

Structure and sequence arrangement of viral DNA
- Genetic organization of HSV genomes
- Genetic techniques for the manipulation of the viral genome

Viral replication
- Overview of HSV replication
- Entry of HSV
- Gene expression in HSV-infected cells
- Viral DNA replication
- Viral nucleocapsid assembly
- Viral egress

Intrinsic immunity, innate immunity, and anti-antiviral defenses
- Overview
- Receptors at the plasma membrane and endosomes
- Cytoplasmic sensing of viral PAMPS
- RNA sensors in the cytosol
- Nuclear defenses
- Evasion and blunting the interferon response
- Catabolic physiological stress responses
- Autophagy
- Programmed cell death

Latent infection
- Overview
- Experimental systems for the study of HSV latent infection
- Description of the latent infection state of HSV

Perspectives

INTRODUCTION

The herpes simplex viruses, herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2), are common human viruses that replicate productively in mucosal epithelium and spread to establish a latent infection in sensory neurons. HSV-1 often infects the oral mucosa and then spreads to the trigeminal ganglia where it establishes a latent infection in sensory neurons. Reactivation of the virus can lead to shedding and recurrent lesions called cold sores or fever blisters. HSV-2 often infects the genital mucosa and spreads to sensory neurons in sacral ganglia to establish a latent infection. Reactivation of the virus leads to recurrent disease and genital herpes. Importantly, HSV-1 infection can also lead to encephalitis, keratitis, and blindness as well as genital herpes, while HSV-2 infection can cause genital herpes, neonatal herpes, and meningitis and is associated with increased human immunodeficiency virus 1 acquisition and transmission (see Chapter 10).

HSV-1 and HSV-2 are two species with formal names of human herpes virus 1 (HHV-1) and human herpes virus 2 (HHV-2). They are classified within the *Simplexvirus* genus in the *Alphaherpesvirinae* subfamily in the *Herpesviridae* family in the *Herpesvirales* order (Chapter 8). These two viruses are sometimes called type 1 and type 2, but they are formally species, so the word “type” is not technically correct. Many of the genetic and phenotypic properties of HSV-1 and HSV-2 are similar, so we will describe them together as HSV where genes and mechanisms are shared by the two viruses.

They share with the other herpesviruses a common virion structure comprising a double-stranded DNA genome within a core in an icosahedral capsid surrounded by an unstructured layer, the tegument, surrounded by a lipid bilayer envelope containing glycoproteins. They also share certain replication and structural proteins with the other herpesviruses, and the ability to establish a latent infection in certain infected cells. Like the other alphaherpesviruses, the HSVs establish a latent infection in sensory neurons. Their ability to undergo lytic infection in one cell type and latent infection in another cell type is one of their most intriguing and novel biological features.

Study of the herpes simplex viruses is important to understand their mechanisms of pathogenesis and latent infection and for the design of prophylactic and therapeutic antivirals and vaccines against them. This basic knowledge is essential to understand the human biology of the virus, as described in Chapter 10. HSV-1 has been the prototype for the study of lytic infection mechanisms by herpesviruses. In addition, the study of the molecular and cellular biology of HSV-1 has illuminated many aspects of human cell and molecular biology. This legacy includes identifying the basic structure of a mammalian cell promoter—the thymidine kinase promoter, nucleoside analogs as inhibitors of DNA polymerases, structures and mechanisms of action of fusogenic proteins, mechanisms of sensing of foreign viral DNA, mechanisms of latent infection by a DNA virus, mechanisms of epigenetic regulation of DNA virus gene expression and infection, critical regulatory events in translation, and mechanisms of innate recognition and evasion.

This chapter will review the basic cellular and molecular mechanisms of HSV lytic and latent infection, their interactions with host cells, how the host cells respond to combat the virus, and the implications of this knowledge for basic cellular biology. Space limitations prevent us

from comprehensively covering the large literature on HSV, and we apologize in advance for not being able to cite all of the many rigorous papers on HSV. Therefore, we have cited mostly new references since 2008 as well as selected classical references. Additional reading can be found in the Supplement in the eBook and the HSV chapter in the sixth edition of Fields Virology.[395]

VIRION STRUCTURE

The HSV virion consists of four elements: (a) an electron-opaque core containing the viral DNA, (b) an icosahedral capsid surrounding the core, (c) a largely unstructured proteinaceous layer called the tegument that surrounds the capsid, and (d) an outer lipid bilayer envelope exhibiting spikes on its surface (Fig. 9.1A). Early studies defined the structure of the HSV virion through electron microscopy and biochemical analysis of the virion components. More recent cryo-electron microscopy studies have defined the nucleocapsid structure of HSV-1 and HSV-2 to approximately 3 Angstrom resolution,[99,497,536] described in detail below. The most detailed analysis of the whole HSV-1 virions used cryo-electron tomography to define its structure to 7-nm resolution (Fig. 9.1B and C[160]). This study defined the HSV-1 virion as a spherical particle with an average diameter of approximately 225 nm, with glycoprotein spikes included in the measurement. The nucleocapsid is displaced from the virion center, however, such that it is close to the envelope at one pole, termed proximal, and is 30 to 35 nm away from the envelope at the other pole, termed distal. Single-particle fluorescence measurements of pseudorabies virus, a related alpha-herpesvirus, containing fluorescently tagged proteins confirmed the eccentric positioning of the capsid.[44] Such an asymmetric arrangement may be specific to alpha-herpesviruses because in virions of beta- or gamma-herpesviruses, capsids are positioned closer to the center.[98,534] The tegument, which lacks any regular structure, fills the space between the nucleocapsid and the envelope, forming a "cap."[160] The glycoprotein spike distribution is likewise asymmetric, with more spikes located at the tegument-rich distal pole than the tegument-poor proximal pole.[160] The pronounced asymmetry of the virions has been proposed to arise from the mechanism of tegument assembly, which appears to initiate at the distal pole. This virion asymmetry could be functionally important because during entry, the incoming virions contact the cell at the proximal pole, which is sparsely populated with glycoprotein spikes.[306]

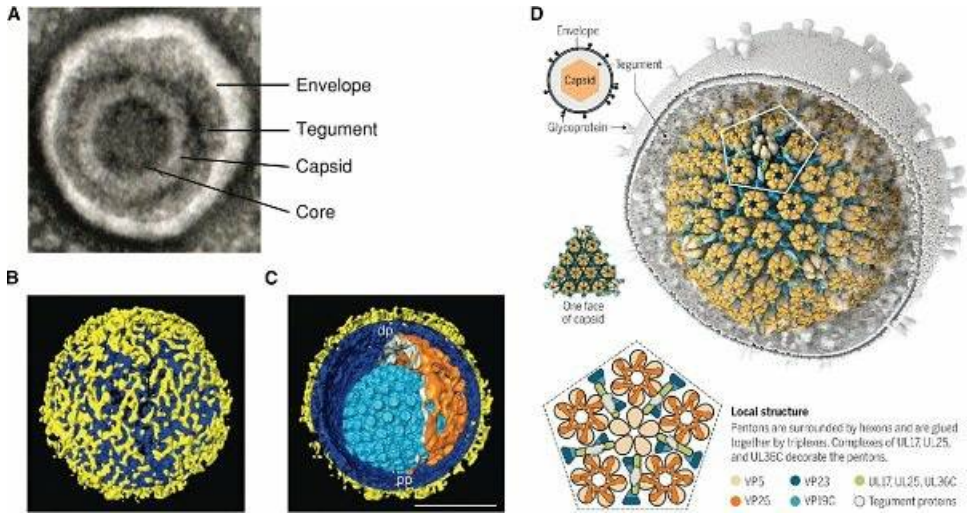

FIGURE 9.1 Structure of the herpes simplex virus (HSV) virion. A: Electron micrograph of a negative-stained HSV-1 virion. The envelope, tegument, capsid, and core are indicated. (Micrograph is provided by Travis Taylor) **B:** Surface image of HSV-1 derived from cryo-electron tomography.[160] The glycoprotein spikes are *yellow*, and the membrane is *blue*. **C:** Cutaway view of the virion interior derived from cryo-electron tomography. Capsid is shown in *light blue*, the tegument is shown in *orange*, membrane is *blue*, and the glycoprotein spikes are *yellow*. (Parts **B** and **C** are courtesy of Alasdair C. Steven) **D:** Schematic view of the HSV-1 capsid structure determined by cryogenic electron microscopy. The capsid is an icosahedron with 20 faces and 12 vertices. The outer shell is composed of four proteins that form pentons, hexons, and triplexes. Three additional proteins form complexes that decorate the vertices. (From Heldwein EE. Up close with herpesviruses. *Science* 2018;360(6384):34–35. Reprinted with permission from AAAS.)

Virion Proteins

Early studies on purified HSV-1 virions suggested that they contain more than 30 distinct proteins, which were designated as virion polypeptides (VP) and numbered sequentially from the top of the gel. HSV proteins have been named based on serial numbering of the virion proteins on a gel (e.g., VP1/2), on the open reading frame encoding them, for example, UL8, or as infected cell proteins, for example, ICP5. Mass spectrometry analysis of purified extracellular HSV-1 virions has detected 44 viral proteins and 49 host proteins.[286] Depletion of several host proteins from mature virions reduces viral replication.[444] Virions are heterogeneous both in composition[44] and structure.[44,160]

Core

The core contains the double-stranded (ds) DNA genome packaged within the capsid as a left-handed spool that is arranged in concentric shells, as revealed by cryo-EM reconstructions.[308] The viral DNA genome is tightly packaged and generates internal pressure of tens of atmospheres,[36] which is capable of driving ejection of the entire viral genome into the nucleus

upon capsid docking to a nuclear pore complex.[436] The genome is tightly packaged such that it adopts a liquid crystalline state[46] with restricted mobility but becomes more fluid at physiological temperatures,[402] which should facilitate its ejection from the capsid. The viral DNA genome is described in detail below.

The core does not contain highly basic proteins, such as histones, that would neutralize the negative charges on viral DNA thereby minimizing the repulsive forces within the capsid. However, highly purified virions do contain the polyamines spermidine and spermine in a nearly constant ratio of 1.6 ± 0.2:1 or approximately 70,000 molecules of spermidine and 40,000 molecules of spermine per virion.[152] The spermine contained in the virion is sufficient to neutralize approximately 40% of the DNA phosphate.[152]

Capsid

Early cryo-EM studies have established that the HSV capsid is approximately 125 nm in diameter, with icosahedral T = 16 symmetry. The capsid is composed of 150 hexameric blocks (hexons), 11 pentameric blocks (pentons), and 1 portal. Both hexons and pentons are formed by VP5 (encoded by the U_L19 gene), the major capsid protein. Each hexon is also decorated with a hexameric ring composed of VP26 (U_L35), the small capsid protein. Instead of a 12th penton, there is a portal composed of 12 copies of the protein UL6,[282,308] through which viral DNA is packaged and, presumably, released. Linking together these hexons and pentons are 320 triplexes, heterotrimers of two copies of VP23 (U_L18) and one copy of VP19C (U_L38). Each vertex is further decorated with two additional proteins, UL25 and UL17, which are essential for reinforcing the capsid[433] so that it can withstand several atmospheres of pressure generated by the large genomes without bursting apart. UL25 and UL17 bind the C terminus of the tegument protein UL36, which anchors the tegument layer (described in detail below) to the capsid. Finally, the capsid also contains VP24 (U_L26),[286,298] the protease that cleaves the scaffold during capsid maturation and DNA encapsidation. Recent cryo-EM reconstructions of HSV-1 and HSV-2 capsids at approximately 3 Angstrom resolution (Fig. 9.1D)[99,497,536] showed extensive noncovalent and covalent interactions, particularly the disulfide bonds, that link nearly 3,000 protein copies in the capsid. These high-resolution studies have also revealed significant conformational diversity, especially in VP5, that likely ensures optimal interactions.

Tegument

The space between the capsid shell and the lipid envelope is occupied by the tegument layer unique to herpesviruses. The tegument includes up to 24 distinct virally encoded proteins (see Supplement Table 9.1 Gene List),[286,351] in addition to several host proteins.[444] The tegument has been traditionally subdivided into the inner and outer tegument.[18] The inner tegument, composed of UL36 and UL37, is directly associated with the capsid, and protein copy numbers are tightly controlled.[44,127] The outer tegument is largely unstructured and associates with the viral envelope instead of the capsid through interactions between tegument proteins and the intraviral, also referred to as cytoplasmic, tails of the envelope glycoproteins. The tegument layer is stabilized by extensive protein–protein interactions and is largely structurally maintained even if the viral membrane is removed. Some outer tegument proteins remain associated with the capsid under conditions that supposedly strip away most of the outer tegument,[44] so the boundary

between inner and outer tegument may not be so clear-cut.

In addition to linking the capsid to the lipid envelope, tegument proteins play other roles during viral infection. Among the best characterized tegument proteins are UL48, also known as VP16, which activates transcription of immediate-early viral genes; the virion host shut-off (vhs) protein (encoded by the *U_L41* ORF), an endonuclease that suppresses host protein expression by degrading mRNA; and UL36, the largest tegument protein (~330 kDa), also known as VP1-2, which is involved in capsid transport,[412] release of viral DNA,[2] inhibition of IFN-β–induced signaling through its ubiquitin-specific protease activity,[535] and a deubiquitinase domain essential for neuroinvasion in pseudorabies virus.[193] Other tegument proteins include UL7, UL11, UL13, UL14, UL16, UL21, UL23, UL37, VP11/12 (*U_L46* gene), VP13/14 (*U_L47*), VP22 (*U_L49*), UL50, UL51, UL55, US2, US3, US10, US11, ICP0, ICP4, and ICP34.5.[286,351] Tegument proteins form an extensive network of interactions that also includes capsid and envelope proteins. Recent analysis of experimentally detected and computationally predicted protein–protein interactions in HSV-1 has expanded this interaction network.[175]

Highly purified HSV-1 virions have been reported to contain cellular and selected viral gene transcripts.[415] HSV-1 virions copurify with exosomes, which contain host and viral mRNAs and miRNAs.[219] Thus, the RNA content of HSV-1 virions needs to be re-examined.

Envelope

The envelope consists of a lipid bilayer with up to 16 distinct virion envelope proteins, of which 12 are glycosylated and 4 nonglycosylated. The virion envelope glycoproteins are gB (encoded by the *U_L27* gene), gC (*U_L44*), gD (*U_S6*), gE (*U_S8*), gG (*U_S4*), gH (*U_L22*), gI (*U_S7*), gJ (*U_S5*), gK (*U_L53*), gL (*U_L1*), gM (*U_L10*), and gN (*U_L49.5*). The presence of all except gJ, gK, and gN has been demonstrated by mass spectrometry of purified extracellular virions.[286] Virion envelopes also contain at least three (*U_L20*, *U_L56*, and *U_S9*)[286] and possibly more (*U_L24* and *U_L43*) nonglycosylated membrane proteins. Envelope protein composition could vary among viral strains or among virions produced in different cell types, which could explain discrepancies in the literature.

It has been assumed that HSV acquires the envelope lipids from its host. The hypothesis that the lipid composition of the viral envelope is determined by the host was supported by the observation that the buoyant density of the virus was host cell dependent on serial passage of HSV-1 alternately in HEp-2 and chick embryo cells.[440] More recent studies[479] suggest that the virion lipids are similar to those of cytoplasmic membranes and different from those of nuclear membranes of uninfected cells.

STRUCTURE AND SEQUENCE ARRANGEMENT OF VIRAL DNA

The bulk of the HSV-1 virion DNA is linear and double-stranded. Some of the ends of the

genomes may be joined or in close proximity inasmuch as a small fraction of the packaged DNA appears to be circular, and the linear DNA circularizes rapidly in the absence of protein synthesis after it enters the nuclei of infected cells. DNA extracted from virions contains ribonucleotides, nicks, and gaps and thus is not super-coiled, as shown on Gardella gels.

The HSV genome can be viewed as consisting of two covalently linked components, designated as L (long) and S (short) (Fig. 9.2A). Each component consists of unique sequences bracketed by inverted repeats.[491] The repeats of the L component, R_L, have been designated as *ab* and *b'a'* (the prime symbol indicating inverted orientation), while those of the S component, R_S, are *a'c'* and *ca* (Fig. 9.2B). The inverted repeats are sometimes labeled TRL (terminal repeat of L) and IRL (internal repeat of L) or TRS (terminal repeat of S) and IRS (internal repeat of S), but these names may be misleading because due to the inversions described below, there are no differences between the terminal and internal inverted repeats. The number of "*a*" sequence repeats at the L–S junction and at the L terminus is variable; thus, the HSV genome as shown in Figure 9.2B can be represented as

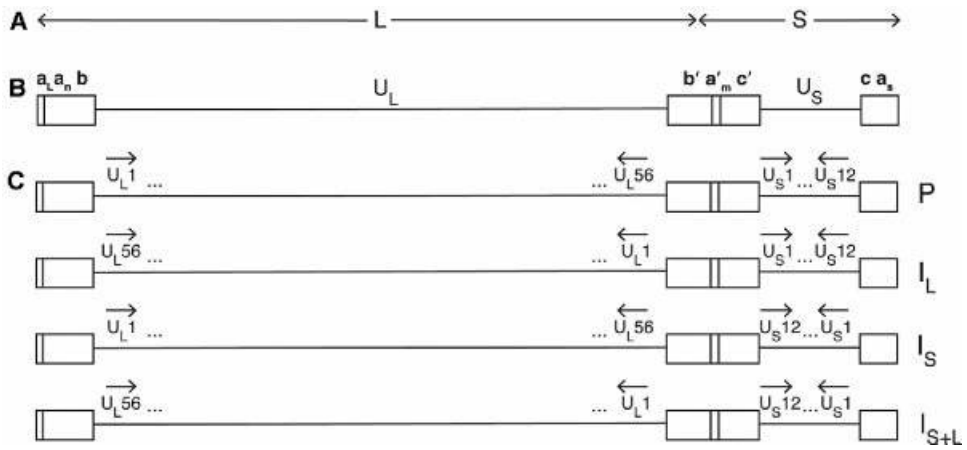

FIGURE 9.2 Schematic representation of the arrangement of DNA sequences in the HSV genome. A: The domains of the L and S components are denoted by the *arrows*. **B:** The line shows the unique sequences (*thin lines*) flanked by the inverted repeats (*boxes*). The letters above the line designate the terminal ***a*** sequence of the L component ($\boldsymbol{a}_L$), a variable (n) number of additional *a* sequences, the ***b*** sequence, the unique sequence of the L component (U_L), the repetitions of the ***b*** sequence and of a variable (m) number of sequences ($\boldsymbol{a}_m$), the inverted ***c*** sequence, the unique sequence of the S component (U_S), and finally the terminal ***a*** sequence ($\boldsymbol{a}_S$) of the S component. **C:** Diagram showing the orientation of the ORFs for the U_L and U_S regions of the genome for the P, I_S, I_L, and I_{SL} isomers of the DNA. The terminal genes of U_L (U_L1 and U_L56) and the terminal genes of U_S (US_1 and U_S12) are shown to denote the orientation. (Copyright, Catherine Sodroski and David Knipe.)

$$a_L a_n \mathrm{b} - \mathrm{U_L} - b' a'_m c' - \mathrm{U_S} - \mathrm{ca_S}$$

where a_L and a_S are terminal copies of the sequences with the unique properties described below, and a_n and a_m are terminal *a* sequences directly repeated 0 or more times (n) or present in one to many copies (m).[491] The overall structure of the *a* sequence is highly conserved, but it consists of a variable number of repeat elements. As an example for one strain, the HSV-1 F strain, the structure of the *a* sequence can be represented as

$$DR1 - U_b - DR2_n - DR4_m - U_c - DR1$$

with DR1 being a 20-bp direct repeat, U_b being a 65-bp unique sequence, DR2 being a 12-bp direct repeat present in 19 to 23 copies per "*a*" sequence, DR4 being a 37-bp direct repeat present in 2 to 3 copies, U_C being a 58-bp unique sequence, and a final copy of DR1. Adjacent "*a*" sequences share an intervening DR1. The size of the *a* sequence varies from strain to strain, reflecting in part the number of copies of DR2 and DR4.[483] Linear virion DNA contains asymmetric terminal *a* sequence ends. The terminal *a* sequence of the L component (a_L) contains a truncated DR1 with 18 bp and one 3′ nucleotide extension, whereas the terminal *a* sequence of the S component (a_S) ends with a DR1 containing only one bp and one 3′ overhanging nucleotide. The two truncated DR1 sequences form a complete DR1 upon circularization.

The L and S components of HSV are found inverted relative to one another, to yield four linear isomers (Fig. 9.2C). Populations of unit-length DNA from HSV-1–infected cells and virions consist of equimolar concentrations of the four predicted isomers. The isomers have been designated as P (prototype), I_L (inversion of the L component), I_S (inversion of the S component), and I_{S+L} (inversion of both S and L components). As a result, restriction endonucleases that cleave outside the inverted repeats yield four terminal fragments, each present in one half of the molecules (also called half molar or 0.5-M fragments), and four L–S component junction fragments that are each present in one-fourth of the molecules (also called quarter molar or 0.25-M fragments).[395]

Genetic studies showed that changes inserted into the S repeat "*b*" sequence are rapidly duplicated in the other copy of the repeat, arguing that a mechanism exists for copying one repeat into the other.[104,238,392] This was also later observed for the L component "*c*" repeats, when insertion of a deletion mutation in the *ICP0* (R_L2) gene was found in both repeats.

The internal inverted repeat sequences are not essential for growth of the virus in cell culture, as evidenced by the isolation of mutant viruses in which portions of the unique sequences and most of the internal inverted repeats have been deleted that have been obtained in all four arrangements of HSV DNA. The genomes of these mutants are frozen in one arrangement of the L and S components and do not invert, but all retain their viability in cell culture.

Biochemical studies originally estimated the genome to be approximately 150 kilobase pairs (kbp), with a G+C content of 68% for HSV-1 and 69% for HSV-2, and electron microscopic analysis demonstrated the internal inverted repeats and terminal direct repeats.[395] The first complete genomic sequence for HSV-1 was completed using conventional sequencing for the HSV-1 laboratory strain 17 genome in 1988, and this described the genome as 152,260 bp and 68.3% G+C[309] (GenBank sequence accession number NC_001806), and minor updates altered this sequence to 152,261 bp. This genomic sequence confirmed that there are inverted sequences of approximately 9 kbp bounding the unique L sequences and inverted sequences of

approximately 6.2 kbp bounding the unique S sequences. The full genomic numbers were approximate, because the genomic numbers included only single copies of the *a* sequence at the ends of the L component and did not take into account the variation in the size of the *a* sequences (200 to 500 bp each) or the variable number of direct repeats present throughout the genome but especially in the inverted repeats flanking the L and S components.

Illumina high-throughput sequencing further defined the genomic sequence of two HSV-1 viruses, the F laboratory strain and the H129 clinical isolate.[454] This analysis defined the unique and single copies of the repeated sequences of the genomes and based the numbers of repeats on the strain 17 prototype genome. Comparison of the three sequences showed a limited amount of sequence diversity, less than 0.7%, between any pairs of the viruses.[454]

Next-generation sequencing of 20 additional HSV-1 genomes from around the world showed that there was limited variability between strains, the mean pairwise identity being 96.8%.[453] There was evidence of extensive recombination and evidence of as many as four geographical clusters.[453] One North American isolate, KOS, clustered with the Asian isolates[453] and seemed to be an outlier, but there has been speculation that the American source of the isolate, K.O. Smith, may have acquired this virus while serving in Asia during the Korean War.[159]

The first complete genomic sequence for HSV-2 was published for the HSV-2 HG52 laboratory strain in 1998, which defined it as 154,746 bp and 70.4% G+C[113] (GenBank sequence accession number NC_001798), and it has served as the reference genome for HSV-2. The original Sanger sequence of HSV-2 HG52 contains some errors, but these were corrected by Illumina sequencing (GenBank accession number JN561323). The complete genome of the first low-passage HSV-2 isolate, SD90e, was published in 2014.[84] Comparison of the HG52 and SD90e genomes showed only a limited number of small indels,[84] consistent with the conclusion that laboratory-passaged HSV-2 strains have not diverged substantially from primary isolates.

The HSV-1 and HSV-2 genomes are colinear and highly similar[113] with the major difference being the size of the U_S4 gene encoding glycoprotein G (gG). Based on the comparison of these initial genome sequences, the HSV-1 and HSV-2 genomes were estimated to have diverged 6.6 million years ago. However, it was later observed that the HSV-2 genome is most highly related to chimpanzee alphaherpesvirus, which suggested that HSV-2 was derived from CHV or another herpesvirus progenitor and jumped to humans in a second event.[513]

Next-generation sequencing of 34 HSV-2 low passage and lab strains showed limited diversity, less than 0.4% nucleotide diversity between any two viral genomes,[335] less than HSV-1 as described above, consistent with the hypothesized more recent divergence of HSV-2 from the chimpanzee alphaherpesvirus.[513] The limited divergence allowed only a weak geographical clustering of the HSV-2 genomes in this study,[335] but a unique sequence signature was observed in the U_S4 gene encoding glycoprotein G (gG) of certain African isolates.[259] gG is used for ELISA tests to detect HSV-1– and HSV-2–specific antibodies; therefore, this altered gG sequence in African isolates might explain the decreased sensitivity of the gG2-based ELISA test in African populations. Further sequencing studies showed no geographical clustering[210,241] or at most two lineages, one from South African isolates and one that is worldwide.[53]

Genetic Organization of HSV Genomes

HSV DNA encodes at least 84 transcriptional units that encode proteins, as well as additional noncoding RNAs. The HSV-1 and HSV-2 genomic sequences and gene maps are available through the NIAID Virus Pathogen Database and Analysis Resource (ViPR) (https://www.viprbrc.org/brc/viprStrainDetails.spg?ncbiAccession=KT899744&decorator=herpes&context=1575390364537). As described in more detail below, these genes are classified into at least four general kinetic classes, immediate-early (IE), early (E), early/late (E/L), and late (L) genes. The HSV genes are distributed largely in separate, nonoverlapping transcriptional units, although there are some in overlapping transcriptional units and antisense transcripts (Supplementary Fig. 9.1). The canonical genes, largely defined by genome sequencing definition of open reading frames and classical RNA mapping techniques, are mapped in Supplementary Figure 9.1 and listed in Supplementary Table 9.1. The genes are numbered from left to right in each region of the genome on the prototype (P) isomer of the viral genome (Fig. 9.2C). Some genes are located in the unique region of the L component or the U_L genes. Some are in the unique region of the S component or the U_S genes, some are in the inverted repeats bounding the L component or R_L genes, and some are in the S repeats, the R_S genes. The IE genes tend to map near the termini of the L and S repeats, while the E and L genes are scattered with the U_L and U_S regions of the genome.

Recent genomic approaches have mapped additional transcripts and ORFs on the viral genome (e.g., see[45,515] and the HSV-1 genomic viewer (https://zenodo.org/record/3465873). Further studies will be needed to provide functional validation of the new transcripts and genes.

Genetic Techniques for the Manipulation of the Viral Genome

The various genetic techniques used for analysis of HSV have been described in detail previously[394]; therefore, we will review this area only briefly. Two general methods remain as the major approaches for manipulation of the HSV genomes for genetic studies, for construction of viral mutant strains for viral vectors and vaccines, and for construction of oncolytic viruses. First, genetic alterations can be introduced into the viral genome by homologous recombination following cotransfection of infectious viral DNA with a viral DNA fragment that contains a marker or mutation to be introduced into the viral genome by a double-crossover event.[238] The progeny virus can then be screened or imposed to a selection to get the correct phenotype. Although this approach can be inefficient, CRISPR/Cas9 has been used recently to promote recombination and select for the desired recombinant viruses, such that the progeny from the initial transfection can be pure recombinants.[340]

The second major technique is based on the use of bacterial artificial chromosomes (BACs) to propagate the viral genome in bacterial cells. Mutations can be introduced into the HSV sequences in the BAC, and transfection of the recombinant BAC into mammalian cells yields infectious virus.[188] The genomes cloned as bacterial accessory chromosomes are also amenable to random insertional mutagenesis by transposons.

It should be emphasized that the procedures for generating site-specific mutations, including transfection of viral DNA into mammalian cells, can introduce unintended mutations at distant sites. The obvious and necessary control is to restore the original sequence and then compare parent, mutant, and rescued virus for the predicted phenotype of the mutation. Genomic sequencing can then confirm the sequence changes between the parental wild-type virus, the

recombinant mutant virus, and the rescued virus to precisely pinpoint the genetic changes responsible for the altered phenotype. Alternatively, the use of two independent isolates of a mutant that confirm the phenotype is another rigorous approach to rule out secondary mutations.

Viral mutants or recombinants are tested for the essentiality of the gene(s) that have been altered by measuring plaque formation or yields on a given cell line. The essential or nonessential nature of the HSV-1 genes is listed for each ORF in Supplementary Table 9.1. Genes dispensable for viral replication in cells in culture fall into several groups whose products are involved in entry of HSV into specific cells, regulation of gene expression in specific cells, posttranslational modification of proteins, exocytosis, inhibition of host response to infection, and spread of virus from cell to cell. Genes may also be nonessential because host functions can substitute for the viral gene function in certain cell types. For example, the viral thymidine kinase and ribonucleotide reductase can be substituted by cellular enzymes in growing cells, but the cellular enzymes are not expressed in resting neurons and other nondividing cells.

If the viral gene to be mutated is essential for growth in a cell line, stable complementing cell lines have often been used to propagate these null mutant viruses.[104] In this protocol, the gene to be mutated is transfected into and stably maintained in a cell line that serves as the complementing cell line. The complementing cell line is then transfected with intact viral DNA and the mutated DNA fragment. The progeny of transfection are screened for mutants that multiply only in the complementing cells or, if a reporter gene expression cassette has been inserted *in lieu* of the viral gene, mutants that form fluorescent or otherwise distinguishable plaques.[104] Complementing cells of this type have been used to produce replication-defective viruses for herpes vaccines[97] and for vaccine vectors and for production of adeno-associated virus gene therapy vectors.[86]

VIRAL REPLICATION

Overview of HSV Replication

We will provide an overview of the HSV lytic replication cycle (Fig. 9.3) as the foundation for the discussion of the detailed mechanisms of viral replication and interaction with host cells.

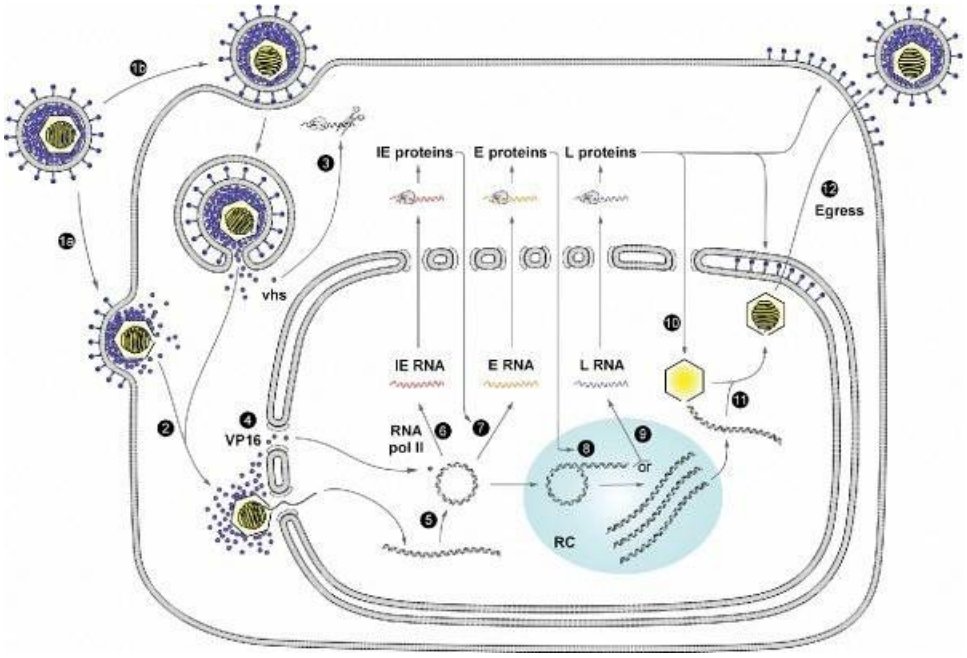

FIGURE 9.3 Diagram of the replication cycle of HSV. The virus binds to the cell plasma membrane and (*1a*) the virion envelope fuses with the plasma membrane or (*1b*) the virus enters by endocytosis, releasing the capsid and tegument proteins into the cytoplasm. (*2*) The capsid is transported to the nuclear pore where the viral DNA is released into the nucleus. (*3*) The *vhs* protein causes degradation of host mRNAs. (*4*) VP16 localizes into the nucleus. (*5*) The viral DNA circularizes and (*6*) is transcribed by host RNA pol II to give first the IE mRNAs. IE gene transcription is stimulated by the VP16 tegument protein. Five of the six IE proteins act to regulate viral gene expression in the nucleus. (*7*) IE proteins transactivate E gene transcription. (*8*) The E proteins are involved in replicating the viral DNA molecule. (*9*) Viral DNA synthesis stimulates L gene expression. (*10*) The L proteins are involved in assembling the capsid in the nucleus and modifying the membranes for virion formation. (*11*) DNA is encapsidated in the capsid. (*12*) The filled capsid buds through the inner membrane to form an enveloped virion, and the virion exits from the cell by mechanisms described below. (Copyright, Catherine Sodroski and David Knipe.)

To initiate infection, HSV must attach to cell surface receptors. Fusion of the envelope with the plasma membrane or an internal membrane rapidly follows the initial attachment. The de-enveloped tegument–capsid structure is then transported to the nuclear pores where DNA is released into the nucleus.

Transcription of the viral genome, replication of viral DNA, and assembly of new capsids take place in the nucleus. Viral DNA is transcribed throughout productive infection by host RNA polymerase (pol) II, but with the participation of viral factors at all stages of infection. The synthesis of viral gene products occurs through a series of groups of viral proteins leading to the expression of the next group in a cascade fashion (Fig. 9.4). The gene products studied to date form at least four groups, immediate-early (IE), early (E), early/late (E/L), and late (L) as a result of both transcriptional and posttranscriptional regulation. These were originally called α, β, and

γ,[186] but we will use IE, E, and L to conform to the more standard terminology for DNA viruses. The IE genes are expressed first and are defined as the genes that are transcribed in the absence of *de novo* viral protein synthesis. The IE gene products are involved in activating expression of the E genes. Several of the E gene products are proteins involved in viral DNA replication and localize to nuclear replication compartments (Fig. 9.5). The bulk of viral progeny DNA is synthesized as concatemers, which are cleaved into monomers during insertion into capsids in the process of nucleocapsid assembly. The L genes are then transcribed efficiently following viral DNA replication, and these gene products are largely involved in assembly of the progeny virions.

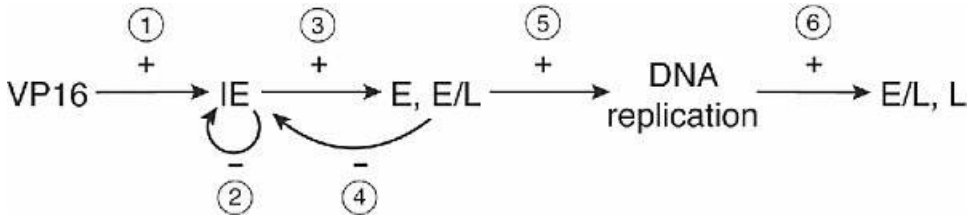

FIGURE 9.4 Schematic representation of the regulation of HSV gene expression. *Arrows* represent events in the reproductive cycle, which turn gene expression "on" and "off". (*1*) Turning on of IE gene transcription by VP16, an L protein packaged in the virion. (*2*) Autoregulation of IE gene expression. (*3*) Turning on of E gene transcription. (*4*) Downregulation of IE gene expression by E or L proteins. (*5*) E proteins promote viral DNA replication. (*6*) Turning on of L gene transcription by IE and E gene products through transactivation of L genes, release of L genes from repression, and replication of viral DNA. Note that E/L genes differ with respect to the stringency of the requirement for DNA synthesis. The heterogeneity is shown as a continuum in which inhibitors of viral DNA synthesis are shown to have minimal effect on E/L gene expression but totally preclude the expression of L genes.

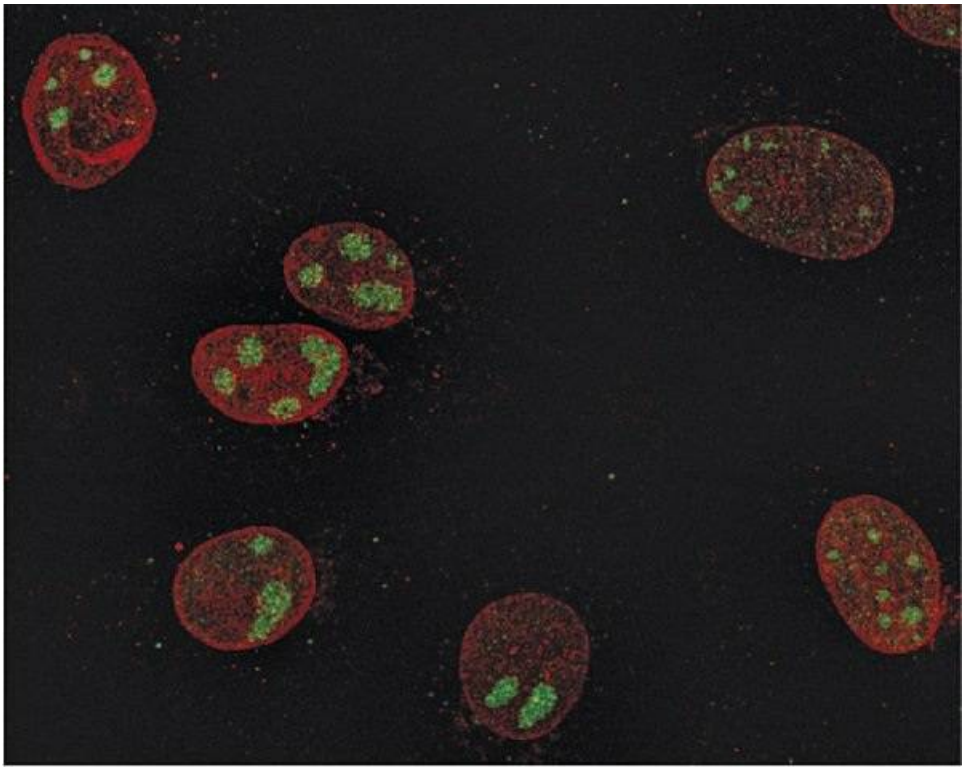

FIGURE 9.5 Replication compartments in the nuclei of HSV-infected cells. Shown are Vero cells infected with HSV-1 strain KOS virus and fixed at 7 hours postinfection and stained with anti-ICP8 antibody (*green*) to mark replication compartments and anti-lamin B1 antibody (*red*) to mark the nuclear lamina and define the boundaries of the nucleus. The punctate structures containing ICP8 within the larger globular replication compartments colocalize with sites of viral DNA synthesis. (Copyright, Lynne Chang and David Knipe.)

Assembly of mature, infectious virions occurs in several stages. After packaging of DNA into preassembled capsids, the nucleocapsid buds through the inner nuclear membrane to generate perinuclear enveloped vesicles that subsequently fuse with the outer nuclear membrane. This process, unique among known vertebrate viruses, allows the capsids to translocate from the nucleus into the cytoplasm. These cytoplasmic capsids next travel along microtubules to vesicles derived from the trans-Golgi network or early endosomes where a second, and final, round of envelopment takes place. There, capsids acquire their lipid envelope and most of the tegument. Cellular secretory machinery transports these mature, infectious virions out of the cell. In normal human fibroblasts, the entire process takes approximately 12 to 24 hours, depending on the multiplicity of infection.

The human host has evolved anti-HSV resistance mechanisms that are expressed constitutively or are induced by innate immunity signaling mechanisms that attempt to block these replication events. In turn, HSV has evolved viral gene products and mechanisms that neutralize these cellular resistance mechanisms. HSV has evolved for millions of years with its human host, and this has resulted in a situation where acute HSV infection is usually not life threatening unless the host is immunocompromised.

Despite the host resistance mechanisms, HSV infection reorganizes the structure of the host cell in many ways to promote its own replication. HSV causes extensive reorganization of cell structure with nuclear changes including margination of chromatin, enlargement of the cell nucleus, formation of replication compartments, disruption of the nuclear lamina and nucleoli, and cytoplasmic changes including disruption of the Golgi apparatus and microtubules.[394] Furthermore, HSV reorganizes much of the molecular machinery of the host cell to redirect transcription and translation to expression of viral RNAs and proteins, and it reorganizes the metabolic apparatus of the cell to promote its own replication. We will consider all of these virus–host interactions as we discuss the mechanisms of viral replication.

Entry of HSV

Routes of HSV Entry Into Target Cells

Early electron microscopy studies by Epstein led to the conclusion that HSV enters cells by fusing its envelope with the plasma membrane. This entry route has been well documented for Vero and HEp-2 cell lines[520] and primary neurons.[293] In contrast, entry by endocytosis only recently became accepted as a significant pathway of entry into many cell types despite the observations that date back to 1969 of enveloped virions in the cytoplasm at early times after infection. HSV enters cell types such as Chinese hamster ovary (CHO), HeLa, corneal epithelial cells, and keratinocytes by endocytosis followed by envelope fusion with the endosomal membrane.[315,336] Furthermore, HSV appears to take different endocytic routes into different cell types as judged by differences in the sensitivity to inhibitors of endocytosis, for example, inhibitors of endosomal acidification.[336] The choice of a particular entry route, thus, depends on the target cell type.

The productive endocytic entry resulting in infection should be distinguished from the dead-end internalization by endocytosis observed under certain conditions. For example, in the absence of gD–receptor interactions, virions can be taken up by endocytosis but are then degraded by lysosomal enzymes.

A few cellular molecules that may specify entry pathways have recently come to light. For example, overexpression of paired immunoglobulin-like type 2 receptor alpha (PILRα) in CHO cells engineered to express HSV-1 receptor nectin-1 switches the HSV-1 entry route from endocytosis to fusion at the plasma membrane.[23] Another example is αv integrins. In the presence of αvβ3, αvβ6, or αvβ8 integrins, HSV-1 enters nectin-1–bearing CHO or J cells (a baby hamster kidney [BHK] cell derivative) by endocytosis that requires both dynamin and cholesterol, whereas in their absence, entry becomes independent of dynamin and cholesterol.[147,150] Nevertheless, HSV internalization routes have not yet been mapped in detail, and the available data are often contradictory, which emphasizes the need for systematic studies.

Viral contributions to the selection of a particular entry route are not well understood. In some herpesviruses, such as human cytomegalovirus (HCMV) or Epstein-Barr virus (EBV), the use of particular entry routes correlates with the involvement of specific viral glycoprotein complexes.[303] By contrast, in HSV-1, the picture is less clear,[222] because the same set of four viral glycoproteins, described in detail below, is required for entry into any cell type. Nonetheless, some nonessential glycoproteins may facilitate the selection of HSV-1 entry routes

into specific cells. For example, the N terminus of gK enables HSV-1 to enter neuronal cells by fusion at the plasma membrane.[198] When the N terminus of gK was deleted, HSV-1 switched the entry route to clathrin- and dynamin-dependent endocytosis.[325]

An Overview of the Entry Mechanism

HSV entry requires multiple viral glycoproteins and diverse host receptors. HSV contains up to 16 distinct virion envelope proteins, 12 glycosylated and 4 nonglycosylated. Only 4 of the glycosylated proteins—gD, gH, gL, and gB—are essential for entry into target cells in tissue culture and in animal models, whereas the other 11 proteins are typically referred to as "nonessential" with regard to entry[126] because their deletions have mild phenotypes, if any, in cell culture.[242] Moreover, gD, gH, gL, and gB can also mediate cell–cell fusion of uninfected, receptor-bearing cells expressing these four glycoproteins.[474] gD, gH, gL, and gB are thus considered the core entry machinery of HSV.

HSV entry proceeds through three distinct steps—initial attachment, binding to one of the entry receptors, and fusion of the viral envelope with the host membrane—and requires the coordinated efforts of gD, gH, gL, and gB.[6,126,408] The prevalent model posits that the four viral glycoproteins orchestrate membrane fusion through a sequential activation process or cascade (Fig. 9.6).[27,126] First, HSV uses its receptor-binding glycoprotein, gD, to engage one of its three entry receptors.[439] Binding of gD to its receptor triggers a conformational change within gD[126,251,261] that enables it to bind the gH/gL heterodimer[58] and activate it.[26,27,146] This event, in turn, activates gB,[27,30,75] the fusogen that mediates the merger of the HSV lipid envelope with the cellular membrane.[90,126]

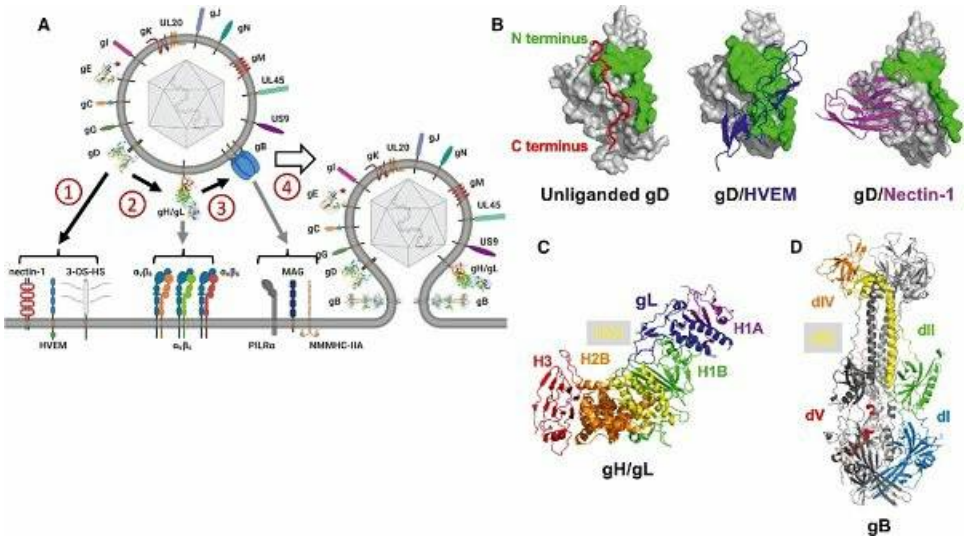

FIGURE 9.6 HSV-1 envelope proteins and their roles in entry and membrane fusion. A: HSV-1 envelope contains up to 16 proteins, 12 glycosylated [gB (RCSB PDB: 5V2S), gC, gD (RCSB PDB: 2C36), gE (RCSB PDB: 2GIY), gG, gH (RCSB PDB: 3M1C), gI, gJ, gK, gL (RCSB PDB: 3M1C), gM, gN], and 3 unglycosylated (UL20, UL45, US9). Entry into cells occurs by fusion of the envelope with the cellular membrane, plasma membrane, or the membrane of an endocytic vesicle and requires

four viral glycoproteins gD, gH, gL, and gB. According to the prevalent model, the four glycoproteins orchestrate entry through a sequential activation process termed regulatory cascade. Binding of gD to one of its three cellular receptors, nectin-1, HVEM, or 3-OS-HS (*step 1*), causes conformational changes in gD that enable it to bind and activate the gH/gL heterodimer by an unknown mechanism (*step 2*). Activated gH/gL, in turn, somehow activates gB (*step 3*), the fusogen that mediates the merger of the HSV lipid envelope with the cellular membrane (*step 4*). Additionally, interactions of gH/gL and gB with cellular receptors (a_V integrins, PILRa, NMHC-IIA, and MAG) can influence entry, but how these interactions fit into the current model is unclear. Only the structure of the postfusion form of gB is known. **B:** Crystal structures of unliganded gD (RCSB PDB: 2C36), gD bound to HVEM (RCSB PDB: 1JMA), and gD bound to nectin-1 (RCSB PDB: 3SKU) shown in the same orientation. Unliganded gD is shown as a monomer, for simplicity. HVEM and nectin-1 bind to distinct sites on gD. The N terminus of gD (*green*) forms a hairpin that serves as the HVEM-binding site. Binding of nectin-1 precludes formation of the N-terminal hairpin, explaining why HVEM and nectin-1 cannot bind gD simultaneously. Binding of HVEM or nectin-1 displaces the regulatory C terminus of gD (*red*), which is thought to trigger the regulatory cascade. **C:** Crystal structure of the heterodimeric HSV-2 gH/gL ectodomain (RCSB PDB: 3M1C), colored by domain, with all domains labeled. **D:** Crystal structure of the trimeric HSV-1 gB ectodomain, in postfusion form (RCSB PDB: 2GUM). A single protomer is colored by domain. Abbreviations: HSV-1, herpes simplex virus type 1; HVEM, herpes virus entry mediator; 3-OS-HS, 3-O-sulfated-heparan sulfate; PILRα, paired immunoglobulin-like type 2 receptor alpha; NMMHC-IIA, nonmuscle myosin heavy chain IIA; MAG, myelin-associated glycoprotein. **Panel A** was generated using BioRender (https://biorender.com/). **Panels B–D** were generated using PyMOL (http://www.pymol.org/). Attachment to the Cell Surface

Regardless of the entry route, HSV initially attaches to the surface of the host cell using gB, along with another glycoprotein, gC, to bind to heparan sulfate moieties of the cell surface proteoglycans (HSPGs). Although the attachment increases the efficiency of infection, it is not required for entry. Lack of HSPG or mutations of the putative HSPG-binding sites of gC and gB to abolish the interaction with HSPG reduces HSV yields 10- to 20-fold. HSV attachment to HSPGs is reversible and likely provides a platform from which virions can interact with entry receptors.

gD Receptors

The interaction of gD with its receptors has been extensively studied in many laboratories. HSV entry into any cell requires the presence of one of its natural receptors that fall into three classes.[439] These various molecules bind gD independently and do not act as coreceptors during entry.

The most widely used HSV receptors are nectins, which are members of the immunoglobulin

superfamily. Nectins are cellular adhesion molecules found at adherens junctions where they help maintain the integrity of cell junctions by forming homo- or heterodimers with nectins on adjacent cells. Nectins are found on the surface of many human cell types and tissues, including epithelial and neuronal cells. Nectin-1 is used by HSV-1 and HSV-2, whereas nectin-2 serves a receptor for HSV-2 and some mutant forms of HSV-1. Under selective pressure, HSV-1 can evolve to use nectin-2, -3, and -4 as entry receptors by acquiring mutations in gD and gB.[475]

The second gD receptor is a protein designated as herpes virus entry mediator (HVEM), a member of the tumor necrosis factor receptor superfamily. Both HSV-1 and HSV-2 can use HVEM as an entry receptor. HVEM is found mostly on T lymphocytes where it binds its natural ligands B and T lymphocyte attenuator (BTLA), CD160, and LIGHT and serves as a molecular switch that delivers bidirectional survival, proinflammatory and inhibitory signals to immune cells including T cells and natural killer T cells.[389]

The third gD receptor is a 3-O-sulfonated derivative of heparan sulfate (3-OS-HS) that results from modification of HS by the HS 3-O-sulfotransferase. This enzyme is present in the brain, but little is known about its role in natural HSV infection.

The presence of nectins on the surface of epithelial and neuronal cells, which are major targets of HSV, suggests that they are the primary HSV receptors. By contrast, lymphocytes are not a common target of HSV, so the importance of HVEM in HSV infection of the host is less clear. Mice with a double HVEM and nectin-1 knockout were resistant to vaginal HSV-2 infection, suggesting that these are the major receptors used during infection of epithelial cells.[465] However, single knockouts of nectin-1 or HVEM have shown that nectin-1 is more important for infection by vaginal route. For example, whereas nectin-1 knockout in mice reduced vaginal HSV-2 infection but could not prevent viral spread to enervating sensory ganglia, HVEM knockout had little effect on either parameter.[465] Likewise, in the intracranial mouse model of infection, nectin-1 knockout precluded infection and the ensuing encephalitis,[243] whereas mice lacking HVEM were indistinguishable from the wild-type mice.[243] Recent studies suggested that HVEM plays an important role during ocular infection in the context of the murine herpes keratitis model. But instead of serving as an entry receptor, HVEM appears to function as a proinflammatory factor.[124]

Both nectin-1 and HVEM are probably important in HSV infection and pathogenesis in humans because 49 tested clinical strains of HSV-1 and HSV-2 could use either nectin-1 or HVEM as entry receptors regardless of the origins of the virus (e.g., obtained from oral or genital lesions, encephalitis, or disseminated herpes of neonates). A major remaining challenge is determining the relative contributions of nectin-1 versus HVEM in human hosts because these molecules are broadly expressed and can both function as HSV entry receptors.

Structure of gD and Its Interactions with Receptors

The mature HSV-1 gD is a 369-amino acid protein, with a 316-amino acid ectodomain. Crystal structures of gD from HSV-1[251] and HSV-2[263] have revealed that the ectodomain has a V-like immunoglobulin (IgV) core, residues 56 to 184, with large N- and C-terminal extensions that are involved in receptor binding and triggering of the fusogenic cascade and undergo large conformational changes.[126] Crystal structures of several gD/receptor complexes, HSV-1 gD/HVEM, HSV-1 gD/nectin-1,[109,541] and HSV-2 gD/nectin-1,[288] along with mutational and

biochemical studies,[126] have characterized gD/receptor interactions in great detail (Fig. 9.6).

The HVEM-binding site of gD is formed by the N-terminal hairpin of gD, residues 1 to 32, buttressed by the IgV core (Fig. 9.6B). Several sets of interactions at the gD/HVEM interface are critical for the stability of the complex. The N-terminal gD hairpin that composes the HVEM-binding site is conformationally flexible and only forms in the presence of HVEM. HVEM is composed of four cysteine-rich domains (CRDs), and gD binds to the most membrane distal CRD1. The gD-binding site on HVEM overlaps the binding site of one of its natural cellular ligands, BTLA, implying a possible function for gD in modulating the host immune response.

3-OS-HS likely binds gD somewhere within its N-terminal hairpin because mutations in this region have a similar effect on interactions with HVEM and 3-OST-HS. Two positively charged pockets on the surface of gD, which are occupied by sulfate ions in the crystal structure of the HSV-1 gD/HVEM complex, could potentially accommodate sulfate moieties of 3-OS-HS, and one such pocket lies in the vicinity of the HVEM-binding hairpin.

The binding site on gD for nectin-1 was mapped using mutational analysis long before the crystal structure of the gD/nectin-1 complex became available. The nectin-1–binding site is located within the IgV-like core near the HVEM-binding site but does not overlap it (Fig. 9.6B). Nevertheless, HVEM and nectin-1 cannot bind to gD simultaneously. The N-terminal hairpin of gD that forms the HVEM-binding site partially occludes the nectin-1–binding site.[109,251] Conversely, binding of nectin-1 to gD precludes the formation of the N-terminal HVEM-binding hairpin. HSV-1 gD interacts with the V domain of nectin-1[109] that mediates nectin-1 dimerization, which explains how gD can disrupt nectin/nectin interactions at cell junctions.[40]

Triggering of the Fusogenic Cascade and the Regulatory Role of the gD C Terminus

According to the prevalent model, a gD receptor triggers a cascade of events in which gD, the gH/gL heterodimer, and gB sequentially undergo conformational changes that lead to membrane fusion[27,126] (Fig. 9.6). Binding of gD to one of its receptors causes conformational changes that enable it to bind and activate the gH/gL heterodimer. The C terminus of the gD ectodomain, residues 261 to 316, plays an important role in receptor-dependent triggering of the regulatory cascade that leads to membrane fusion. The C terminus of gD, especially, a proline-rich region within the gD C terminus referred to as the profusion domain, is required for viral entry and fusion, and its truncations render gD unable to promote fusion. Moreover, antibodies targeting the gD C terminus inhibit cell–cell fusion and viral spread.[117,262]

The C terminus is disordered in the isolated, monomeric HSV-1 gD ectodomain. However, in the dimeric form stabilized by an engineered intermolecular disulfide at position 316—designed to mimic the stabilizing influence of the transmembrane domain[251]—the C terminus folds against the IgV-like core. The disulfide mutant is thought to recapitulate the native HSV-1 gD dimer on the viral envelope. The positioning of the C terminus in the unliganded HSV-1 gD occludes the nectin-1–binding site and prevents the formation of the HVEM-binding hairpin. Therefore, the C terminus must exist in a dynamic equilibrium that would enable its displacement by either nectin-1 or HVEM. Indeed, engineered disulfides that lock the C terminus in place prevent receptor binding.[251] Conversely, mutations in gD that either eliminate the C terminus or block its interactions with the IgV-like core increase the affinity of gD for both

receptors.[251] A gD mutant containing a point mutation that precludes binding of the C terminus to the IgV-like core—which effectively disrupts its autoinhibitory conformation—is constitutively active in fusion even in the absence of gD receptors,[143] albeit at a reduced level. The displacement of this C terminus is thus sufficient to trigger the downstream events required for fusion. The apparent autoinhibitory nature of the C terminus of gD likely serves to couple receptor binding to the triggering of the regulatory cascade. This mechanism can also explain how binding of gD to three very different receptors produces the same triggering effect.

Additional evidence in support of the C terminus as key in downstream events comes from gD chimeras—engineered forms of gD that no longer bind its natural receptors and instead interact with heterologous receptors, used in retargeting HSV for oncolytic therapy. Surprisingly, much of gD could be substituted with heterologous sequences without any apparent defect in fusion activation. How binding of a heterologous receptor to gD chimeras can trigger subsequent fusion events is unknown, but all chimeras had the native C terminus. One possibility is that the gD chimeras may be unable to adopt the autoinhibitory conformation and are, thus, constitutively active, akin to the mutant in which the C terminus cannot bind the IgV-like core.

How the release of the C terminus activates gH/gL is unknown. It has been proposed that the C terminus binds gH/gL directly.[146] An alternative hypothesis, based on characterization of neutralizing anti-gD antibodies that do not block its receptor interactions, is that gH/gL binds the IgV-like core at a site in the vicinity of the receptor-binding site rather than the C terminus.[28,58,262] The respective interaction sites on gD and gH/gL have been mapped using antibodies that block their interactions[57,58] but await confirmation by high-resolution structures of the gD/gH/gL complexes.

gB Is the Conserved Viral Fusogen

gB is conserved across all three subfamilies of herpesviruses and is essential for viral entry, spread, and cell–cell fusion.[90,126] gB is also the target of neutralizing antibodies.[59] The first suggestion that gB was the fusogen came from the crystal structure of the postfusion form of HSV-1 gB[171] that revealed unexpected structural similarities to the fusogen of vesicular stomatitis virus (VSV), glycoprotein (G).[386] Since then, a number of structural and mutagenesis studies have firmly established gB as a viral fusogen responsible for mediating virus and host membrane fusion during viral entry.[85,126]

Viral fusogens mediate the merger of the viral envelope and host membrane during entry and cell spread by pulling the two apposed membranes together while undergoing large-scale refolding from the metastable prefusion to the stable postfusion form.[168] Three classes of viral fusogens are currently recognized.[168] gB is one of the founding members of class III, which also includes G of rhabdoviruses, for example, VSV, gp64 from baculoviruses of insects,[216] and Gp of thogotoviruses.[361] It is the newest, least well-characterized class, partly because the high-resolution structures of both the prefusion and the postfusion forms are known only for VSV G.[386] The 2.7-Angstrom crystal structure of the postfusion form of HSV-1 gB ectodomain revealed a trimeric spike composed of five distinct domains.[171] The recently determined approximately 9-Angstrom cryo-ET reconstruction of the trimeric prefusion form[490] showed a more compact conformation consistent with substantial conformational rearrangements. Therefore, despite being unusual in requiring several additional proteins for function, like other

viral fusogens, gB appears to facilitate membrane fusion by undergoing large refolding.

The Fusogenic Activity of gB Is Controlled by Its Cytoplasmic Domain

In addition to the ectodomain, gB also contains the membrane-proximal (MPR), the transmembrane (TMD), and the cytoplasmic (CTD) domains that are essential for function.[90] Moreover, the CTD appears to restrain the fusogenic activity of gB because a number of point mutations, insertions, or truncations within this domain, termed hyperfusogenic or syncytial mutations, increase cell–cell fusion in the context of infected cells or uninfected cells expressing gD, gH, gL, gB,[90] presumably due to a reduced kinetic energy barrier for the fusogenic refolding of the gB ectodomain.[390] The 3.6-Angstrom crystal structure of the full-length postfusion gB from HSV-1 revealed that the MPR-TMD-CTD forms a uniquely folded trimeric pedestal underneath the ectodomain, a dynamic structure stabilized by extensive protein/protein and protein/membrane interactions.[89] Although the postfusion conformation of the ectodomain suggested that the CTD also adopted the postfusion form, the hyperfusogenic mutations target interfaces and structural motifs that stabilize the observed CTD structure, which suggests that a similar CTD structure stabilizes gB in its prefusion form. This has led to a “clamp” model whereby the CTD acts as a clamp that inhibits the fusogenic refolding of gB by somehow stabilizing the ectodomain in its prefusion conformation. Hyperfusogenic mutations would then lower the energy barrier and increase gB activity by destabilizing the inhibitory CTD structure.[89]

gB Receptors

In addition to its conserved fusogenic role, gB has been reported to bind three cellular receptors, paired immunoglobulin-like type 2 receptor-α (PILRα), nonmuscle myosin heavy chain IIA (NMMHC-IIA), and myelin-associated glycoprotein (MAG). PILRα is an inhibitory component of an immunoregulatory receptor pair, binds gB, and supports HSV-1 entry into certain cell types in the absence of gD receptors but is not required for HSV entry into all cells.[409] This receptor may contribute to infections of retinal[427] and corneal[24] epithelial cells, but the clinical significance has not yet been established. The other two receptors, NMMHC-IIA[21] and MAG,[450] have been both reported to enhance HSV entry.

Role of gH/gL

gH and gL form a stable 1:1 complex and, in HSV, neither protein appears stable without the other. HSV-1 gH is an 838-amino acid glycoprotein that has an 802-amino acid ectodomain, a single C-terminal transmembrane anchor, and a short intraviral (or cytoplasmic) tail. HSV-1 gL is a 224-amino acid glycoprotein that lacks a transmembrane region and is retained on the viral envelope or cell surface due to its interaction with gH. The crystal structure of the extracellular portion of the HSV-2 gH/gL revealed an unusual boot-shaped complex with no structural or functional similarity to any other proteins.[75] gH is composed of individual domains H1A, H1B, H2A, H2B, and H3, sequentially arranged from N to C terminus. gL is “sandwiched” between domains H1A and H1B and interacts extensively with both, illustrating why gH and gL are always found as a complex. A similar architecture was observed in gH/gL structure from another alphaherpesvirus, varicella-zoster virus (VZV).[522]

The precise function of the gH/gL heterodimer is unclear. Initially proposed to have fusogenic properties, gH/gL does not resemble any known viral fusion proteins nor does it have a known functional counterpart in other enveloped viruses.[75] In some herpesviruses, gH/gL binds cellular receptors either directly, for example, in Kaposi's sarcoma herpesvirus (KSHV),[164] or indirectly, by forming a complex with a receptor-binding protein, for example, in HCMV.[215,303] In HSV-1, however, the evidence as to whether or not gH/gL binds integrins to enter cells is conflicting,[148,150] and the integrin-binding RGD motif in HSV-1 gH is not required for its function. Nonetheless, the requirement of gH/gL for entry and cell–cell fusion in all herpesviruses indicates a conserved function. gH/gL has been proposed to act as a unique herpesviral adaptor that transmits the triggering signals from various nonconserved receptor-binding proteins to the highly conserved fusion protein gB.[443] Specifically, HSV gH/gL is currently thought to receive a triggering signal from receptor-bound gD and transmit it to gB to activate its fusogenic function.[30,75]

To do so, gH/gL must interact with gB, but relevant complexes have not yet been detected in any herpesviruses, although a covalent gB-gH/gL complex of unknown function has been observed in HCMV.[481] Instead, gB/gH interactions have been inferred from fluorescence complementation experiments, in which two complementary segments of a split fluorescent protein were fused to the C termini of gB and gH.[29] In uninfected, receptor-bearing cells expressing gH, gL, and gB, the addition of soluble gD triggers cell–cell fusion, and in this system, fluorescence complementation was detected only in the presence of gD.[29] This observation suggested that gH/gL and gB interact only in response to a gD/receptor interaction, which implied that the gD/receptor interaction causes gH/gL to activate gB instead of relieving repression of gB by gH/gL. Several neutralizing antibodies against gB or gH/gL inhibited both fluorescence complementation and fusion, which led to the conclusion that gB and gH/gL interact through their ectodomains and that this interaction is required for membrane fusion.[27,30,75] Elucidating the role of gH/gL in promoting fusion and the mechanism by which it does so would benefit from a detailed understanding of how it interacts with gB.

Several mutational studies have shown that the 14-amino acid cytoplasmic tail of HSV-1 gH is required for fusion.[90] For example, a systematic study of HSV-1 gH C-terminal truncation mutants demonstrated a correlation between the extent of cell–cell fusion and the length of the gH cytoplasmic tail.[390] However, the mechanism is yet unclear.

Entry and Signaling

Virion attachment to cells triggers multiple signaling events inside the cell. Indeed, binding of HSV-1 to the cell surface releases intracellular Ca^{2+} stores[71] and increases intracellular levels of Cl^{-} ions,[544] both of which appear important for subsequent entry. One important signaling event is the activation of the cellular phosphoinositide 3-kinase (PI3K),[71,544] which induces several signaling cascades, each of which has been reported to promote virus entry, for example, Akt[70,71] and Cdc42.[343] PI3K/Akt signaling triggers calcium release from the endoplasmic reticulum.[71] PI3K/Akt signaling also leads to activation of NF-κB, which is necessary for establishing infection.

These signaling events appear to promote infection through multiple mechanisms. For example, by inhibiting actin depolymerization, HSV can promote actin polymerization

underneath the cell membrane that may cluster receptors near the virion, aiding in entry.[544] Calcium release from the ER, which controls cytoskeletal dynamics, may promote capsid trafficking to the nucleus upon entry.

Translocation of Capsids to the Nucleus from the Site of De-envelopment

Upon fusion of the viral envelope with a cell membrane, the capsid—along with the tegument—is deposited into the cytoplasm. Early studies documented the accumulation of empty capsids at the nuclear membrane. The capsid must, therefore, traverse the cytoplasm, dock at a nuclear pore, and release its genome into the nucleoplasm. However, being approximately 125 nm in diameter, the capsid is too large to passively diffuse to the nucleus through the viscous, crowded cytoplasm. Instead, capsids move from the periphery to the nucleus along microtubules[436] by recruiting the microtubule motor proteins.[375,436]

This process initiates with a partial disassembly of the tegument. Most, if not all, of the outer tegument proteins dissociate from the capsid, and their destinations within the cells vary. Some stay in the cytoplasm, for example, UL41, also known as the viral host shutoff (vhs) protein, whereas others, such as VP16, travel to the nucleus independently of the capsid. The two longest known and best studied of these virion-delivered effectors are vhs, an endonuclease that rapidly shuts off host protein synthesis by degrading mRNA, and VP16, which activates transcription of viral IE genes. The roles of these and other virion-delivered tegument proteins in infection are described in detail later on in this chapter.

By contrast, the inner tegument proteins UL36, UL37, and US3 remain capsid associated as demonstrated by immunogold electron microscopy and by live-cell imaging of recombinant fluorescent viruses.[7,19] US3 is a kinase that in pseudorabies virus has been shown to activate cellular protein cofilin, which disassembles actin filaments.[197] This activity is thought to allow the capsids to breech the barrier of cortical filamentous actin, which impedes intracellular capsid trafficking.[306] UL36 facilitates capsid transport by recruiting the microtubule motor proteins dynein, dynactin, and kinesins.[375,537]

In mammalian cells, dynein and its cofactors transport cargo toward the minus-end of microtubules, whereas multiple kinesins mediate plus-end-directed transport.[381] Dynein, along with dynactin and cytoplasmic linker protein 170 (CLIP-170), is responsible for capsid trafficking toward the nucleus and their inhibition or depletion blocks long-range capsid movement postentry.[212] Dynein does not transport the capsids all the way to the nucleus, however, because the minus-ends of microtubules are bundled around the centrosome, also known as the microtubule-organizing center (MTOC). Microtubules are produced at the centrosome and radiate out from it. Indeed, capsids have been observed to transiently accumulate at the centrosome on their way to the nucleus.[436] Therefore, a plus-end-directed motor is required to transport the capsids from the centrosome to the nucleus. Kinesins have been hypothesized to fulfill this role, but this has not been formally tested yet. However, another cellular protein, dystonin/BPAG1, plays an important role during the final step of capsid transport[307] and is recruited to the capsid by binding UL37.[356] Although the precise contribution of dystonin/BPAG1 to this process is unknown, its depletion reduces transport from the centrosome to the nucleus.[307] The nuclear localization signal of UL36 also contributes to this final transport

step to the nucleus.[2]

Upon reaching the nucleus, capsids bind to nuclear pore complexes (NPCs).[18] Host nuclear factor importin β as well as the nucleoporins that extend from the cytosolic surface of the NPC, Nup358/RanBP2 and Nup214/CAN, are involved in docking of capsids to nuclear pores.[91,344,355] Furthermore, *in vitro* reconstitution studies showed that capsids bind to the NPC and release viral DNA in the presence of cytosol and an energy source.[344] Interaction of the capsid with the NPC thus seems to trigger the release of the viral genome.

Both UL36[1,3] and UL25[192,369,388] are critical for the release of the viral genome from the capsid. Early studies with the temperature-sensitive HSV-1 *ts*B7 mutant, which was subsequently mapped to the U_L36 gene, showed that at the nonpermissive temperature, DNA-containing capsids accumulate at nuclear membranes.[235] The DNA is released from the capsids on temperature shift-down, and viral gene expression ensues. More recent studies have shown that UL36 must be cleaved to allow release of the viral DNA.[211] UL25, just as HSV-1 capsids, can bind to Nup214/CAN.[355,369] Mechanistic roles of either UL36 or UL25 in genome release remain unclear, however.

Capsids dock at NPCs such that a vertex points into the pore.[344] After docking, viral DNA genomes are likely released through the portal, located at one of the vertices, by a pressure-driven ejection mechanism, similar to bacteriophages.[330]

Gene Expression in HSV-Infected Cells

Classification of Viral Gene Products: General Summary

The total coding capacity of HSV includes at least 84 canonical ORFs, which encode a diversity of lytic proteins (see eBook Supplementary Fig. 9.1), a number of long noncoding RNAs, and as many as 29 microRNAs as described in the eBook Supplementary Table 9.1. Viral lytic gene products form several groups expressed coordinately in a cascade fashion defined originally in human HEp-2 cells and are grouped based on their kinetics of and requirements for expression[185,186] (Fig. 9.4). The immediate-early (IE) genes are expressed first followed by early (E), early/late (E/L) or leaky-late, and late (L) or true-late genes. The designations reflect the order of their accumulation in infected cells, and the accumulation of IE and E gene products proceeds normally in the presence of inhibitors of viral DNA synthesis. IE genes do not require prior viral protein synthesis for their expression. A common property of the six IE genes encoding the proteins ICP4, ICP0, ICP22, ICP27, US1.5, and ICP47 is the presence of a response element in their upstream sequences that is bound by a VP16-mediated complex of host proteins. At least two of the six IE proteins, ICP4 and ICP0, are required for the optimal expression of E genes, exemplified by the U_L29 gene encoding ICP8 and the U_L23 gene encoding the viral thymidine kinase. The accumulation of the products of L genes, as exemplified by the U_S11, U_L38, and U_L44 gene products, strictly requires viral DNA synthesis and the viral proteins ICP4, ICP0, ICP22, ICP27, and US1.5. A characteristic of at least some L genes is that the requirement for viral DNA synthesis is encoded within the 5′ transcribed noncoding domains.

In contrast to the E gene products, the accumulation of E/L gene products exemplified by

ICP5/VP5, the major capsid protein, is affected to various degrees by inhibitors of viral DNA synthesis. Neither E nor E/L promoters share common response elements, and most likely the order and quantity of the gene product that accumulates in the infected cells reflects the cellular response elements embedded in the viral promoter and the abundance of transcriptional factors present in the infected cells.

In permissive infected cells, progeny virus accumulates at an exponential rate between 6 and 18 hours after infection and at a reduced, linear rate until at least 24 hours. In cells exposed to 10 PFU of virus per cell, IE gene products reach peak rates of synthesis between 2 and 4 hours after infection, although the actual synthesis of the proteins continues for many hours. The E gene products are expressed very soon thereafter. Overall, E gene products are readily detected by 4 hours after infection but reach highest rates of accumulation between 6 and 12 hours after infection. Viral DNA synthesis can be detected as early as 3 hours after infection and continues for at least 10 to 12 more hours.

Early Events After Entry of the DNA into the Nucleus

After entry of viral DNA into the nucleus, as described above, several events are thought to take place, including circularization of at least part of the viral DNA, induction of a limited DNA damage repair response, and loading of heterochromatin onto the input viral DNA (Fig. 9.7).

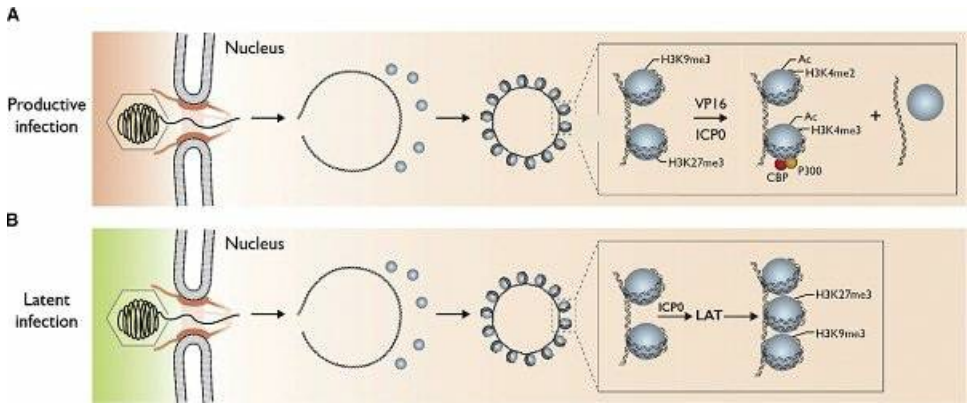

FIGURE 9.7 Epigenetic regulation of HSV-1 lytic and latent infection. A: Following infection of epithelial cells, the capsid is transported to the nuclear pore where the viral DNA is released into the nucleus where it rapidly circularizes and becomes associated with histones. VP16 from the virion tegument forms a complex with HCF-1 and Oct1 that binds to viral IE promoters and HCF-1 recruits histone modification enzymes and chromatin remodeling complexes that decrease histone association with viral IE genes and increase euchromatin marks on the remaining associated histones. ICP0 is expressed as an IE protein, and it promotes the same processes on the rest of the genome. **B:** Following infection of neuronal cells, the capsid is also transported to the nuclear pore where the viral DNA is released into the nucleus where it rapidly circularizes and becomes associated with histones. VP16 cannot be transported into the neuronal nucleus and/or HCF-1 is not localized in the nucleus, so viral IE genes are not transcribed efficiently. Instead, the latency-associated transcript is expressed, and it promotes the further association of facultative

heterochromatin marks on the viral chromatin. (Copyright, Catherine Sodroski and David Knipe.)

Circularization of Viral DNA

Upon entry into the nucleus, viral DNA circularizes quickly and in the absence of viral protein synthesis, as first shown using assays that detected (a) viral DNA end joining in cells infected with recombinant viruses lacking internal repeated sequences or (b) circular viral DNA as detected in pulsed-field gels and other biochemical assays. These results also led to the development of viral DNA replication models involving theta molecule intermediates and rolling circle mechanisms, as described below. Furthermore, a later study of an HSV recombinant strain containing an insertion of the cleavage/packaging sequence within the genome confirmed the circularization of the HSV-1 genome during productive infection.[448] Results from the latter study also argued that the end joining reported earlier was not due to concatemer formation or recombination between terminal repeats but rather was due to circularization.[448] Circularization of viral DNA, formation of endless genomes, and efficient viral DNA synthesis and viral replication requires the cellular DNA ligase IV and its cofactor XRCC4, as shown by studies of mutant cell lines and siRNA-mediated knockdown. Knockdown of DNA ligase IV or XRCC4 causes a 100-fold reduction in viral yield, supporting the idea that early circularization of the viral DNA is part of the productive infection pathway.

Induction of the First Phase of the DNA Damage Response

HSV-1 infection causes DNA damage response (DDR) proteins to be recruited to replication compartments and to interact with viral proteins and promote viral replication.[466] HSV-1 infection activates DDR pathways,[319,511] but these could be due to input or progeny viral DNA. Various DDR proteins localize adjacent to incoming viral DNA, and ICP0 inhibits localization of at least two of these proteins: 53BP1 and BRCA1.[276] The incoming viral DNA with nicks and gaps and some linear ends as described above is an appropriate stimulus for the DNA damage response. Consistent with that, viral DNA transfected into cells induces phosphorylation of RPA, which is catalyzed by ATR and DNA-PK.[432] Infection of normal human fibroblasts with the HSV-1 *d*109 virus, which delivers its DNA to the cell nucleus but expresses little in the way of viral gene products, causes the activation of a limited DNA damage response, including the phosphorylation of Chk2 and H2AX, as well as low amounts of p53 serine 15 phosphorylation.[314] Full activation of the DNA damage response occurs after viral DNA replication and that will be discussed below in the DNA replication section. It is not apparent whether the DNA damage response to the incoming DNA in the amounts delivered by input virions is antiviral, proviral, or just a preview of things to come.

Association of Viral DNA With Histones

It was originally thought that lytic viral genomes were not associated with nucleosomes because nuclease digestion studies showed no nucleosomal-protected DNA band in lytic viral DNA.[224] However, the use of chromatin immunoprecipitation (ChIP) techniques showed that histones are associated with viral DNA during lytic infection[176,224] and that changes in the viral heterochromatin were associated with changes in viral gene expression.[176]

It then became clear that, like transfected plasmid DNAs, cells rapidly load histones on viral DNA molecules within a couple of hours (Fig. 9.7),[82,274,342] likely in an attempt to epigenetically silence the foreign, unchromatinized DNA.[234] The histones associated with viral DNA lacked euchromatin marks such as histone acetylation[82] but contained heterochromatin marks such as histone H3 lysine 9 trimethylation (H3K9me3).[264,274] However, HSV has evolved mechanisms to combat the epigenetic silencing of its lytic genes by the host cell, and to this end, VP16 organizes a complex of cellular proteins that remove histones and heterochromatin marks from IE gene promoters, ICP0 promotes the degradation of host restriction factors, leading to the reduction of histone loading on E and L gene promoters, and viral DNA replication also helps to reduce histone loading on the viral DNA molecules.[236,237]

Experiments involving pull down of labeled input viral DNA did not detect core histones associated with that DNA.[105] It is unclear why this technique gives a different result from the extensive results using ChIP, but it has been shown that nucleosomes on viral DNA are less stable in HSV-infected cells.[256,257] Therefore, the association of histones with viral DNA may not be stable enough to show association with viral DNA using pull down of labeled DNA.

Intranuclear Targeting of HSV DNA

Input viral genomic DNA is targeted to a location near the nuclear periphery and/or lamina early after entry into the nucleus. The HSV-1 genome is found initially in genome complexes and small replication compartments near the nuclear periphery.[102,428,429] The localization of the genome to the nuclear periphery may be the result of IE gene transcription rather than a cause of IE transcription, because localization of genome complexes to the periphery is reduced in cells infected with a VP16 acidic activator domain mutant virus.[429] It is noteworthy that transcriptionally active HSV genomes localize to the nuclear periphery as most of the literature considers the nuclear lamina to be silencing.[137,382] This may reflect targeting of the viral genome to specific nuclear lamina microdomains that are associated with actively transcribed chromatin.[424]

Early replication compartments, as detected by ICP8 immunofluorescence,[102,428] then form near the inner nuclear membrane. Knockout of the lamin A/C gene in mouse embryonic fibroblasts (MEFs) leads to the release of replication compartments from the nuclear periphery, increased viral heterochromatin, and reduced viral gene expression.[428] Assembly of the VP16 activator complex likely occurs on the nuclear lamina,[429] possibly because Oct-1 is believed to be associated with nuclear lamina.[299] Conceivably, this could help ensure the transcriptional activation of viral genomes immediately following nuclear entry.

Association of Viral DNA With ND10 Structures and Other Nuclear Proteins

Concurrent with the association of viral DNA with histones, histone- and chromatin-modifying enzymes, and repressors, entering viral DNA was first observed to localize in genome complexes near punctate structures within the nucleus called nuclear domain 10 (ND10) bodies or PML oncogenic domains. Later studies argued that ND10 components relocate to sites associated with the viral genome complexes.[132] While early imaging studies argued that the ND10 structures and viral DNA were adjacent, some recent studies have argued that the ND10 components are

wrapped around the viral genome.[9] Thus, while we do not know the exact events taking place, we do know that at least some components of the ND10 bodies, including PML, ATRX, SP100, and SUMO2, as well as IFI16 localize to input viral genomes labeled *in situ* by click chemistry within minutes after infection.[9,55,105]

ND10 bodies have been associated with many functions including transcriptional activation and epigenetic regulation of gene expression.[470] They are dynamic structures that contain upwards of 20 proteins with PML protein acting as a scaffold. The role of ND10 body structures in viral infection is not well defined. ND10 bodies were observed to be associated with transcribing genomes and replication compartment formation and therefore were originally considered to be proviral. As described below, the protein components are antiviral under certain circumstances. Although ND10 component proteins are expressed constitutively, some are induced by interferon treatment and can act to restrict virus reproduction. In fact, interferon treatment of cells increases the number of ND10 bodies, and the effects of PML and IFI16[437] have been shown to be amplified in interferon-treated cells.

Because PML, ATRX, and IFI16 increased the steady state levels of heterochromatin under various conditions,[55,284,348] it was thought that these might be the host cell factors involved in the initial deposition of heterochromatin onto viral DNA. However, analysis of early times of infection showed that ATRX, PML, and IFI16 are not needed for loading of heterochromatin but for maintenance of heterochromatin if the genome is subjected to transcription or replication.[55,312]

Once assembled in heterochromatin, access of the viral genome to transcription factors and RNA pol II, which transcribes the HSV genome throughout infection, is restricted. The cascade of viral gene expression, while originally thought to involve transactivation of viral transcription, involves to a large part overcoming several epigenetic silencing hurdles to de-silence the viral genes, enabling the expression of the IE genes, then the expression of E and E/L genes followed by L genes.

De-Silencing and Transcription of IE Genes

IE gene promoters are loaded with histone H3 bearing heterochromatin markers by 30 minutes postinfection, but H3 levels are reduced as the infection progresses.[274] The key players in the de-silencing and transcriptional activation of IE genes are the protein complex involving the viral VP16 protein; the unique IE gene response element; the host factors recruited by the VP16 complex including Set1, LSD1, CLOCK; and a large number of epigenetic and transcriptional factors discussed below.

The IE gene promoters contain numerous cellular transcription factor binding sites, including SP1 binding sites (Fig. 9.8), but the sequence ATGCTAATGARATTCTTT,[249] sometimes shortened to TAATGARAAT, is the key sequence element defining IE gene promoters. It is present in one or several copies within several hundred base pairs upstream of the cap site (e.g., ICP4 Fig. 9.8).

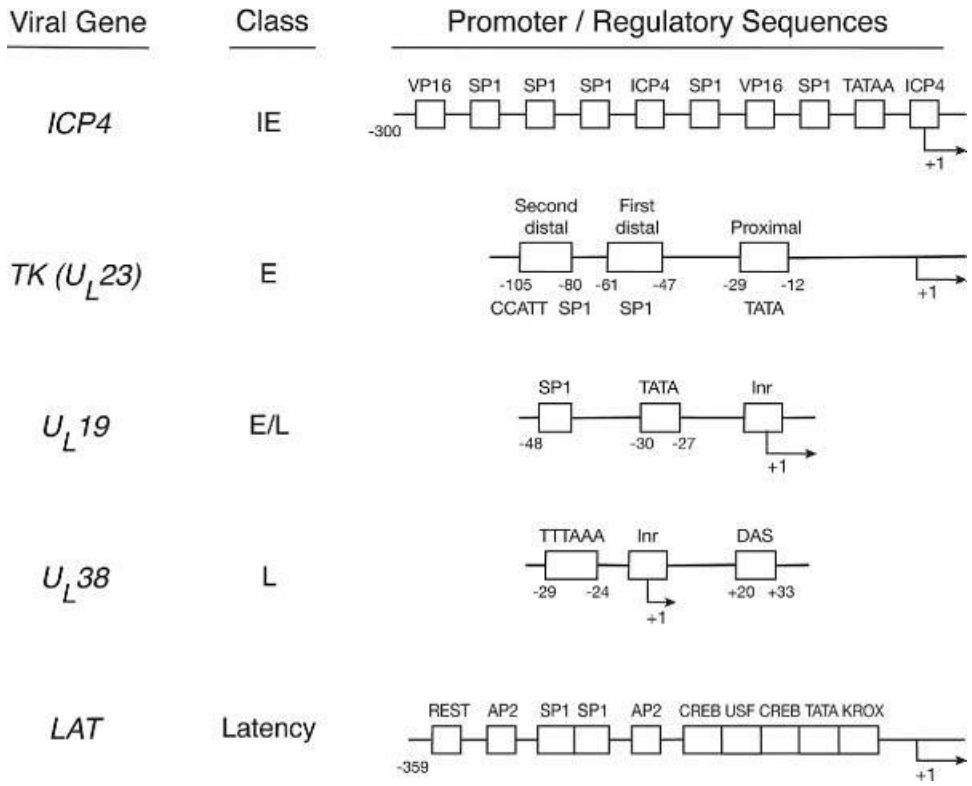

FIGURE 9.8 Diagrammatic representation of the structure of prototypic HSV gene promoters. The promoter/regulatory sequences of prototypic genes of IE, E, E/L, L lytic classes of genes and the LAT promoter of the latency gene are diagrammed. (Copyright, Catherine Sodroski and David Knipe.)

The IE gene promoter element described above is targeted by a complex of host proteins organized by the tegument protein VP16. VP16, encoded by the U_L48 gene, is 1 of 18 virion tegument proteins, and upon entry into the host cell in the virion, it is a key component of the complex of proteins that de-silences and activates IE gene expression. Upon release from the tegument, VP16 binds to a cellular protein called host cell factor 1 (HCF-1). It has been reported that HCF-1 carries VP16 into the nucleus in transfected cells, but VP16 localizes normally to the cell nucleus at late times in infected cells that express a temperature-sensitive mutant HCF-1 or in cells in which HCF-1 is knocked down. Thus, at late times and conceivably at early times in infected cells, other factors, such as other viral tegument proteins, assist in nuclear localization of VP16. Within the infected cell nucleus, the VP16–HCF-1 complex binds to the cellular protein Oct-1 to form the core transcription activator complex. Oct-1 is an abundant ubiquitous transcriptional factor that, as its name indicates, binds to the ATGnTAAT octamer. Oct-1 binds to viral DNA at the octamer sequence found in the IE promoters and anchors the complex at the IE gene promoters. VP16 binds to adjacent DNA sequences and to HCF-1 to complete the complex.

Through the actions of this complex, VP16 acts to reduce the loading of histones and heterochromatin marks and promote the addition of euchromatin marks on viral IE gene promoters.[176] The mechanism of this has been at least partially elucidated by a variety of experiments. A key step in the expression of IE genes is the recruitment of lysine-specific

demethylase 1 (LSD1), also known as lysine (K)-specific demethylase 1A (KDM1A), to the viral IE gene promoters by the HCF-1 protein in the complex. LSD1 is a flavin-dependent monoamine oxidase, which can demethylate mono- and dimethylated lysines, specifically histone 3 lysines 4 and 9 (H3K4 and H3K9). In the VP16 complex, LSD1 demethylates H3K9me2 and H3K9me moieties bound to IE promoters to shift the chromatin away from heterochromatin and enable IE gene transcription.[274] Depletion of LSD1 or pharmacologic inhibition of LSD1 increased H3K9me3 modification of histones associated with HSV IE gene promoters and decreased IE gene transcription.[274] Furthermore, HCF-1 is part of the Set1 and MLL1 histone H3 Lys4 methyltransferase complexes; therefore, the VP16 complex recruits the HCF-1-SetI or HCF-1-MLL1 histone methyltransferase (HMT) complex to IE promoters resulting in the euchromatic histone modification, trimethylation of the histone H3 lysine 4 residue (H3K4me3), which provides a euchromatic modification and binding of various factors that stimulate IE gene transcription.

The second step in IE gene expression is the activation of transcription. Part of this process involves the recruitment by the VP16 acidic C-terminal domain of transcription factors IIB (TFIIB), TFIIH, TATA-binding protein, and TBP-associated factors, which promote formation of the RNA pol II preinitiation complex on IE promoters. VP16 has also been reported to recruits chromatin-modifying coactivator proteins CBP, p300, Brg-1, or Brm onto viral promoters.[176] CBP and p300 have histone acetyltransferase (HAT) activities associated with them and promote active chromatin or euchromatin. BRM and BRG-1 are the mammalian homologs of the ATPase subunit of the yeast SWI/SNF complex, which remodels host chromatin. Interestingly, knockdown of these coactivators did not reduce HSV IE gene transcription under certain conditions, suggesting that their function is redundant with unknown host factors in some cells and/or infection conditions.[254] VP16 interacts with numerous components of the Mediator complex.[341] Because the Mediator complex plays a central role in transcriptional activation, these interactions serve to recruit the Mediator complex for transcription of the IE genes.

HCF-1 also participates in transcriptional elongation in that it recruits components of a network of transcriptional elongation components including the super elongation complex.[13] IE gene transcriptional requires the SEC-P-TEFb complex, and BET inhibitors that increase TEFb levels increase lytic reactivation and reactivation from latency.[13] Moreover, inhibitors of TEFb reduce IE gene transcription and lytic infection.[12]

Shut Off of IE Gene Expression

There is evidence for several mechanisms by which HSV controls the accumulation of at least two IE gene products, ICP4 and ICP0.

First, ICP4 can repress its own expression by binding to its own promoter. ICP4 binds to DNA in either a sequence-specific or sequence nonspecific manner. The first ICP4-specific binding sequence reported by Faber and Wilcox was ATCGTCNNNNYCGRC and is defined as the consensus binding site. The second set of sequences bears no relationship to the consensus binding sites or for that matter, to each other. Consensus binding sites that span transcription initiation sites serve as sites for repression of transcription by ICP4, as illustrated by the *ICP4* gene in Figure 9.8. Binding of ICP4 to these sites at the 5′ end of its gene leads to repression of its expression. It is less clear whether ICP4 represses the expression of the other IE genes. ICP4 binds upstream of the *ICP0* gene transcriptional initiation site, and ICP4 represses the ICP0

promoter in transfected cells. Nevertheless, the specific effect of ICP4 on *ICP0* gene expression in infected cells has not been defined by construction of a mutant virus with the binding site in the *ICP0* gene mutated. Consensus ICP4-binding sites are not evident in or near the promoters of the other IE genes. ICP4-binding sites are also found in the *ORF P* and *LAT* gene promoters and have a negative regulatory effect on their transcription. ICP4 is more generally distributed on the viral genome as the infection progresses,[116] presumably to stimulate E and L gene transcription.

Second, during productive infection, E gene products down-regulate IE gene expression.[185] One E protein identified as a candidate repressor is ICP8, the single-stranded DNA-binding protein encoded by the U_L29 gene. ICP8 has been shown to coat viral progeny DNA and to decrease the expression of all genes from those progeny genomes, in particular transcription of the *ICP4* gene,[155] which may further inhibit viral transcription. Although the mechanism of this effect of ICP8 is not known, it may involve the sequestration of viral DNA molecules in replication complexes, changes in the conformation of viral DNA, or displacement of DNA to sites of DNA synthesis away from those required for transcription.

At early times, the virion host shutoff (vhs) function has been shown to degrade both viral and cellular mRNAs. The observation that in cells infected with *vhs* mutants, the transition from IE to E and subsequently to L protein synthesis lags behind that observed in wild-type virus–infected cells led to the conclusion that one function of *vhs* is to synchronize sequential viral gene expression. The proposed model is that the rate of transcription of viral genes exceeds the ability of vhs to degrade the mRNAs and that unless destabilized, IE mRNAs would outcompete L mRNAs, and so on. Vhs is described in more detail below.

De-Silencing and Expression of E and E/L Genes

Viral E genes are associated with heterochromatin marks by 1 to 2 hpi, and this is reduced as infection progresses to allow their transcription.[82,264] Because the temporal order of expression of E and E/L genes overlap, it is convenient to lump them together. Expression of these genes requires ICP4 and is increased by ICP0, in particular at low multiplicities of infection and in normal human cells. ICP0 acts in general to make the viral genome more accessible to transcription factors and RNA pol II, and ICP4 acts to recruit the transcription factors and RNA pol II to the viral genomes. Expression of these genes also requires, to a variable extent, ICP27, ICP22, US1.5, and, in the case of E/L genes, the onset of viral DNA synthesis. We will consider the role of these viral proteins individually.

ICP0

ICP0 is an E3 ubiquitin ligase that plays a major role in the de-silencing of the post-IE genes by countering host chromatin silencing mechanisms and in countering innate immune signaling and other host responses. ICP0 is not essential for viral replication in certain cell types at high MOI. At low MOI, cells infected with *ICP0* deletion mutants yield approximately 10- to 1,000-fold less virus than cells infected with wild-type virus, with the yield reduction varying with the cell type. At greater than 5 PFU per cell or greater, the yields of ICP0 mutant virus may be similar to those of wild-type virus in tumor cells and certain cell lines. The cell line most permissive for *ICP0* mutant viruses is U20S, which is defective for restriction factors because it does not express ATRX[290] or functional IFI16 protein.[347] Thus, U20S cells serve as the standard for infectivity titrations of ICP0 mutant virus stocks for experimental studies. Even using this cell

line for titrations, the particle:PFU ratio for ICP0$^-$ mutants may be higher than the ICP0$^+$ viruses[349,391]; thus, this may be a factor in differing results in certain papers. Nevertheless, ICP0 promotes HSV-1 replication by at least 10^3-fold in normal human fibroblasts,[348] consistent with the host restriction being more effective in normal human cells.[347]

The major functions of ICP0 in promoting viral replication are (a) de-silencing of the viral genome, in particular on the E and L genes and (b) inhibition of host innate immune signaling and other host responses. The former function is thought to be mainly through its E3 ubiquitin ligase-promoted degradation of restriction factors but may also occur due to disruption of inhibitory complexes.

Several lines of indirect evidence first raised the idea that ICP0 enables the expression of E genes by epigenetic de-silencing of these genes: (a) Histone deacetylase inhibitors (HDACs), such as trichostatin A and sodium butyrate, can rescue at least part of the ICP0 mutant gene expression defect, suggesting that ICP0 is overcoming epigenetic silencing in part by inhibiting HDAC activity. (b) ICP0 was reported to interact with class II histone deacetylases and to reverse repressive effects of these HDACs in transfected cells. (c) ICP0 binds to CoREST *in vitro* and dislodges HDAC1 from the HDAC1/CoREST/LSD1/REST (HCLR) complex in wild-type virus–infected cells. (d) Replacement of both copies of the *ICP0* gene with a gene encoding a dominant negative CoREST capable of binding REST but unable to bind HDAC1 led to a 100-fold increase in the yield of virus in Vero cells and an at least 10-fold increase in HEp-2 cells following low PFU/cell infection. A virus encoding an ICP0 unable to bind CoREST showed reduced ability to reactivate quiescent HSV-1, consistent with a role for REST/CoREST/HDAC1/2/LSD1 in repression of quiescent genomes.[135] Despite the weight of this evidence, knockdown of CoREST did not affect replication of an *ICP0* mutant in human HepaRG cells, a liver progenitor cell line.[130] The differences here may be due to the differences in cell types used or to the fact that CoREST both inhibits viral gene expression and stabilizes LSD1, which is needed for viral IE gene expression.[547]

Direct evidence for ICP0 promoting the de-silencing of viral chromatin came from the observation that ICP0 mutant viruses show increased total histone H3 association with viral promoters and decreased acetylation of histone H3 that is associated with viral promoters, a histone modification associated with euchromatin or active chromatin.[82] ICP0 also promotes the rapid removal of the heterochromatin H3K9 trimethylation marks from E gene chromatin in infected cells.[264] Furthermore, ICP0 promoted the removal of heterochromatin markers from viral chromatin during reactivation from quiescent infection in cell culture.[135] An unresolved issue is whether ICP0 also affects host chromatin. ICP0 increases the expression of host gene products, including p21, gadd45, and mdm2, potentially due to chromatin effects. HSV infection reduces histone H3 levels on the *GAPDH* gene promoter[166] but not on a *GAPDH* pseudogene.[82] Further studies are warranted to determine the effects of HSV infection and ICP0 specifically on host gene chromatin.

Role of the E3 Ubiquitin Ligase Activity of ICP0 in Promoting Protein Degradation

ICP0 promotes the degradation of a number of host resistance factors that can potentially restrict virus reproduction, and this is considered to be one of the major ways that ICP0 promotes the de-silencing of the viral genome. We will examine the mechanisms by which ICP0 promotes the

degradation of these host proteins and then discuss the host resistance factors and their mechanism of action.

The RING domain in exon 2 of ICP0, which is a C_3HC_4 zinc-binding domain[33] from residues 106 to 149, contains a ubiquitin E3 ligase activity. The RING domain E3 ligase activity is essential for ICP0's functions in transactivation of post-IE gene expression and for promotion of viral replication at low MOI. This is likely due to ICP0's promotion of the ubiquitination of cellular restriction factors followed by their subsequent degradation. ICP0 promotes the degradation of a large number of proteins, including PML; the SUMO-modified form of Sp100; centromere proteins CENP-A, -B, and -C; the catalytic subunit of DNA-PK[354]; the ubiquitin-specific protease 7 (USP7); the RNF8 cellular RING finger ubiquitin ligase[277]; ubiquitinated histones[277]; the RNF168 cellular E3 ligase[277]; IFI16[349]; and ATRX.[214]

Mechanism of Ubiquitination

It has been puzzling that ICP0 is able to promote the degradation of so many proteins. There is evidence for some direct interactions that lead to ubiquitination. ICP0 does bind directly to a protein with ubiquitin-specific protease activity, USP7, also called herpesvirus-associated ubiquitin-specific protease or HAUSP and promotes its ubiquitination *in vitro*. ICP0 binds to the DNA repair protein RNF8 and purified ICP0 ubiquitinates RNF8 *in vitro*.[277] The interaction between ICP0 and RNF8 is believed to be due to the forkhead domain of RNF8 binding to a specific domain on ICP0 that is phosphorylated.[67] These are the only known direct substrates of the ICP0 E3 ligase activity. At least one potential contributing factor to the broad effect of ICP0 is that it contains several SUMO-interacting domains (SIMs)[47] that bind to the common peptide moiety named SUMO (small ubiquitin-like modifier), which is covalently linked as a posttranslational modification to the epsilon amino group of lysine in the tetrapeptide consensus motif Ψ-K-x-D/E where Ψ is a hydrophobic residue, K is the lysine conjugated to SUMO, x is any amino acid, and D or E is an acidic residue. Mutations in multiple SIM domains in ICP0 reduce degradation of PML isoforms in general.[47] However, the PML I isoform is also degraded in a SUMO-independent manner.[47] Therefore, the role of the SIM may be either as the primary interaction of ICP0 with proteins or to bring ICP0 into the area of proteins with which it interacts directly or indirectly for ubiquitination. Evidence for the latter was that SIM function was necessary but not sufficient for ICP0 promotion of PML isoform II degradation.[545] Proteomics analysis of ICP0 interactors showed mostly the direct binders of ICP0,[88] suggesting that the SUMO interactions may be weak interactions.

Degradation of Host Restriction Factors

A number of host cell responses to viral infection have been defined, and they have been broadly classified as intrinsic resistance and innate immune responses. Intrinsic resistance is often defined as constitutively expressed host factors that reduce viral replication, while innate immunity is considered to be factors that are induced by signaling pathways. However, this breaks down for several host factors such as PML and IFI16, which are expressed constitutively but are induced by interferons, so they could be considered to be effectors of either intrinsic resistance or innate immunity.

Host Cell Restriction Factors Affected by ICP0

Promyelocytic Leukemia (pml) Protein

The PML protein is a member of the tripartite motif (TRIM) family of proteins and contains a RING domain, two zinc-binding B-box domains, and a coiled-coil domain. As described above, PML protein localizes with and serves as a scaffold for other cellular proteins in ND10 bodies, including Sp100, DAXX, and ATRX. These proteins have all been associated with restriction of HSV gene expression.[48] PML can act independently of Sp100 and Daxx to inhibit HSV-1 replication in HepaRG cells and fibroblasts.[154] Interestingly, some studies at low multiplicity of infection show that PML can enhance HSV replication.[313,524,525] Furthermore, Ishov et al.[195] reported that PML-NBs may provide a platform for HCMV gene expression and replication, and PML-NBs have been reported to localize near incoming and early-replicating HSV-1 viral DNA (vDNA). Thus, PML is part of both a constitutive resistance mechanism and the antiviral mechanism of IFNs but may also support viral replication by other mechanisms.

PML acts to restrict HSV ICP0$^-$ mutant virus plaque formation by three- to fivefold as shown using shRNA depletion or by threefold in wild-type MEFs versus knockout MEFs. The detailed mechanism of the restriction by PML has not been defined, but PML has been shown to increase loading of heterochromatin of histone H3.3 with H3K9me3 modifications during HSV-1 quiescent infection of fibroblasts and to promote the maintenance of heterochromatin modifications including H3K9me3 and H3K27me3 on ICP0$^-$ virus genomes.[55] While it is generally thought that PML promotes epigenetic silencing of the viral genome, some have reported that PML encases incoming viral DNA and sterically blocks RNA pol from transcribing the genome.[9] Thus, there are multiple mechanisms by which PML might act to epigenetically silence HSV DNA.

α-Thalassemia X-Linked Intellectual Disability (ATRX)

ATRX, a SWI/SNF chromatin remodeler protein, is a crucial epigenetic regulator of eukaryotic gene expression and silenced heterochromatin. ATRX and death domain-associated protein (Daxx) together form a histone chaperone complex that loads the noncanonical histone variant 3.3 (H3.3).[115,269] This complex is also critical for maintaining repressive heterochromatin at many repeat-rich regions, including telomeres,[287] pericentric repeats,[129] and endogenous retroviruses,[129] and mutations in the *ATRX* gene are linked to a developmental disorder and several cancer types.[287] ATRX and DAXX are also two of the core components of ND-10 structures, as described above. Depletion of ATRX increased plaque formation by an ICP0$^-$ virus by sixfold, and restoration of ATRX reduced plaque formation to control levels, while ATRX depletion did not significantly affect plaque formation by an ICP0$^+$ virus.[290,413,420,472] Depletion of Daxx also increased plaque formation by an ICP0$^-$ virus but did not affect ICP0$^+$ virus plaque formation. The Daxx interaction site on ATRX was needed for the restriction and recruitment of ATRX to genome complexes.[290,413,420,472] In total, these results argue that ATRX and Daxx act in a complex to restrict HSV-1 ICP0-deficient virus replication. HSV-1 infection reduces levels of ATRX by several mechanisms, including ICP0-promoted protein degradation, miR-H4 reduction of mRNA levels, and vhs reduction of mRNA levels.[214]

Recent studies have shown that ATRX localizes to the input HSV-1 genome within minutes after infection.[9,55] However, ATRX did not promote histone association as measured for histone H3; rather, it promoted maintenance of histone H3 and heterochromatin marks on the viral

genome when the genome was transcribed or replicated to restrict transcription from parental and progeny templates.[55] Recent studies have shown that although H3 is loaded to normal levels as determined by ChIP, accessibility of the viral genome as measured by ATAC-seq is increased when ATRX is knocked out.[54]

Interferon Gamma–Inducible Protein 16 (IFI16)

IFI16 is a member of the PYHIN protein family. It contains an N-terminal pyrin domain, which mediates protein–protein interactions, and two C-terminal HIN domains, which confer sequence nonspecific double-stranded DNA (dsDNA)-binding ability.[203] IFI16 binds to dsDNA and diffuses along the DNA until it multimerizes with other IFI16 molecules to give stable binding[449]; however, positioning of a nucleosome on the DNA molecule prevents translocation and multimerization of IFI16 and inhibits stable binding of IFI16 to the DNA molecule.[449]

Depletion of IFI16 in human fibroblasts leads to an increase in replication of ICP0-null viruses and enhanced viral gene expression,[348] and overexpression of IFI16 leads to restricted replication of ICP0$^-$ viruses[348] and restricted viral gene expression of ICP0$^+$ viruses.[207] When IFI16 levels are increased by γ-interferon treatment of human fibroblasts, IFI16 can restrict replication and gene expression of wild-type, ICP0$^+$ HSV-1 and HSV-2.[437] Thus, at baseline levels, IFI16 serves as a restriction factor for ICP0$^-$ viruses and when overexpressed or when induced by interferon-γ, for wild-type viruses.

Although IFI16 has been observed to associate with ND10 proteins[110] and to colocalize with PML and ATRX at input viral genomes and genome complexes,[131,348] IFI16 restricts gene expression from both parental and progeny viral genomes by independent mechanisms.[313] It localizes to input viral genomes within 15 minutes after entry into the nucleus[55] and stabilizes histone H3 on viral chromatin.[312] In contrast, at later times after viral DNA replication in ICP0$^-$ mutant–infected cells, IFI16 forms filaments decorated with PML, Sp100, and ATRX within a subset of viral replication compartments, and there is evidence that these filaments act in *trans* to reduce RNA pol II loading onto viral genomes to restrict viral transcription.[312] While the mechanism(s) of this novel structure have not been elucidated, the evidence thus far is consistent with IFI16 binding to progeny DNA molecules, multimerizing on them, and recruiting a series of restriction factors in a structure that initiates a general epigenetic restriction of viral transcription,[312] similar to supramolecular organizing centers that initiate innate signaling.[217]

Infection with viral strains expressing ICP0 causes a RING-finger–dependent, proteasome-dependent loss of IFI16, consistent with ubiquitination and degradation.[349] Some have observed no specific degradation of IFI16 due to ICP0,[94] but certain cells, especially tumor cells, were shown to encode nonfunctional IFI16.[347] The bulk of the evidence supports IFI16 functioning in normal cells and being degraded by ICP0 in those cells but that IFI16 may be defective in tumor cells,[347] due to its inhibitory effects on cell growth,[438] and thus may not be binding to viral DNA and not activated to interact with ICP0, resulting in a lack of IFI16 degradation in those cells.

DNA-Dependent Protein Kinase

The DNA-dependent protein kinase (DNA-PK) complex, consisting of the catalytic subunit (cs) and the Ku70/Ku80 heterodimer, binds to DNA breaks or ends and activates a DNA damage response (DDR) that results in repair by nonhomologous end joining. The linear ends of the

incoming viral DNA may be recognized and joined together to block circle formation by DNA ligase IV/XRCC4. Consistent with this, mutant cells defective for Ku70 showed increased viral replication.[466] As described above, ICP0 promotes the degradation of DNA PKcs.

Inhibition of Activity of Host Factors

ICP0 may inhibit or sequester other host factors without promoting their degradation. ICP0 blocks the nuclear accumulation of interferon-regulatory factor 3 (IRF-3) but does not prevent its phosphorylation in the cytoplasm. There is some reduction of IRF-3 levels due to ICP0 but that shows later kinetics than the ICP0-dependent inhibition of interferon expression. At early times postinfection, ICP0 may sequester IRF-3 at nuclear sites and away from the *IFNβ* gene promoter.[350]

ICP4

ICP4 fulfills the second function needed for post-IE gene transcription, that is, recruitment of transcription factors and RNA pol II to these gene promoters. ICP4 is required for maximal levels of all post-IE gene expression,[238] and the effect of ICP4 is exerted at the transcriptional level in infected cells, as demonstrated by nuclear run-off assays.[155] ICP4 has been shown to also activate gene expression in transfected cell assays and in *in vitro* transcription systems.[395]

ICP4 is thought to function by the general mechanism of binding to the viral genome and recruiting transcription factors and RNA pol II. As discussed above, ICP4 has both sequence-specific and nonspecific DNA-binding activities. Sites bound by ICP4 with the strongest affinity are known to have their transcription repressed rather than activated by ICP4 (e.g., at the transcription initiation sites of the *ICP4* or *ORF P* genes), and destruction of the sole sequence-specific binding site of ICP4 upstream of the transcription initiation site of the *ICP4* gene attenuated repression in the context of the viral genome. With regard to the role of DNA binding in the transactivation function of ICP4, early mutational analysis studies showed that the sequence-specific binding activity of ICP4 correlated in most studies with its ability to activate E gene expression in infected cells. In addition, insertion of ICP4-binding sites was reported to render reporter genes responsive to ICP4, albeit in transfected cells. Furthermore, there was a postulated role for the DNA-binding ability of ICP4 in stabilizing the binding of cellular transcription factors to E and L gene promoters. However, one viral mutant was obtained in which the DNA-binding activity of ICP4 was greatly reduced, but the ability to activate E genes in infected cells was nearly unchanged. Originally, it was thought that most post-IE genes did not have recognizable consensus binding sites for ICP4, and mutation of consensus sites did not affect the level of expression of the surrounding genes in the viral genome. However, recent ChIP-Seq studies of ICP4 binding to the viral genome in infected cells have defined the *in vivo* consensus site as A/G/T-T-C/G/T-T/G/C-G/C/T-G/A/T/C-T/C/A-G/C/T/A-G/C/A/T-CTA-C/G-G,[116] similar to the original consensus sequence. This recent study showed that ICP4 is distributed across the viral genome, providing a potential mechanism for ICP4 to transactivate a broad range of viral genes.[116]

Second, ICP4 has been shown to interact with basal transcription factors to form complexes with TATA-binding protein, TFII-B and TAF250[268,404,492] as well as ICP27, ICP22, and the cellular CLOCK HAT.[220] ICP4 promotes the formation of transcription preinitiation complexes *in vitro* on the *gC* gene promoter, at least in part by stimulating the binding of TFIID to the

promoter to form preinitiation complexes. ICP4 also interacts with the Mediator complex,[268] a large protein complex that bridges upstream activators and the preinitiation complex. ICP4 binding across the viral genome is essential for the recruitment of TBP, Mediator, and RNA pol II, and transcription of the viral genome.[116]

ICP27

ICP27 is an IE protein that is reported to have multiple regulatory functions in viral gene expression, including promoting expression of certain E proteins, L gene transcription, viral RNA export from the nucleus to cytoplasm, and translation of viral mRNAs. ICP27 comprises the following functional domains from N to C terminus: a leucine-rich region, an acidic region–nuclear localization signal, an RGG box RNA-binding domain, two predicted KLH RNA-binding domains, and a zinc finger–like region.[469] It also forms a homodimeric structure through multiple interactions in the C-terminal half of the molecule, as shown by the crystal structure of residues 241 to 512.[473]

Early studies of viral gene expression concluded that ICP27 is required only for viral DNA replication and L gene expression, but further studies showed that ICP27 is also needed for efficient expression of certain E genes, in particular the less abundant viral DNA replication proteins. Thus, ICP27 is required at least in part indirectly for viral DNA replication by increasing the mRNA levels of E gene products essential for viral DNA synthesis. These studies showed that ICP27 increases the mRNA levels for these E genes, but it has not been determined if this effect is transcriptional or posttranscriptional. ICP27 affects the cytoplasmic levels of only a subset of E mRNAs because Northern blot studies have shown that an ICP27 null mutant virus expresses levels of ICP8 mRNA at 6 hpi that are equivalent to wild-type virus. These early studies were conducted in Vero (African green monkey) cells, and similar studies in normal human cells are warranted.

HSV ICP27 mutant viruses are defective for L *gC* gene transcription as assayed by infected cell pulse labeling of RNA. ICP27 associates with the RNA pol II holoenzyme through its interaction with the C-terminal domain of the large RNA pol II subunit, consistent with an ability to enhance initiation or termination of transcription. ICP27 has been shown to bind to ICP4, to alter ICP4 phosphorylation, and to localize to replication compartments. ICP27 interacts directly with ICP8, which associates with viral progeny DNA. Therefore, ICP27, through its interactions with ICP8 and RNA pol II, is proposed to link RNA pol II to progeny viral DNA to promote late viral gene transcription. Consistent with this, some immunofluorescence studies have shown that certain *ICP27* mutant viruses are defective for recruitment of RNA pol II to replication compartments in infected cells, but others have failed to see a defect in RNA pol II recruitment with the HSV-1 *n*406 and *n*504 ICP27 mutant viruses (with nonsense mutations at the indicated codons) in human U2OS cells.[310] The difference in the latter results may be due to the fact that U2OS cells are known to have reduced restriction factor expression and activity.[290,347,532] In general, these properties are consistent with effects on transcription of late HSV genes. The ability of ICP27 to promote L viral gene expression is at least partly distinct from its ability to stimulate viral DNA synthesis because at least one mutant virus, *n*504, separates these two functions. This mutant is defective for L gene expression while maintaining normal levels of viral DNA synthesis. The *n*504 mutant virus has been used to demonstrate that ICP27 stimulates transcription of L genes independently of its role in stimulating E gene expression and viral DNA replication.[200] This study found that ICP27 promotes transcription of at least two L genes,

U_L44 and *U_L47*, in infected cells, as assayed by *in vivo* pulse labeling of RNA, without any apparent effects on transport or stability of these transcripts. ICP27 has also been reported to affect the elongation, termination, and/or polyadenylation site selection during transcription. A recent study reported that ICP27 disrupts cellular 3′ RNA processing by binding and disrupting the cleavage and polyadenylation specific factor (CPSF) complex but preserves viral 3′ RNA processing by binding to a GC-rich sequence in viral 3′ UTRs and recruiting an alternative CPSF complex to viral transcripts.[501]

ICP27 has been shown to shuttle between the nucleus and cytoplasm and is reported to promote viral RNA export in several studies. However, in some cases, the viral mutants used may have an additional defect in late gene transcription. There are differing results on the role of ICP27 in viral mRNA export because one study found that E ICP8 mRNA is present in the cytoplasm of an *ICP27* null mutant virus–infected cell at nearly normal levels (82%) compared to that in wild-type virus–infected cells, while another study found substantially lower amounts of *ICP8* as well as other E and L transcripts in the cytoplasm of *ICP27* mutant–infected cells. Furthermore, measurement of viral transcript levels by microarray technology shows a broad spectrum of viral poly $(A)^+$ transcripts are retained in the nucleus in cells infected with *ICP27* mutant viruses,[209] while studies looking at specific viral mRNAs using Northern blot hybridization found that (a) the long *U_L24* gene transcript was increased in the nucleus of *ICP27* mutant–infected cells, but the short *U_L24* gene transcript was unaffected; (b) VP16 mRNA export was not altered in *ICP27* mutant–infected cells[128]; and (c) ICP27 is not required for cytoplasmic accumulation of gD and ICP5 mRNAs.[140] Therefore, these studies showed a limited number of specific transcripts that show a dependence on ICP27 for nuclear export and cytoplasmic accumulation. In total, ICP27 binds to RNA pol II, promotes late gene transcription, promotes association of RNA-binding proteins to late transcripts, may escort mRNAs to the cytoplasm, and enhances the binding of translation factors to mRNA, as discussed below.

ICP27 binds to the cellular factor Aly or REF, and this interaction promotes mRNA export out of the nucleus.[209,469] Aly/REF is an RNA export factor that functions as a molecular chaperone and export adaptor involved in nuclear export of spliced and unspliced RNAs. Aly/REF can act as a chaperone to promote dimerization of transcription factors containing basic leucine zipper (bZIP) domains and thereby promote transcription.[422,488] Aly/REF is recruited to the 5′ end of the RNA transcript by the cap-binding complex and recruits other export factors such as the TREX complex,[488] which stimulates RNA export. Thus, the interaction of ICP27 with Aly/REF could act to stimulate any of the stages of synthesis, processing, or export of viral mRNAs.

Effects of IE Gene Products on Host Transcription and RNA Splicing

HSV infection inhibits host cell transcription, including RNA pol II and RNA pol I transcription,[395] and this requires ICP4 and ICP27. Pulse labeling of nascent transcripts with 4-thiouridine (4sU), ribosomal profiling, and analysis by next-generation sequencing have confirmed the decrease in host cell transcription in infected cells. However, it was also observed that the remaining active cellular transcription units show a defect in transcriptional termination.[400] The transcriptional readthrough gives novel splice sites and an apparent inhibition of RNA splicing. ICP27 was not needed for a reduction in transcriptional termination in infected cells in an initial publication,[400] but further studies showed that ICP27 when

expressed alone disrupted transcriptional termination.[501] The proposed mechanism of ICP27 action is binding to CPSF, an mRNA 3′ processing factor, and inducing the assembly of a complex that is unable to cleave 3′ ends of mRNAs.[501] Viral transcription termination continues because ICP27 binds to GC-rich regions on viral mRNA 3′ ends and activates 3′ end processing. Finally, ICP27 interacts with and leads to modification of a number of cellular splicing factors and inhibits splicing.[463,464] While most HSV mRNAs do not contain introns, some viral mRNAs (ICP0, ICP47, ICP22, UL15) are spliced; thus, viral mechanisms exist that allow these viral transcripts to be spliced in the infected cell.

Organization of E and L Gene Promoters

Unlike IE genes, E or L genes do not have unique promoter elements that predict the timing, duration, or abundance of gene expression. Rather, the overall impression is that they appear to be made up of a diversity of elements, and both the organization and the context in which these elements are placed determine the expression of the gene. Nevertheless, the E gene promoters thus far studied contain binding sites for two to three cellular transcription factors upstream of the transcriptional start site (thymidine kinase (*tk*) gene–Fig. 9.8). The mechanism of activation of E genes has also been approached in studies attempting to map the *cis*-acting sequences needed for activation by virus infection or ICP4. The most extensively studied E gene promoter is that of the U_L23 or *tk* gene. Extensive mutagenic analyses of the promoter showed that the sequences needed for basal level transcription and activated transcription were the same (Fig. 9.8): a proximal signal from bp −12 to −29 containing a TATA box and two distal signals from bp −47 to −61 and −80 to −105 containing an SP1 transcription factor binding site and an SP1 site and a CCAAT transcription factor (CTF) site, respectively. These studies also supported the hypothesis that ICP4 transactivates E gene promoters through interactions with cellular basal transcription factors.

Expression of L Genes

Once viral DNA replication (described below) has initiated, expression of L genes is increased,[185] largely as a result of increased transcription.[155] Late transcription takes place in replication compartments within the infected cell nucleus, as evidenced by (a) the localization of ICP4 and RNA pol II, to replication compartments at late times, and (b) RNA-pulse labeling of replication compartments at late times.

We know that during late gene expression: (a) transcription of late genes increases upon replication of the viral genome,[155] (b) alteration in the viral DNA template during DNA synthesis is cis-acting, (c) certain forms of heterochromatin are removed or diluted by viral DNA synthesis,[264] (d) ICP4 binding to the genome decreases to only the high affinity sites,[116] (e) ICP8 assembles on the progeny viral DNA, and (f) the ICP4, ICP22, ICP27, and ICP8 proteins are required for optimal L gene expression. The cis-acting effect on the template could be due to changes in the viral DNA molecules themselves by exposure of single-stranded regions or by conversion of the viral genome from a circular form to a linear form. Alternatively, the *cis*-acting effect could be due to proteins tightly bound to the viral parental DNA that do not exchange to other DNA molecules in the infected cell. ICP4 promotes L gene transcription by promoting the assembly of preinitiation complexes on the L *gC* gene promoter. ICP27 and ICP8 have been hypothesized to stimulate late gene transcription by recruiting RNA pol II onto progeny DNA

through a direct interaction that bridges ICP27 bound to RNA pol II with ICP8 bound to viral progeny DNA. Additional interactions of RNA pol II holoenzyme with ICP4 would lead to preinitiation complexes on late gene promoters.

As a general rule, while sequences upstream of transcriptional initiation sites are sufficient to endow a reporter gene with E gene expression kinetics both in transfected cells and in the context of the viral genome, this is not generally true of L genes. In the context of the viral genome, expression of reporter genes as L genes also requires regulatory elements present in the 5′ transcribed noncoding domains. Even then, such chimeras are expressed as E genes in cells transfected with the chimera and then superinfected with the virus.

The HSV E/L promoters have not been studied as extensively as some of the other viral promoters, but the *ICP5* (*U_L19*) gene promoter elements have been defined (Fig. 9.8). The essential elements of the minimal *ICP5* gene promoter are (a) an SP1 binding site at −48, a TATA box at −30, and an essential cis-acting element between −2 and +10 whose sequence resembles the HIV initiator element. A cellular factor that binds at the cap site has been identified. The E/L gene promoters are heterogeneous in that the minimal VP16 gene promoter from bp −90 to +6 contains an E Box (CACGTG) at −85, a CAAT box at −77, and an SP1 site at −48, and a different initiator element.

Analyses of L viral gene promoters have shown that the upstream sequences consist of a TATA box with few other upstream transcription factor binding sites and with additional sequences needed for activation within the 5′ untranslated region. For example, the L *U_L38* gene promoter (Fig. 9.8) contains three elements: (a) an unusual TATA element with the sequence TTTAAA at −29, (b) a consensus initiator element at the transcriptional start site, and (c) a downstream activation sequence (DAS) from bp +20 to +33 that is required for normal levels of gene expression. The DAS seems to increase transcriptional initiation, and several other HSV L genes, including *U_S11*, *gC* (*U_L44*), *gB* (*U_L27*), *L/ST*, and *U_L49.5*, have similar downstream control elements in their promoter. In addition, the *gC* gene DAS can partially substitute for the *U_L38* DAS, suggesting that common mechanisms may act on the different DAS sequences. The Ku70 or DNA-binding subunit of the DNA-dependent protein kinase and hTAF(II)70 have been identified as factors binding to the DAS. Given that HSV infection leads to the degradation of the catalytic subunit of DNA-PK and loss of kinase activity, this effect may free up the Ku70 subunit for interaction with viral DNA.

ICP22/US1.5

ICP22 is required in certain cell types for optimal accumulation of a subset of late (L) gene products exemplified by the US11, UL38, and UL41 proteins. This function largely maps to the C-terminal domain of ICP22 and can also be contributed by the smaller *U_S1.5* gene product.[320] In particular, in human lung fibroblasts at late stages of infection, viral transcript levels are reduced to some extent across all kinetic classes in the absence of ICP22 expression.[141] ICP0 is among the affected IE genes, and ICP22 and US1.5 have been shown in transient transfection assays in Vero cells to also limit ICP0-mediated transactivation of reporter genes.[49,320] Whether this effect is independent of ICP22-dependent effects on viral gene expression remains unclear; nor is it yet known whether the effects of ICP22 on viral transcript levels are transcriptional or posttranscriptional.

ICP22 interacts with a number of cellular proteins, and the resulting changes to the infected

host cell may explain its effects on viral gene expression. First, ICP22 alters RNA pol II phosphorylation during infection, potentially affecting RNA pol II transcriptional activity. In conjunction with the UL13 protein kinase, ICP22 causes accumulation of a form of RNA pol II phosphorylated at the serine-5 position in the C-terminal domain. In addition, early in infection and independently of UL13, ICP22 causes the loss of serine 2-phosphorylated RNA pol II. ICP22 has also been found to interact with cdk9, and this complex can phosphorylate the C terminus of RNA pol II in a US3 kinase–dependent manner.[122] Second, ICP22, in conjunction with the UL13 protein kinase, mediates the activation of the cdc2 kinase and the degradation of the cdc2 binding partners, cyclins A and B. cdc2 subsequently acquires a new partner, the UL42 DNA polymerase processivity factor. The cdc2-UL42 complex recruits topoisomerase IIα in an ICP22-dependent manner to promote L gene expression. It has been proposed that the ICP22/UL42/topoisomerase complex enables transcription of newly synthesized concatemeric DNA, which in the absence of this complex could accumulate in tangles, blocking access of the transcriptional machinery. ICP22 is also required for the formation of nuclear foci that contain cellular chaperone proteins, proteasomal components, and ubiquitinated proteins.[35] These foci typically form near replication compartments and could potentially affect viral gene expression in replication compartments. Lastly, there is also evidence that ICP22 promotes the elongation of viral gene transcripts through the recruitment of cellular transcription elongation factors to viral DNA late in infection.[141] ICP22 may thus facilitate viral late gene expression through specific effects on transcription elongation.

Export of Viral RNA From the Nucleus

The export of cellular mRNA from the nucleus is coupled to RNA splicing in the nucleus. As HSV infection inhibits RNA splicing, this thus raises the question of how nascent viral transcripts are transported from their site of transcription in the nucleus to the cytoplasm for translation in HSV-infected cells. In addition to the potential role of ICP27 in nuclear export of viral RNAs as described above, HSV replication compartments move from the periphery of the nucleus of infected cells and coalesce at nuclear speckles, a movement process involving active transport using nuclear actin and myosin and ongoing transcription. This coalescence of compartments and the resulting nuclear arrangement promotes export of late viral mRNAs, the vast majority of which lack introns.[64] This argues that a new export system for viral mRNAs may be assembled in the nucleus of infected cells.

Posttranscriptional Control of Viral Gene Expression in the Cytoplasm

Subverting Host Signaling Pathways that Regulate Ribosome Loading onto mRNA

Like host cell mRNAs produced by the cellular RNA pol II, all HSV mRNAs contain a modified 5′-terminal “cap” structure composed of 7-methylguanosine (m^7G) joined via a 5′-5′ triphosphate bridge to the transcript 5′-end that is installed cotranscriptionally by cellular capping enzymes. Besides providing mRNA stability, this 5′-cap ensures recognition of viral mRNAs by host translation initiation factors that load 40S ribosomes onto mRNA.[360] While host protein

synthesis is curtailed in HSV-1–infected cells, the cellular protein synthesis machinery is stimulated by multiple, independent viral functions designed to subvert host regulatory controls that normally limit mRNA translation in response to physiological stress.[199,446] Loading 40S ribosomes onto capped mRNA is tightly regulated and dependent upon eukaryotic translation initiation factors (eIFs) (Fig. 9.9). Cap recognition by the cellular cap-binding protein eIF4E is normally followed by binding to the large scaffolding component eIF4G, which associates with an ATP-dependent RNA helicase eIF4A and the eIF3-bound 40S ribosome. By binding to and sequestering the cap-recognition protein eIF4E, the eIF4E-binding protein (4E-BP) family of translational repressors regulates eIF4E availability, restricts eIF4G-binding and 40S ribosome loading, and controls cap-dependent translation.[360,446] Activation of PI-3 kinase-Akt signaling in uninfected cells stimulates mTORC1, which hyperphosphorylates 4E-BP1 and releases eIF4E from the repressor. This regulatory circuit is tightly controlled in normal primary cells and contains a negative feedback circuit to limit PI-3 kinase Akt-dependent activation of mTORC1. To prevent 4E-BP1 from restricting virus protein synthesis and enforce high-level mRNA translation in infected cells, HSV encodes the α-herpesvirus–specific ser/thr protein kinase US3 to ensure constitutive mTORC1 activation during the productive growth cycle[78] (Fig. 9.9). Even though US3 exhibits little resemblance to any specific cellular ser/thr kinase, which confounds target substrate prediction, it shares many substrates with the cellular kinase Akt, including tuberous sclerosis complex (TSC) subunit 2. By directly phosphorylating TSC2 on identical sites targeted by Akt, US3 prevents TSC from inhibiting mTORC1 and constitutively stimulates mTORC1-dependent phosphorylation and inactivation of the 4E-BP1 repressor[78] (Fig. 9.9). This guarantees availability of sufficient, active eIF4E cap-binding protein pools during the viral productive replication program needed to support HSV mRNA translation.

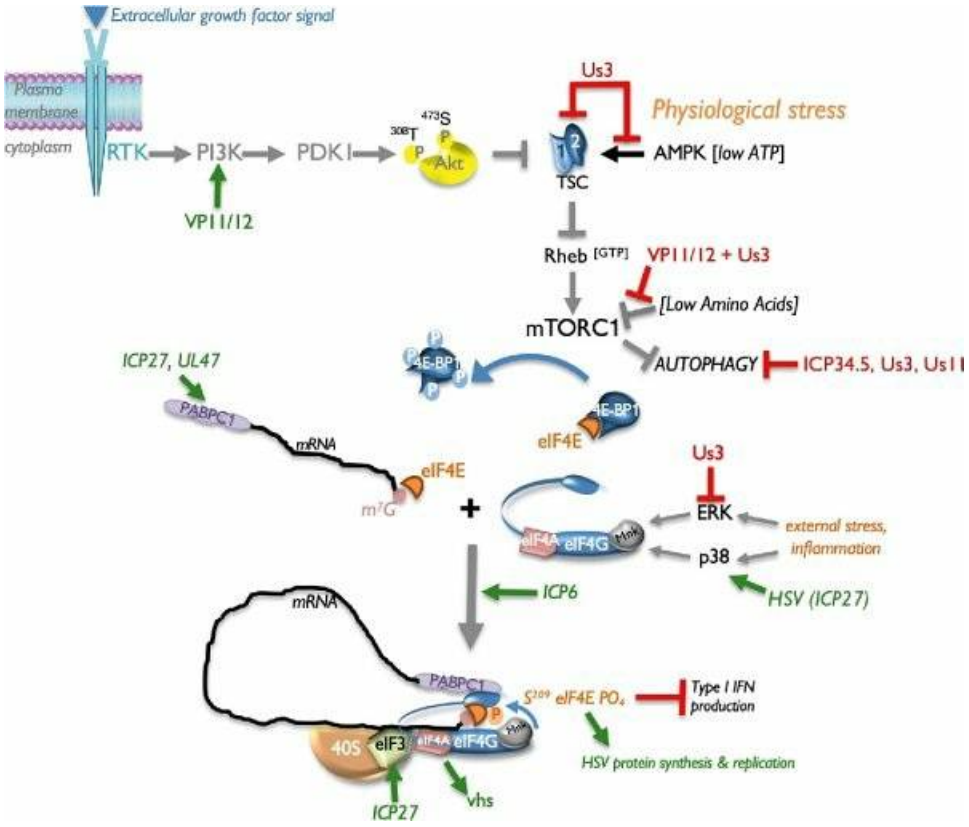

FIGURE 9.9 Regulation of the cellular cap-dependent translation initiation machinery in HSV-infected cells. Cell signaling pathways are depicted that sample extracellular and intracellular cues to regulate mTORC1 activity and allow mRNA translation to be responsive to changing environmental and physiological conditions (including infection). In uninfected cells, Akt phosphorylation (T308, S473) and activation in response to an activated growth factor receptor tyrosine kinase (RTK) represses the tuberous sclerosis complex (TSC1/2). Subsequent Rheb-GTP accumulation in response to TSC inhibition activates mTORC1. Physiological stress (energy, amino acid [aa] insufficiency) represses mTORC1 through specific effectors. Phosphorylation and inactivation of 4E-BP translational repressor family members, including 4E-BP1, by mTORC1 stimulates m^7G cap-dependent translation initiation by regulating availability of the cap-binding protein eIF4E. Once released from 4E-BP1, eIF4E physically associates with eIF4G, which interacts with the DEAD-box-containing RNA helicase eIF4A, and assembles a multisubunit protein complex called eIF4F on the m^7GTP-capped mRNA 5′-terminus (*m^7G*). Regulated assembly of eIF4E, eIF4G, and eIF4A into the eIF4F complex controls cap-dependent mRNA translation as eIF4F recruits eIF3-bound 40S subunits to the mRNA capped 5′ end. HSV-encoded factors that stimulate (*green*) and repress (*red*) the indicated cellular effectors to regulate mRNA translation in infected cells are indicated.

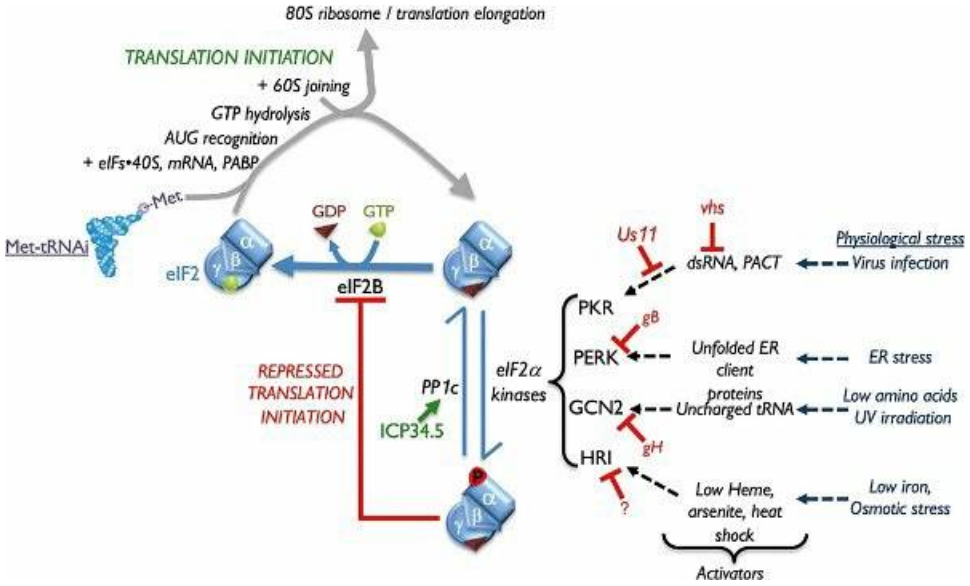

FIGURE 9.10 Multiple, independent HSV-encoded functions prevent eukaryotic initiation factor eIF2α phosphorylation and support translation initiation. **Left:** eIF2 is a GTP-binding, cellular translation initiation factor composed of three subunits (α, β, γ). It functions to load eIF3-bound 40S ribosomal subunits with methionyl-transfer RNA (Met-tRNAi). Following recruitment of mRNA, recognition of the AUG start codon, and GTP hydrolysis stimulated by eIF5, 60S subunit joining with 40S subunits completes 80S ribosome assembly and translation initiation commences. Inactive eIF2•GDP is released, and the guanosine nucleotide exchange factor (GEF) eIF2B is required to recycle active GTP-bound eIF2. Upon phosphorylation of eIF2α on S51 by either of four known eIF2α kinases, tight binding of eIF2B to phospho-eIF2 inhibits recycling of inactive eIF2•GDP to active eIF2•GTP thereby repressing translation initiation. **Right:** Each cellular eIF2α kinase is stimulated by specific activator molecules (*activators*) that accumulate in response to a discrete physiological stress. Partnered with the HSV-encoded regulatory subunit ICP34.5, the protein phosphatase 1 catalytic subunit (PP1c) promotes eIF2α dephosphorylation. HSV functions that activate (*green*) or repress (*red*) the indicated host effectors are shown.

Besides overcoming translational repression dependent upon 4E-BP1, translation initiation requires 40S ribosome recruitment onto viral mRNAs. This is stimulated by the multifunctional HSV-1 ICP6 protein, which physically interacts with eIF4G and promotes eIF4G binding to eIF4E[494] (Fig. 9.9). As eIF4G associates with eIF3-bound 40S ribosomes, this provides a molecular mechanism whereby 40S ribosome loading onto capped mRNA is stimulated in HSV-infected cells. It further represents an early role for the multifunctional ICP6 protein, originally identified as the large ribonucleotide reductase subunit, and potentially explains in part why the large subunit is expressed earlier than small subunit, the latter being required in a complex with ICP6 for ribonucleotide reductase activity.

By stimulating binding of eIF4E to eIF4G, ICP6 also stimulates eIF4E phosphorylation (Fig. 9.9) by bringing the cellular eIF4G-associated kinase Mnk1 into proximity of its substrate eIF4E.[494] Phosphorylation of eIF4E regulates selective mRNA translation and in doing so

impacts innate immune responses by stimulating translation of IκBα mRNA, which in turn limits NF-κB activation and type I interferon production.[173] Thus, in addition to stimulating assembly of a translation initiation factor complex needed for viral mRNA translation, HSV functions also stimulate modification of eIF4E to selectively prevent cell intrinsic antiviral responses.

The recruitment of 40S ribosomal subunits to mRNA is also stimulated by ICP27, which associates with the host PABPC1 C-terminal domain.[431] By interacting with PABPC1, an ICP27-MS2 fusion protein tethered to a reporter gene containing 3′-MS2–binding sites enhanced translation in an eIF4G-dependent manner.[431] ICP27 is found associated with PABPC1, eIF4G, and eIF3 and stimulates translation of a subset of viral late mRNAs in infected cells.[112,128,140] Paradoxically, PABPC1 subcellular distribution is altered upon infection in an ICP27-independent manner, and the majority of the protein accumulates within nuclei late in infection.[112,403] Nuclear retention of PABP could potentially facilitate selective deposition of PABPC1 onto viral mRNAs coincident with their ICP27-dependent export, because PABPC1 nuclear export in mammalian cells predominantly reflects mRNA trafficking,[157] and ICP27 enables nuclear export of viral mRNAs.[469] PABC1, however, is not effectively retained upon isolation of cap-binding translation initiation factor complexes from HSV-1–infected cells,[493] in contrast to findings in uninfected and HCMV-infected cells. Further investigation is needed to better resolve the roles of PABPC1 in HSV-infected cells.

Finally, properties of ribosomes themselves may be altered in response to HSV-1 infection. Originally regarded as invariant, homogenous components charged exclusively with decoding mRNA, evidence now suggests that ribosome protein composition is heterogeneous and can regulate gene expression. Results from a recent siRNA screen targeting individual ribosome proteins (RPs) revealed that overall protein synthesis in uninfected cells was more sensitive to RP depletion than in HSV-1–infected cells.[485] Continued protein synthesis despite RP depletion required late viral gene expression and was specifically dependent upon the HSV-1–encoded RNA-binding protein VP22. Thus, VP22 is able to overcome RP insufficiency, which could conceivably support viral protein synthesis and replication and in response to RP variations across cell types and physiological conditions. Further work is required to decipher the underlying mechanism of how VP22 compensates for RP insufficiency.

Preserving Translation Initiation Capacity

The translation initiation factor eIF2 plays a fundamental role in uninfected and infected cell protein synthesis and is targeted by virus-encoded and host regulatory mechanisms.[446] A heterotrimeric GTP-binding protein composed of a regulatory α subunit, an RNA-binding β-subunit, and a GTP-binding γ-subunit, the GTP-bound form of eIF2, loads the 40S ribosome with initiator methionine tRNA (Fig. 9.10). Following the initiation of protein synthesis subsequent to 60S subunit joining, eIF2•GDP is released and must be recycled to the GTP-bound, active form by the guanine nucleotide exchange factor (GEF) eIF2B (Fig. 9.10). As cell intrinsic innate immune response components, several host ser/thr eIF2α kinases are activated by discrete physiological stresses and impact eIF2 activity in response to stresses including virus infection (Fig. 9.10).[446] Transcription from numerous opposing transcriptional units on opposite DNA strands in the HSV genome likely results in the accumulation of double-stranded (ds) RNA,[101] a pathogen-associated molecular pattern (PAMP) indicative of virus infection. Prior to stimulation, the cellular dsRNA-activated protein kinase PKR remains catalytically inactive until

it detects and binds dsRNA in HSV-1–infected cells or is stimulated by a protein activator PACT.[446] Activated PKR phosphorylates eIF2α on residue S51 (Fig. 9.10). Phospho-eIF2 remains bound to eIF2B and inhibits the GEF from regenerating active eIF2•GTP (Fig. 9.10). Because the GEF eIF2B is limiting in most cells, modest increases in phosphorylated eIF2α can largely inhibit new protein synthesis by antagonizing eIF2B and restricting infected cell protein synthesis.[199,446] PKR itself is an interferon-stimulated gene product, emphasizing its role as an anti-HSV host defense factor.

To preserve sufficient pools of active eIF2 that are required to initiate protein synthesis, multiple independent HSV-encoded functions act to prevent phosphorylated eIF2α accumulation and/or activation of eIF2α kinases including PKR.[446] The amount of HSV genome coding capacity devoted to controlling eIF2 phosphorylation and its impact on virulence and pathogenesis emphasizes the importance of this process to virus infection biology. The viral R_L1 gene encodes the ICP34.5 protein, which shares homology in its C terminus with the cellular GADD34 gene product. Both ICP34.5 and the host GADD34 are regulatory subunits that physically bind to the cellular ser/thr protein phosphatase 1α (PP1α) catalytic subunit and target the enzyme to specific substrates including eIF2[272] (Fig. 9.10). By functioning as a constitutively active PP1α regulatory subunit in HSV-infected cells, ICP34.5 preserves unphosphorylated eIF2α and potentially counteracts any cellular eIF2α kinase, including PKR. Significantly, ICP34.5-deficient viruses are unable to sustain infected cell protein synthesis at late times postinfection in numerous cell types, and although L mRNAs accumulate normally, late protein synthesis is arrested due to the accumulation of phosphorylated eIF2α. Not only are ICP34.5-deficient viruses hypersensitive to interferon,[62,323] they are profoundly neuroattenuated following delivery into the CNS by direct intracranial injection in mice.[74] Of all the HSV genes identified to date, removal of the gene encoding ICP34.5 results in the greatest loss of neurovirulence compared to any other single virus gene, establishing ICP34.5 as a major genetic virulence determinant.[74]

In contrast to ICP34.5, which acts broadly to counter eIF2α kinases, HSV also encodes specific effectors dedicated to inhibiting discrete eIF2α kinases (Fig. 9.10). Chief among these is the US11 gene product. The U_S11 gene is expressed with true-late (L) kinetics and encodes an 18 Kd predicted MW protein that migrates with an apparent MW of approximately 21 Kd on SDS–polyacrylamide gels. This aberrant observed migration is likely due to a repetitive region composed of varied Arg-X-Pro motif iterations within the US11 C terminus among different HSV strains. Approximately 600 copies of the US11 protein are packaged within the tegument allowing US11 to be delivered into the host cytoplasm immediately upon infection. Although US11 has been found associated with polyribosomes at times that precede viral gene expression and accumulates within infected cell nucleoli, specific US11 functions ascribed to these discrete subcellular locales remain to be defined. Early work showed that US11 specifically binds to 60S rRNA, while later studies showed sequence and structure-specific binding of US11 to RNA.[50,228] Indeed, the repetitive R-X-P motif functions as a dsRNA-specific binding module that can physically associate with PKR in a ribonuclease-insensitive manner.[228] While US11-deficient viruses replicate to near wild-type levels in the permissive monkey kidney Vero cell line, they replicate to reduced levels and direct reduced rates of protein synthesis in primary human fibroblasts and are hypersensitive to interferon.[323] Isolation and mapping of an extragenic suppressor mutation that allowed replication of an *ICP34.5* deletion mutant in nonpermissive cells provided the first evidence that US11 and ICP34.5 were partially redundant factors that

functioned in the same signaling circuit to regulate eIF2α phosphorylation. In the absence of ICP34.5, temporal deregulation of US11 allowing it to be expressed as an IE gene instead of a L gene product was sufficient to preclude both the accumulation of phosphorylated eIF2α and the premature cessation of infected cells protein synthesis prior to the completion of the viral productive growth cycle. Subsequent genetic studies confirmed that this required the C-terminal 68 RXP repeat-containing region of US11 that bound both dsRNA and PKR.[228] US11 also prevented PKR activation in response to the protein activator PACT.[366] Thus, US11 functions as a dedicated eIF2α kinase antagonist specific for PKR.

Besides PKR, three additional eIF2α kinases exist in mammals and their activities are likely countered by the ICP34.5 PP1 regulatory subunit (Fig. 9.10).[446] One of these, the ER-resident kinase PERK, is activated by ER stress resulting from accumulation of unfolded client proteins in the ER lumen.[221] HSV-1 was found to be resistant to experimentally induced ER stress, and gB was found to physically associate with the ER luminal domain of PERK. Furthermore, gB regulates viral protein accumulation in a PERK-dependent manner, defining a virus-encoded PERK-specific effector together with a new strategy by which viruses are able to maintain ER homeostasis.[322] While gB displays the hallmarks of a viral PERK-specific antagonist and US11 is a PKR-specific antagonist, gH reportedly interacts with GCN1, which is a GCN2 trans-acting positive effector, and regulates eIF2α phosphorylation in infected cells (Fig. 9.10).[179] A discrete HSV function that specifically targets the remaining cellular eIF2α kinase HRI has not been identified and may or may not exist.

Controlling Infected Cell Gene Expression by mRNA Decay

Manipulation of host gene expression begins immediately following entry when virus tegument components are released into the cytoplasm. Among them is the endoribonuclease UL41 or vhs. Early studies showed that the rapid suppression of host protein synthesis following HSV infection coincided with disruption of polyribosomes and suggested the involvement of a virion structural component. Mutant viruses unable to impair protein synthesis in the presence of actinomycin D, which prevents transcription, were isolated from mutagenized stocks and defined a single open reading frame (U_L41) encoding the virion host shutoff (vhs) function. Besides the host shut-off deficiency, vhs mutants exhibited deregulated temporal accumulation of viral IE mRNAs, consistent with a deficiency in posttranscriptional control of viral gene expression and were shown to lack a function that destabilizes viral and host mRNAs. Subsequent studies established that the vhs polypeptide is an intrinsic endoribonuclease that preferentially cleaves at single-stranded C or U residues within mRNA. Although vhs accelerates turnover of many normally stable viral and host mRNAs, its activity within infected cells principally requires a host cell translation initiation factor, eIF4H, which imparts selectivity and specificity limiting endoribonucleolytic cleavage to mRNA in polyribosomes.[407] As eIF4H stimulates the RNA helicase eIF4A that is associated with the multisubunit translation initiation factor complex assembled onto the capped mRNA 5′-end, the vhs-eIF4H association provides a mechanism to specifically load vhs onto mRNAs destined to be translationally active. Following targeting to the mRNA 5′-terminal region and primary endonucleolytic cleavage by vhs in the vicinity of translation initiation sites,[423] subsequent 5′-3′ directional degradation of the uncapped transcript body 3′-terminal fragment is dependent upon the cellular exoribonuclease Xrn1.[142] An alternate mode of vhs action has been proposed for short-lived mRNAs that contain 3′-AU–rich elements (AREs) in their 3′-UTRs, many of which encode inflammatory cytokines or stress-responsive

proteins. Through a physical interaction with tristetraprolin, which recognizes AREs and promotes degradation of ARE-containing mRNAs via the exosome in uninfected cells, vhs cleavage is detected at or near AREs. While the resulting vhs-dependent 3′-cleavage products on ARE-containing mRNAs are unstable and presumed degraded by Xrn1, the remaining 5′-capped mRNA fragments reportedly have longer half-lives.

While many viral mRNAs have been shown to be sensitive to vhs-dependent turnover,[357] at least four additional virus-encoded proteins reportedly associate with vhs to regulate its endoribonuclease activity and have been proposed in part to orchestrate the accumulation of different kinetic classes of HSV-1 mRNA. Three of these proteins are tegument components (UL47, VP22, VP16) that are produced late in infection and can neutralize vhs activity.[426] This provides a mechanism to limit vhs nuclease activity while allowing quantities of vhs to accumulate for incorporation into virions. Upon delivery into the host cytoplasm following infection, vhs is released from the tegument via an unknown mechanism and accumulates in small, punctate cytoplasmic granules while it promotes selective degradation of cellular and viral mRNAs, cleaves mRNA in polyribosomes, and contributes to polyribosome disruption early in infection. Recently, vhs and cofactors including VP22 were also found to regulate nuclear export of late viral mRNAs in human fibroblasts, exposing an additional mechanism through which vhs regulates gene expression posttranscriptionally.[367]

vhs has also been found to associate with the ICP27 IE protein and the UL47 protein.[426,455] Whereas vhs is thought to load onto the mRNA 5′ end via association with cap-dependent translation initiation factors, ICP27 and UL47 interact with PABPC1, which is bound to polyA tails at the mRNA 3′-terminus.[112,403] The proximity of mRNA 5′ and 3′ ends mediated by an interaction between PABPC1 and the translation initiation factor eIF4G at the 5′ end could conceivably allow for transfer of vhs from the mRNA 5′ end to ICP27 and/or UL47 tethered via PABPC1 at the 3′ end.[426] In theory, this could provide a mechanism to regulate vhs activity and possibly spare ICP27-bound mRNAs on ribosomes from vhs-mediated destruction. Alternatively, such vhs-containing subcomplexes involving other tegument proteins could represent an early stage in virion assembly that limits unrestricted vhs activity that would otherwise suppress viral protein synthesis.[380] In addition, vhs stimulates polysome recruitment and translation of naturally occurring HSV mRNAs at late times postinfection via an unknown mechanism.[100]

While bulk host mRNA turnover is accelerated by vhs, all host mRNAs are not equivalently susceptible and mRNAs that survive vhs-induced decay have been identified. GADD45β and tristetraprolin are inducible mRNAs that did not detectably decay in productively infected cells, and their encoded polypeptide products accumulated. In addition, prior splicing or artificially tethering exon junction complex (EJC) components stabilized a reporter mRNA from virion-delivered vhs degradation and enhanced accumulation of its encoded protein late in infection.[401] While the underlying mechanism of how the splicing history of an mRNA influences its sensitivity to vhs imposed decay remains to be determined, it could impact the expression of the few spliced HSV mRNAs. Although the functional consequences of mRNAs that escape vhs-mediated turnover remain incompletely understood, accelerated mRNA decay imposed by vhs coupled with reduced transcription from cellular RNA pol II promoters and suppression of mRNA splicing by ICP27 together ensure that the vast majority of cytoplasmic mRNAs in cells productively infected with HSV are viral and effectively shut-off or severely restrict host protein synthesis.

In addition to sculpting and sharpening temporal transitions between IE, E, and L kinetic classes of viral mRNAs by promoting mRNA decay, the vhs endoribonuclease antagonizes host defenses by accelerating host mRNA decay and thereby restricting production of critical host defense components including cellular intrinsic innate immune effectors like ATRX, cytokines, IFI16, and type I interferons.[214,347,357] Notably, vhs-deficient mutants replicate to reduced levels in interferon-treated cells, more proficiently activate dendritic cells,[92] have reduced capability to down-regulate MHC class I and are severely attenuated in small animal models. Together, this underscores the critical role the HSV endoribonuclease plays in potentially modulating both innate and adaptive immunity and in pathogenesis.

Besides impacting mRNA decay, vhs also influences double-stranded RNA (dsRNA) formation in infected cells. dsRNA accumulates and concentrates at stress granules (SGs) in cells infected with vhs-deficient HSV-1.[52] SGs are dynamic aggregates comprising mRNA, translation factors, and RNA-binding proteins that accumulate in the cytoplasm in response to perturbations in protein synthesis including those associated with virus-induced shutoff of host protein synthesis.[372,446] They typically form following phosphorylation and inactivation of the translation initiation factor eIF2α, a substrate of the dsRNA-activated protein kinase PKR, and serve as hubs to potentiate PKR activation during infection. Indeed, vhs is one of several viral factors that plays a role in limiting PKR activation (Fig. 9.10),[417] interferes with SG accumulation,[138] and regulates the accumulation of viral dsRNA composed of complimentary transcripts derived from opposing DNA coding strands in infected cells.[101] Surprisingly, while innate immune activators like dsRNA and sensors including PKR are enriched at SGs in HSV-1–infected cells, this did not detectably influence IFN induction by HSV-1. Instead, the biggest effect on IFN induction was mediated by cGAS and IFI16.[52]

Viral DNA Replication

Production of progeny virus requires the amplification of the input viral DNA genomes for assembly into progeny viral particles. Many of the viral E proteins prepare the infected cell for or are directly involved in viral DNA replication through (a) targeting and assembling viral and cellular proteins into intranuclear structures where viral DNA replication initiates (prereplicative sites) and where viral DNA replication proceeds (replication compartments; Fig. 9.5), (b) enhancement of levels of nucleotide precursors for viral DNA synthesis in resting cells, and (c) catalyzing the synthesis of viral DNA. As described in the Gene Expression section above, the input viral genomes target to the nuclear periphery soon after entry into the nucleus. Following IE and E gene transcription from the viral DNA molecules, likely at these sites, the viral DNA replication proteins then localize to these genomes on the nuclear periphery to form structures called prereplicative sites.[102,374] The prereplicative sites near ND-10 bodies are the sites of initial viral DNA replication, and these structures grow into replication compartments as DNA replication proceeds.[102] The replication compartments enlarge, merge, and fill the nucleus, concomitant with peripheral margination of the host chromatin,[430] suggesting that the HSV replication compartments displace the cellular chromatin from internal sites in the nucleus. The replication compartments serve to concentrate the viral and cellular proteins needed for viral DNA replication, L gene transcription, and encapsidation of the viral DNA and exclude the cellular epigenetic silencing components and host restriction and innate sensing molecules, all of which enhance viral replication.

The full mechanism of viral DNA replication has not been elucidated, although we have significant knowledge about the viral gene products and origins of replication. Seven viral proteins are required for viral DNA replication. The seven gene products are the viral DNA polymerase catalytic subunit (UL30) and its processivity factor (UL42), an origin-binding protein (UL9), the ICP8 ssDNA-binding protein (SSB; UL29), and the helicase–primase complex of three proteins, UL5, UL8, and UL52.[63] Host cell factors are presumably also involved in viral DNA synthesis, but these have not been identified, in large part because HSV DNA replication involving origin-dependent initiation and synthesis has not been reconstituted *in vitro*. Nevertheless, it seems likely that host enzymes, including the DNA polymerase α-primase, DNA ligase, and topoisomerase II, are also required. Early immunofluorescence studies showed that cellular replication protein A (RPA), PCNA, Rb, p53, DNA ligase 1, and DNA polymerase α colocalized with ICP8. Inhibition of topoisomerase II prevents efficient replication of HSV-1 DNA, possibly by preventing decatenation of newly synthesized daughter molecules. Proteomic studies showed that a large number of cellular DNA repair, DNA damage response, and recombination proteins are associated with ICP8[466] and localize to prereplicative sites and replication compartments.[466] Mre11, Rad50, Nbs1, RPA, MSH2, BRCA1, BLM, WRN, DNA ligase 1, RAD51, and Ku86 are located in prereplicative sites and replication compartments.[158,275,466] Cells defective for WRN helicase[466] or Mre11 or ATM[275] show reduced HSV replication so these proteins promote viral replication in some way. It is not known, however, if these host proteins are directly involved in viral DNA replication.

Viral DNA Replication Proteins

The seven essential HSV DNA replication proteins are reviewed in detail elsewhere,[393,512] but brief overviews of these seven proteins and relevant accessory proteins are included below.

DNA Polymerase

The HSV DNA polymerase has been studied extensively, partly as a result of its potential as a target for antiviral drugs. A new DNA polymerase activity was detected in HSV-infected cells in the 1960s, but formal genetic proof that it was virus encoded was not provided until the late 1970s when temperature-sensitive and drug-resistant mutations affecting the properties of the polymerase were isolated and mapped to the viral genome. The HSV DNA polymerase holoenzyme is a heterodimer of the 136-kDa UL30 protein complexed with the 65-kDa UL42 protein.

UL30

The UL30 protein contains the polymerase activity, and it contains three sequence motifs that are homologous and align with sequence motifs I, II, and III of other DNA polymerases. The UL30 protein also has an intrinsic 3′-5′-exonuclease activity, which can serve as a proofreading activity during viral DNA synthesis. The crystal structure of the UL30 protein defined the following domains: pre-NH2 domain, NH2-terminal domain, 3′-5′-exonuclease domain, polymerase palm subdomain, finger subdomain, and thumb subdomain. The RNase H activity of HSV-1 DNA pol is encoded within the 3′-5′ exonuclease domain.[260] The HSV DNA polymerase interacts with a broader range of deoxynucleoside triphosphates than cellular polymerases, and this has allowed the development of drugs that specifically inhibit the viral DNA polymerase and are used

clinically (Chapter 10).

UL42

The UL42 subunit increases the processivity of the UL30 DNA polymerase activity. The structure of UL42 protein bound to the C-terminal fragment of UL30 has been determined, and UL42 is unusual in binding DNA directly as a monomer rather than as a toroid wrapping around the DNA like other processivity factors. UL42 is capable of linear diffusion along DNA despite its high affinity binding to DNA. The interaction between UL30 and UL42 is essential for viral DNA replication *in vivo*, and these interaction sites are being investigated as possible targets for antiviral compounds. UL42 also interacts with cdc2 and topoisomerase IIα.

Origin-Binding Protein (UL9, OBP)

The UL9 origin-binding protein forms a homodimer and binds specifically to the sequence CGTTCGCACTT. UL9 also has ATP-binding and DNA helicase motifs that are essential for viral replication. Binding of UL9 to origin sequences induces a bend in the DNA and formation of a single-stranded stem loop structure. The addition of the HSV single-stranded DNA-binding protein, ICP8, allows UL9 to unwind Box I of *ori*S if an 18-nucleotide single-strand tail is present 3′ to Box I. Thus, ICP8 may provide a single-stranded DNA region in the AT-rich region, from which UL9 can separate the strands. As an origin-binding protein, UL9 would play a role in origin-dependent synthesis originating from circular or linear molecules, but once synthesis has converted to a rolling circle or recombination-based mode, UL9 would presumably not be needed as an origin-binding protein. Consistent with this, overexpression of UL9 inhibits viral DNA synthesis.

Single-Stranded DNA–Binding Protein (ICP8, UL29)

ICP8 is an abundant protein in HSV-infected cells and was first identified as the major DNA-binding protein in HSV-infected cells. ICP8 binds preferentially to single-stranded DNA, and this ssDNA-binding (SSB) function is essential for viral DNA replication. ICP8 exhibits a helix-destabilizing activity but can also catalyze the renaturation of complementary single strands. Probably as a consequence of the latter two activities, ICP8 can promote strand transfer and this may contribute to the high frequency of homologous recombination observed in infected cells.

In addition to its SSB function, ICP8 interacts with several other viral DNA replication proteins. ICP8 physically interacts with UL9 and stimulates UL9 helicase activity, co-immunoprecipitates with UL8, and stimulates UL5/8/52 helicase activity, and functionally interacts with the viral DNA polymerase. Consistent with these numerous interactions, ICP8 is required for localization of other viral proteins and cellular proteins to prereplicative sites in infected cell nuclei.[102] Given its size (128 kDa) and numerous protein interactions, ICP8 is likely to play a scaffold role in the assembly of HSV DNA replication complexes. The crystal structure of a 60-residue C-terminal deletion form of ICP8 showed a novel fold consisting of a large N-terminal domain (residues 9–1038) and a small C-terminal domain (residues 1049–1129). The overall structure provided a potential groove containing aromatic and basic amino acid residues that could serve as the ssDNA-binding site. ICP8 possesses strand-melting and strand-annealing activities and has been reported to mediate limited strand exchange. ICP8 can also promote strand invasion.[339] ICP8 has the molecular properties of a DDE recombinase, and mutation of this domain (E1086A/D1087A) led to a greater than 100-fold reduction in DNA replication.[51,527]

HIV integrase inhibitors that reduced HSV recombination also inhibited the ICP8 strand invasion activity.[527] Mutant viruses with defective ICP8 annealing activity show reduced DNA synthesis.[509]

DNA Helicase–Primase

This complex, which contains the viral protein products of the U_L5, U_L8, and U_L52 genes, was first identified as a helicase activity from infected cells. The complex unwinds short oligonucleotides annealed to single-stranded M13 DNA in the 5′ to 3′ direction. A complex of UL5 and UL52 has DNA-dependent ATPase and GTPase, helicase, and primase activities so this constitutes the core enzyme. UL8 promotes the nuclear localization of this complex and, in concert with ICP8, stimulates optimal activities of the core enzyme. Thus, the holoenzyme can unwind a 2.3-kbp nicked plasmid in the presence of ICP8. The primase activity produces oligoribonucleotides 6 to 13 bases in length, and the preferred template sequence is 3′AGCCCTCCCA, with synthesis initiating at the first C.

Accessory Viral Gene Products Involved in Viral DNA Synthesis

Several other HSV gene products, including the thymidine kinase, ribonucleotide reductase, deoxyuridine triphosphatase, and uracil–DNA glycosylase, are not essential for viral replication in cultured cells but are likely to be essential for nucleotide metabolism, viral DNA synthesis, and/or repair in resting cells, such as neurons. The corresponding host cell enzymes are expressed at low levels or not expressed in resting cells, and it is likely that the virus encodes these enzymes to optimize its own DNA synthesis in these cells.

Thymidine Kinase (TK)

This enzyme was first identified as a deoxythymidine kinase, which gave rise to its name. In fact, it phosphorylates pyrimidines and even purine nucleosides. In addition, it has a thymidylate activity. Its broad substrate specificity allows it to phosphorylate nucleoside analog molecules (e.g., acyclovir), which then can serve as antiviral compounds. The HSV TK consists of a homodimeric complex of the UL23 protein, the structure of which has been solved. HSV presumably encodes a TK activity to provide nucleoside triphosphate precursors for DNA synthesis in resting cells such as neurons, where the cellular enzyme is not expressed. The viral enzyme leads to an increase in dTTP pools relative to that seen in uninfected cells or early in infection. This complicates the use of radioactive thymidine for labeling of viral DNA synthesis in infected cells because the specific activity of the labeled DNA will be lower at later times of infection.

Deoxyuridine Triphosphatase (dUTPase)

The HSV dUTPase, a monomer of UL50 protein, hydrolyzes dUTP to dUMP and pyrophosphate, preventing the incorporation of uracil into DNA. HSV-1 dUTPase mutants are attenuated for neurovirulence, neuroinvasiveness, and reactivation from latency.

Ribonucleotide Reductase

Ribonucleotide reductase enzymes catalyze the reduction of ribonucleoside diphosphates to the corresponding deoxyribonucleoside diphosphate. The HSV enzyme consists of a complex of the

UL39 and UL40 proteins as an $\alpha_2\beta_2$ tetramer. The HSV ribonucleotide reductase is not subject to the same allosteric controls as the cellular enzyme; thus, the HSV enzyme is not inhibited by the increased dTTP pools in HSV-infected cells. The HSV ribonucleotide reductase is required for viral replication in nondividing cells. The large subunit has an intrinsic autophosphorylating kinase activity that is separable from the ribonucleotide reductase activity.

Uracil N-Glycosylase

This enzyme removes uracil bases from DNA, bases that arise in DNA by the deamination of cytosine to form uracil, by the cleavage of the *N*-glycosidic bond linking uracil to the deoxyribose sugar. The site is then repaired so that a mutagenic event converting a G-C basepair to an A-T basepair does not occur. The HSV enzyme is encoded by the U_L2 gene.

Alkaline Nuclease

This enzyme is a phosphoprotein encoded by the U_L12 gene, has endo- and exonuclease activities, and is active at pH 9 to 10. As described below, this nuclease plays a role in viral DNA synthesis, DNA maturation, and encapsidation. The HSV nuclease may be required to resolve concatenated viral DNA for packaging. UL12 interacts with ICP8, possibly to allow the nuclease to act directly on viral replication intermediates or products. UL12 and ICP8 facilitate strand exchange *in vitro,* and ICP8 stimulates nuclease activity by increasing processivity of the enzyme.

Origins of Replication

The origins of viral DNA synthesis were identified through mapping of sequences found in defective viral genomes and sequences needed for plasmid DNA amplification in transfection studies.[489] The origins include *oriS*, a sequence located in the *c* sequences bounding the S component and therefore present in two copies in the viral genome, and *oriL*, a sequence located between the divergent transcription units of the U_L29 and U_L30 genes encoding the viral DNA replication proteins, ICP8 and DNA polymerase, respectively. Both *oriL* and *oriS* are palindromic structures, *oriL* being a 144-bp palindrome and *oriS* being a shorter palindrome of 45 bp, that center around AT-rich regions of 20 and 18 bp, respectively. Inverted repeats that contain binding sites for the UL9 protein, called Box I, are located on either side of the AT-rich region of *oriL*. *OriS* contains a Box I sequence to the 5′ side of the AT-rich region and a similar sequence with a 10-fold lower binding affinity for UL9, called Box II, located 3′ to the AT-rich region. In *oriL*, the Box I sequences are flanked by another homologous sequence, called Box III, which has greatly reduced affinity for UL9. *OriS* contains one copy of Box III flanking the 5′ Box I. *OriL* is notoriously unstable when cloned into plasmids, so little genetic analysis has been performed on this sequence. Box I is required for *oriS* function, and mutations in Box II greatly reduce DNA replication. Although Box III shows weak binding to UL9 *in vitro*, mutations in Box III reduce replication by approximately fivefold in transfection assays.

The reason(s) for three potential origins of replication in the viral genome are not apparent at this time. Neither origin is specifically required for viral replication. A mutant virus with a deletion in *oriL* is viable and showed normal burst size and latent infection. In addition, mutant viruses with both *oriS* sequences deleted showed at most a fourfold reduction in viral yields and only slightly delayed viral DNA synthesis. It has been suggested that one of these origins may

represent vestigial origins from the L and S components of the viral genome and that one of these origins, *oriL*, may function in reactivation from latent infection. One study found that an *oriL* mutant virus shows reduced replication in mouse tissues and reduced reactivation from latent infection. Thus, *oriL* may be required for DNA replication in certain tissues; alternatively, the expression of the bounding U_L29 and U_L30 genes may be affected in these tissues.

Mechanisms of Viral DNA Replication

There is evidence that HSV DNA replication is a two-stage process in which an initial stage of DNA synthesis dependent on UL9 binding of viral origin sequences is followed by a switch to an origin-independent replication mechanism. The major viral DNA replicative products inside infected cells are long “head-to-tail” concatemers containing the four sequence isomers described above, and this is an important aspect of any model. There are two main basic models of HSV DNA replication as shown in Figure 9.11. The original model[37] involved binding of the HSV UL9 origin-binding protein to an origin on a circular viral DNA and subsequent formation of the HSV DNA replication complex, which replicates the molecule through an intermediate such as a Cairns circle or theta molecule (Fig. 9.11). Concatemers are then proposed to be generated following a conversion of the initial bidirectional replication to rolling circle replication. Alternatively, a replicative intermediate could undergo recombination to generate concatemeric molecules.

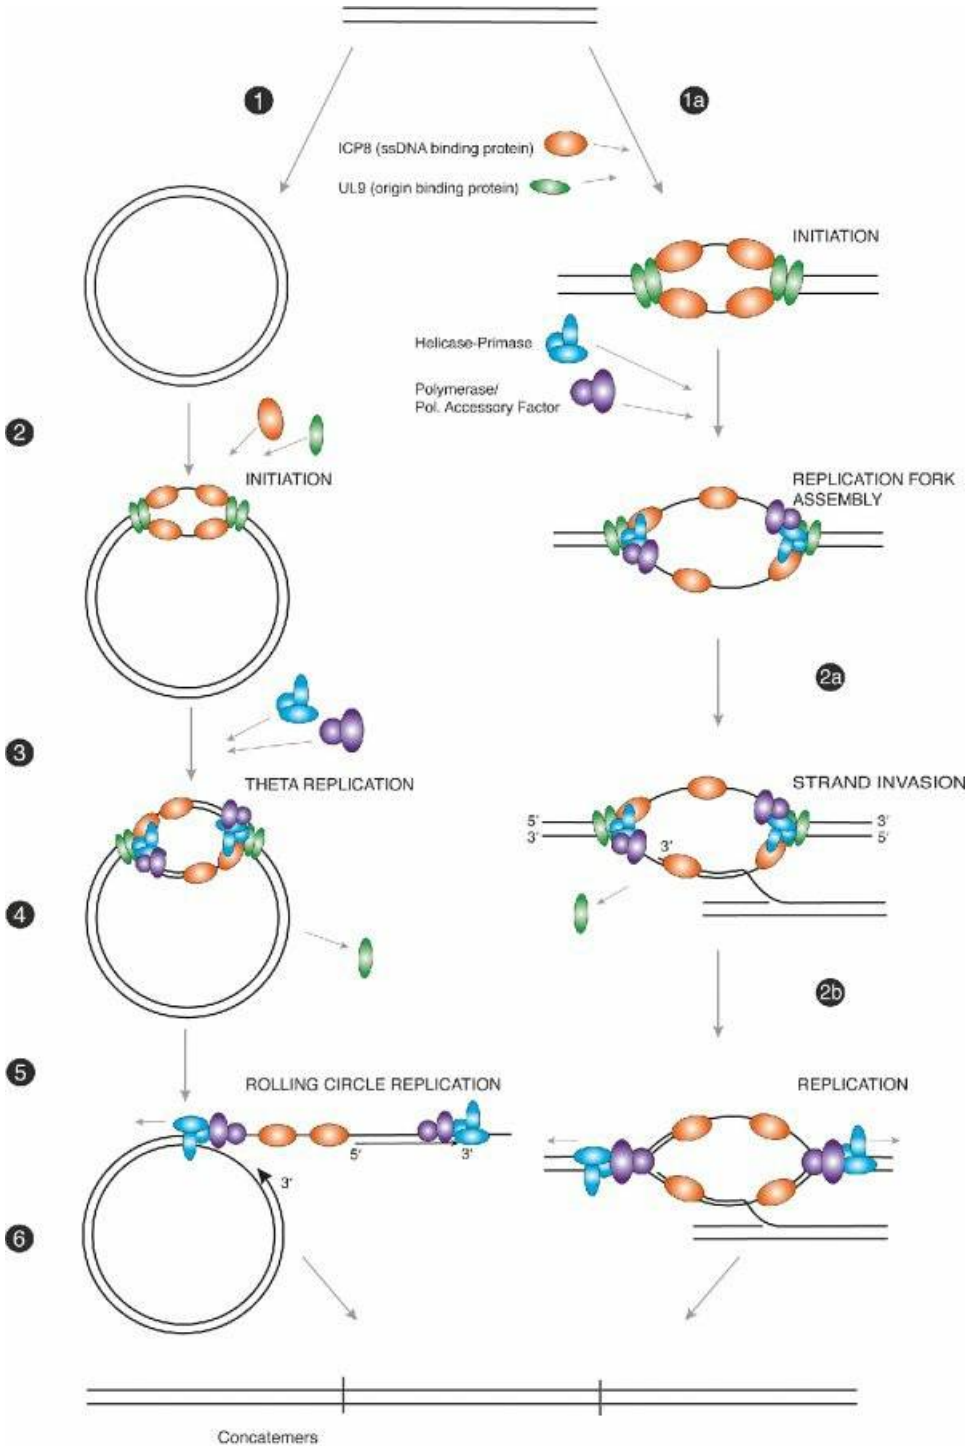

FIGURE 9.11 Diagram of models of HSV-1 DNA replication. Left: *Rolling circle replication*. (*1*) Input DNA is circularized upon entry into the nucleus. (*2*) UL9 (the origin binding protein) initially binds to specific elements in the origin (either *oriL* or *oriS*) and begins to unwind the DNA. UL9 then recruits ICP8 (the single-stranded DNA–binding protein) to the unwound single-stranded DNA. (*3*) UL9 and ICP8 recruit the five remaining viral DNA replication proteins to the replication forks. (*4*) The helicase–primase proteins and the viral polymerase complex assemble at each

replication fork for initial rounds of theta form replication. (*5*) Replication switches from theta to rolling circle mode by an unknown mechanism. UL9 is not necessary for rolling circle replication, as it is not origin dependent. (*6*) Rolling circle DNA replication produces long head-to-tail concatemers of viral DNA, which are cleaved into monomeric molecules during packaging.**Right:** *Recombination-dependent replication*. (*1a*) Input DNA in linear or circular form is bound by UL9 to initiate viral DNA synthesis with subsequent recruitment of ICP8 to the unwound DNA followed by recruitment of the helicase–primase proteins and the viral polymerase complex to form an active replication fork. (*2a*) ICP8 promotes strand invasion from a separate viral genome. Strand invasion from broken strands of viral DNA or free genomic termini, resected by cellular or viral nucleases to yield single-strand templates, primes DNA synthesis. (*2b*) Recombination-dependent synthesis following priming by strand invasion enables formation of viral DNA concatemers. (Copyright, Catherine Sodroski and David Knipe.)

In the rolling circle model (Fig. 9.11), the first steps in HSV DNA replication involve the binding of UL9 protein to one or more of the origin sequences and the subsequent looping and distortion of the origin sequences by UL9. ICP8 then binds to UL9 and/or ssDNA regions, and the UL9 helicase activity unwinds the DNA. The helicase–primase complex is then recruited to the origin by interactions with UL9 and/or ICP8. Leading strand synthesis involves the unwinding of the DNA and synthesis of a primer by the HSV helicase–primase complex, from which leading strand synthesis can be accomplished by the HSV DNA polymerase UL30-UL42 holoenzyme. Alternatively, primers may be synthesized by the cellular polymerase α-primase. Lagging-strand synthesis is then accomplished by primer synthesis and UL30–UL42 extension of the DNA strand. HSV-1 progeny DNA is largely in the form of head-to-tail concatemers; thus, when viral DNA synthesis is converted to a rolling circle replicative mechanism, this would yield the concatemeric molecules observed in infected cells.

Replication mechanisms involving recombination have also been proposed.[339] By this model (Fig. 9.11), initiation could occur on a linear molecule or a circular molecule. ICP8 promotes strand invasion of another viral DNA molecule at a replication fork or other exposed homologous single-stranded regions of viral DNA, such as gaps in viral DNA at stalled replication forks or genomic termini, to prime viral DNA synthesis. This could then lead to the synthesis of concatemeric molecules.[509] It has been proposed that ICP8 interactions with the helicase–primase complex and the alkaline nuclease protein UL12 also contribute to recombination-mediated synthesis of viral DNA.

In support of the rolling circle model, there is evidence that viral DNA is rapidly circularized after entry.[448] In addition, DNA ligase IV and XRCC4 are required for circularization of the input viral genome for replication and knockdown of ligase IV or XRCC4-reduced viral DNA replication by 10- to 25-fold, arguing that circularization of the viral DNA leads to the majority of viral DNA synthesis. Furthermore, rolling circle replication on preformed templates has been achieved *in vitro*, and it is simpler to see how this mechanism could generate and propagate the tandem repeats of viral DNA observed in defective viral genomes.[37]

Evidence in support of recombinational mechanisms includes the need for the UL12 nuclease for optimal levels of viral DNA replication[156] and the large reduction in viral DNA replication

by mutant viruses expressing ICP8 molecules that are defective for recombinase activity[51,527] or annealing activity.[509] Genomic inversions occur coincident with viral DNA synthesis[542] and are dependent upon the presence of the seven essential viral replication proteins, arguing that HSV-1 DNA synthesis and recombination are linked. Viral DNA replication intermediates include branched molecules and lariats, and this has been interpreted as evidence of recombination during replication. Alternatively, formation of these structures could be due to genomic inversions and recombination following DNA synthesis.

Rolling circle and recombinational mechanisms are not mutually exclusive, however, because models involving both rolling circle replication and recombination have been proposed.[392] Alternatively, ICP8 could play a role in strand invasion from a viral DNA molecule into the replicating circle to initiate rolling circle replication. By the latter hypothesis, both recombination and rolling circle replication would be involved in viral DNA synthesis and generation of concatemeric progeny DNA molecules. Finally, recombination could facilitate the re-start of DNA synthesis at stalled replication forks. Thus, there is evidence for both recombination and a form of rolling circle replication playing roles in HSV DNA replication in separate or combined pathways.

Genomic inversions have been discussed above but do appear to occur concomitantly with viral DNA synthesis. This may be as a part of viral DNA synthesis, as proposed by Roizman et al.,[392] or by recombination following synthesis of the concatemeric molecule.

Viral DNA Recombination

Homologous recombination is very efficient in HSV-infected cells, and multiple crossover events between coinfecting viral genomes are apparent in progeny viruses, even between HSV-1 and HSV-2 genomes. Viral DNA replication is required for this high level of homologous recombination, and the time courses of DNA replication and recombination are parallel in cells transfected with viral *oriS* plasmids. As discussed above, the relationships between viral DNA replication and recombination are not well defined, but the single-stranded regions or the concatemeric molecules might be targets for cellular or viral recombination machinery. In addition, ICP8 is known to promote strand transfer, so it might play a role in recombination in infected cells. In support of this idea, HIV integrase inhibitors that inhibit the ICP8 recombinase activity reduce the generation of recombinant viruses in HSV coinfected cells.[527]

Inversion of the genomic L and S segments also involves recombination between the terminal repeats and the internal inverted repeats. As described above, HSV virion DNA contains four populations of molecules bearing the four orientations of the L and S components of the genome. This novel feature of the genome of HSV and certain other, but not all, herpesviruses (see Chapter 8) has long intrigued the field, and interest has been further piqued by the observation that viruses without internal repeats replicate well in continuous cell lines but poorly in primary human cells. These mutant viruses are nonpathogenic, suggesting that the internal inverted repeats play a key role in primary human cells and *in vivo*. The L–S junction sequences and in particular the ***a*** sequences promote high-efficiency inversion in that insertion of a copy of these sequences at other sites in the genome leads to inversion of these sequences. Duplication of certain other viral sequences at a second site in the viral genome can lead to additional inversion events, but these events appear to be less efficient than ***a*** sequence-mediated inversion. The 95bp *Uc-DR1* sequence is specifically required for inversion at the ***a*** sequence, but it remains to be

determined if this event involves site-specific recombination or is a hot spot for recombination.

Activation of Host DNA Damage Response Pathways

The interactions of HSV with DNA repair pathways are complex. The presence of nicks and gaps in the incoming viral DNA is likely to result in activation of DNA repair pathways, as discussed in the Gene Expression section above. Consistent with this, HSV infection has been shown to activate the host DNA damage repair pathway.[275] Some of this host response is likely due to parental viral DNA,[314] but the peak response requires and/or coincides with viral DNA replication.[275] Phosphorylation of ATM is observed as early as 0.5 hpi but increases until 8 hpi during times of viral DNA synthesis.[275] Phosphorylation of ATM requires viral DNA replication, supporting the concept that replicating or replicated viral DNA serves as the stimulus for a more robust DDR pathway activation.[314] Thus, DNA damage sensors may recognize the input viral DNA, but the optimal response involves newly replicated DNA. HSV infection activates the ATM-dependent signaling pathway, while it inhibits the DNA-PKcs and ATR-dependent pathways.[275,318] To counter the inhibitory effects of DNA repair mechanisms on viral replication, ICP0 promotes the degradation of RNF8 and RNF168, which are mediators in the ATM pathway.[276,277] The effects of the DNA repair components on HSV replication are complex in that some components are inhibitory to viral replication while others stimulate viral replication.[275,466] It is conceivable that while HSV inhibits the DNA repair pathways, it has co-opted DNA repair mechanisms for its own genome replication, much as the host cell uses DNA repair mechanisms as part of its genomic synthesis.

In addition to maintaining genome integrity, the cellular DNA damage response (DDR) acts as an innate cell intrinsic barrier capable of limiting virus reproduction. In particular, how the repair of DNA damage associated with incoming HSV genomes and viral DNA synthesis influences virus reproduction is incompletely understood. Upon delivery of HSV-1 DNA into the host nucleus as a linear dsDNA genome containing nicks and gaps,[432] an elaborate DDR is elicited. To avoid activation of the cellular multisubunit DNA-dependent protein kinase (DNA-PK) in response to productive infection with HSV-1, the catalytic subunit is degraded in some but not all cultured cell lines in an ICP0-dependent manner.[354] Furthermore, DNA-PK–deficient murine cells support greater levels of HSV-1 productive growth.[354,466] This is consistent with proposed roles for DNA-PK as a nuclear DNA sensor that can limit virus reproductive growth.[136] While viral functions remodel facets of the host DDR to prevent viral genome silencing and suppress intrinsic antiviral defenses,[510,511] others including the cellular Fanconi anemia (FA) pathway are activated by HSV-1 infection.[223] Significantly, the FA pathway is critical for repairing interstrand DNA cross-links ensuring genome stability during DNA replication and plays a key role in the repair of endogenous dsDNA breaks (DSBs) that arise naturally during DNA synthesis through processes like replication fork stalling.[61] Cells rely on either error-prone nonhomologous end joining (NHEJ) or the more accurate homologous recombination (HR) repair pathways to repair DSBs.[66] FA pathway proteins function in part to antagonize error-prone DSB repair by NHEJ and instead stimulate more faithful DSB repair via HR. While productive HSV-1 replication was substantially impaired in FA-deficient cells, virus growth can be substantially restored by inhibiting DNA-PK to suppress NHEJ. Besides crippling the dsDNA innate immune sensor DNA-PK, FA-mediated inhibition of NHEJ via inactivating DNA-PK may represent a more physiological means to interfere with NHEJ in cells where

DNA-PK is not degraded in response to HSV-1 productive growth. Although the NHEJ component DNA-PK restricts lytic virus reproduction in a cell intrinsic manner, DNA-PK activation regulates latent infections in neurons,[190] a cell type proficient in DSB repair by NHEJ compared to HR. This raises the possibility that cell type–specific, intrinsic DDR responses to DSBs play roles balancing lytic versus latent infection outcomes and will be discussed in detail in the latent infection section below.

Viral Nucleocapsid Assembly

Following their synthesis, the capsid proteins localize into the infected cell nucleus where capsid assembly occurs. Empty shells containing an internal scaffolding are assembled first and then viral DNA is inserted or encapsidated into the capsid concomitant with the loss of the scaffolding. Our knowledge of the mechanisms of assembly of the HSV capsid has come from several lines of experimentation: (a) study of infected cell complexes and structures, (b) assembly of capsid structures from extracts of insect cells infected with baculoviruses expressing HSV capsid and scaffolding proteins, (c) study of protein localization using immunofluorescence, (d) genetic analysis of the functions of capsid and scaffolding proteins, and (e) three-dimensional reconstructions obtained by cryo-EM. Each of these approaches has contributed important information to our understanding of this process.[32,87]

Immunofluorescence studies have shown that the pre-assembly starts in the cytoplasm where complexes involving at least some capsid proteins form prior to translocation to the nucleus. Several capsid proteins, including VP5, VP23, and VP26, cannot even enter the nucleus on their own and must bind a capsid protein partner that has a nuclear localization signal. For example, VP5, the major capsid protein, forms a 1:1 complex with pre-VP22a, a scaffold protein. Similarly, two copies of VP23 bind VP19C to form the heterotrimeric triplex. VP26, the small capsid protein, localizes into the nucleus only when it is coexpressed with VP5 and either VP19C or pre-VP22a.

Electron microscopic studies have shown that the final assembly of capsids occurs in the nucleus. Three types of capsids, called A-, B-, and C-capsids, have been identified in infected cell nuclear extracts using sucrose density gradient ultracentrifugation.[151] All three types of capsids are approximately 125 nm in diameter with an icosahedral outer shell (T = 16 symmetry) consisting of 150 hexons and 11 pentons made up of six or five copies of the major capsid protein VP5 (U_L19), respectively. Each hexon is additionally crowned with a hexamer of VP26 (U_L35), the small capsid protein. The hexons and pentons are linked by 320 triplexes, heterotrimers of two copies of VP23 (U_L18) and one copy of VP19C (U_L38). In each capsid, 1 of the 12 vertices contains a single portal composed of 12 copies of the portal protein UL6,[282,308] through which viral DNA is encapsidated during assembly[333] and ejected into the nucleus early in infection.[329] Each capsid also contains VP24 (U_L26),[286,298] the protease that cleaves the scaffold during capsid maturation and DNA encapsidation, described below.

C-capsids contain the viral DNA genome and go on to mature into infectious virions. Each vertex is decorated by five copies of the complex referred to as either the capsid vertex–specific complex (CVSC)[83,471] or the capsid-associated tegument complex (CATC).[99] This complex was originally thought to be specific for C-capsids but has also been observed in reconstructions of A- and B-capsids[83] albeit at, perhaps, lower amounts.[87] Each CVSC/CATC is composed of two

copies of UL25, one copy of UL17 and two copies of the tegument protein UL36, or rather, its C-terminal helix.[99] UL17 and UL25, referred to as the auxiliary capsid proteins, are essential for proper DNA retention in the mature capsid and reinforce the outer shell of the capsid[433] to help it withstand the internal pressure of approximately 18 atmospheres from the encapsidated DNA genome.[36] In turn, UL36 anchors the tegument layer to the capsid.

Two additional icosahedral capsid types observed in infected cells are the empty A-capsids and the scaffold-containing B-capsids. B-capsid cavities contain VP22a and VP21, the cleaved forms of the scaffold protein, and the viral protease, VP24. A-capsids are not filled with either the DNA or the scaffold. Both capsid types are thought to be by-products of capsid assembly that result from failed attempts to package DNA.[32] Alternatively, A- and B-capsids have been proposed to represent assembly intermediates.[459]

Scaffold Proteins and Maturational Protease

HSV capsids are assembled around a protein scaffold and require proteolytic cleavage. The scaffold proteins and maturational protease are encoded by the overlapping U_L26 and $U_L26.5$ genes, which encode a complex set of gene products involved in formation of a core for capsid assembly and for capsid maturation. The U_L26 gene encodes a precursor protein with an intrinsic serine protease activity that is required for capsid assembly. The protease cleaves either in cis or in trans at two sites within the precursor molecule, the release (R) site and the maturation (M) site. Cleavage at the R site generates two products, the N-terminal VP24, a protease, and the C-terminal VP21, the large scaffold protein, which can serve as a scaffold for capsid assembly but is not the main scaffold component. Cleavage at the R site is required for viral infectivity. The $U_L26.5$ ORF initiates within the U_L26 gene and encodes a protein in the same reading frame as U_L26. This protein, pre-VP22a (or ICP35), is equivalent to the C-terminal 329 residues of VP21 and functions as the main scaffold protein for capsid assembly. The use of two overlapping genes, U_L26 and $U_L26.5$, ensures the greater than 10-fold over abundance of the scaffold proteins relative to the protease. The C termini of pre-VP22a and VP21 are recognized by VP5 during capsid assembly. Cleavage of pre-VP22a (which generates VP22a) or VP21 at the M site is thought to be involved in release of the scaffolding protein from the capsid interior. A considerable effort has been devoted to identifying specific inhibitors of the HSV protease as possible antiviral compounds, and the crystal structures of the HSV-1 and HSV-2 homologs have been determined.

Capsid Assembly

According to the currently accepted model, a spherical procapsid self-assembles in the nucleus from VP5, VP19c, VP23, and UL6, along with the scaffolding proteins, mainly, pre-VP22a. Assembly of the capsid is nucleated by the dodecameric portal around which the rest of the capsid is assembled into a sphere.[332] This strategy ensures a single portal per capsid. Assembly of the spherical structure composed of VP5–pre-VP22a complexes is driven by oligomerization of the pre-VP22a molecules, and the triplex proteins VP19c and VP23 are added subsequently. The resulting procapsid has hexons and pentons but is not angularized. Once the procapsid is assembled, the protease, triggered by an unknown mechanism, cleaves the scaffolding proteins per-VP22a and VP21 at the M site, which release them from the floor of the procapsid.[334] This

causes the procapsid to undergo a structural transformation to become icosahedral. During genome encapsidation, the scaffolding proteins are expelled from the capsid interior, whereas VP24 remains inside. The icosahedral capsid then recruits outer capsid proteins, UL25, UL17, and VP26.[334]

Much of our mechanistic knowledge of the capsid assembly process comes from analyses of structures formed in insect cells infected with baculoviruses expressing HSV capsid or scaffolding proteins and in extracts from these infected cells. In these studies, a series of baculovirus recombinants were constructed that each express one capsid or scaffolding protein, and B-capsids with normal structure were formed when insect cells were coinfected with viruses encoding the VP5, VP19C, VP23, and U_L26, or $U_L26.5$ gene products. When the U_L26 and $U_L26.5$ genes were left out, no intact capsids were formed, indicating that these gene products are needed to form a scaffold structure around which VP5 and the triplex proteins could form a spherical capsid. Similar phenotypes were observed with HSV strains in which the U_L26 and $U_L26.5$ genes were mutated. In the baculovirus studies, when the U_L26 gene was omitted, B-capsids with large cores were observed because in the absence of the protease, the pre-VP22a protein was not cleaved. Thus, cleavage of the scaffolding proteins leads to condensation of the core. When the $U_L26.5$ gene was omitted, intact capsids were observed, but no core structure was apparent. Viruses mutated for $U_L26.5$ can still produce infectious virus, but progeny virus yields are reduced by 10^2- to 10^3-fold relative to wild-type virus. These data indicate that although the U_L26 gene products can serve as scaffolding proteins, they do not form a proper core necessary for assembly and maturation.

B-capsids can also assemble *in vitro* when extracts from insect cells individually infected with baculoviruses expressing VP5, VP19C, VP23, U_L26, and $U_L26.5$ gene products are mixed and incubated. However, coincubation of the purified viral components VP5, VP19C, VP23, and a scaffolding protein *in vitro* only leads to the assembly of procapsids, which suggest that while assembly of procapsids does not require the viral protease, angularization does. It has been hypothesized that the viral genomes are packaged into procapsids, similar to genome packaging into the prohead structures of bacteriophages.

Capsid assembly takes place at early times of infection within replication compartments at sites near those of viral DNA replication and at later times, perhaps, also in nuclear structures called “assemblons,” in certain cell types. Genome encapsidation likely also takes place in replication compartments.

Encapsidation of Viral DNA

During encapsidation of HSV DNA, the terminal L components of concatemeric HSV progeny DNA molecules are fed into capsids in an energy-dependent process, and the concatemers are cleaved into genome-length units by a linked process, originally described for pseudorabies virus. If the L component is the first to be packaged into the capsid, then the S component would be packaged last, which is consistent with the S component being the first to exit the capsid.[330] The mechanism of the encapsidation process is not yet well defined, but the concatemeric progeny DNA molecules are likely packaged into the capsid as the scaffolding molecules, VP21 and VP22a, are displaced from it. The viral DNA concatemer is thought to be cleaved upon encapsidation of a length of DNA that fills the capsid or when a “headful” (a term that originated

with bacteriophage head assembly) of DNA has been inserted. The signals for cleavage and packaging were first mapped within the U_b and U_c domains of the ***a*** sequences and later mapped precisely. The two DNA packaging elements were designated as *pac1* and *pac2*, respectively.[103]

Cleavage of the viral DNA concatemers occurs site specifically within the DR1 sequences of the ***a*** sequences and involves two site-specific breaks at defined distances from the *pac1* and *pac2* packaging signals.[103] The maturational process duplicates the sequences between these two cleavage sites so that cleavage at sites bearing only one ***a*** sequence leads to two molecules with terminal ***a*** sequences. Several models have been proposed to explain the cleavage and metabolism of viral DNA during encapsidation.[103] In general, these models propose that a packaging complex binds to the DNA and scans for a U_c sequence. Cleavage occurs at a DR1 element proximal to the U_c sequence, and then the packaging complex will scan the DNA as it is packaged until a directly repeated junction is encountered. Alternatively, two cleavages at the L and S termini will produce a monomer molecule. The amplification of the ***a*** sequence may occur by staggered nick-repair or gene conversion. The terminal ***a*** sequence generated by the cleavage may be recombinogenic in either a single-stranded or a double-stranded form and promotes inversions and/or ***a*** sequence amplification. In any event, the process must yield the proper viral genome, with an L terminus containing one or more ***a*** sequences and a 3′ single-base overhang, a unit-length genome with an L and S component, and an S terminus containing a single ***a*** sequence and a 3′ single-base overhang.

Encapsidation of viral DNA requires at least seven viral proteins, including UL6, UL15, UL17, UL25, UL28, UL32, and UL33.[87] Viral DNA is packaged into the capsid through the dodecameric portal at one capsid vertex[333] by an ATP-driven packaging motor/terminase complex of UL15, UL28, and UL33 proteins that cleaves concatemeric DNA into single-genome lengths and translocates them into the capsids. The recently 3.5-Angstrom cryo-EM structure of the HSV-1 terminase complex revealed a hexameric ring composed of UL15, UL28, and UL33.[529] The UL15 protein has an ATPase domain homologous to bacteriophage terminases. The structures of UL15 and CMV UL89, a homolog of UL15, have revealed an RNase H-like nuclease domain, which suggested that UL15 homologs also have the nuclease activity necessary for DNA cleavage.[326,418,529] The UL28 protein binds to the *pac1* cleavage-packaging sequence, a sequence needed for termination of DNA packaging, and is thus thought to provide cleavage specificity. Therefore, UL28 and UL15 provide the specific DNA-binding, nuclease, and ATPase activities needed for a terminase. Both UL28 and UL33 reinforce the terminase complex.[418,529] The cryo-EM structure of the terminase suggests a packaging mechanism in which the arginine-containing finger-like loops within UL15 that line the central pore of the terminase hexamer sequentially bind, translocate, and release the DNA, pulling it through the portal into the capsid in a manner that is coupled to the ATP hydrolysis, much like bacteriophage terminases.[418,529]

Viral Egress

Once the mature nucleocapsid is formed in the nucleus, it must traverse several membranes (the nuclear and the plasma membranes) and the cytoplasm on its route to the extracellular space while completing its maturation by acquiring the lipid envelope and the tegument layer.[205] Cell lysis typically occurs very late during HSV infection, so viral egress must occur through a specialized secretion pathway. Transit from the nucleus to the cytoplasm represents a particular obstacle because the nucleus is surrounded by a double membrane consisting of the inner nuclear

membrane (INM) and the outer nuclear membrane (ONM), and most transport in and out of the nucleus occurs through nuclear pores, which are approximately 39 nm in diameter. But being approximately 125 nm in diameter, HSV capsids are too large to pass through the nuclear pores and must use a different route.

According to the prevalent model,[42,93,396] nucleocapsids first become enveloped at the inner nuclear membrane forming perinuclear enveloped virions (PEVs) in the perinuclear space (primary envelopment) (Fig. 9.12). The PEVs then fuse with the outer nuclear membrane releasing the capsid into the cytoplasm (de-envelopment). The capsid then undergoes second, final budding at cytoplasmic membranes (secondary envelopment). During this step, the capsid matures into an infectious virion by acquiring its final lipid envelope and the tegument and is released from the cell by exocytosis. While unusual, this model is the most widely accepted and is backed up by substantial data as detailed below.

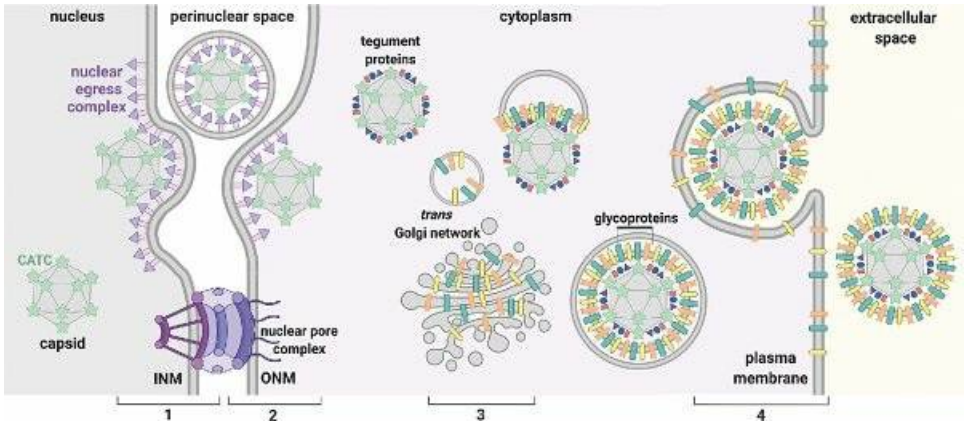

FIGURE 9.12 Overview of herpesvirus egress. Viral nucleocapsids are assembled in the nucleus and must translocate into the cytoplasm where they complete their maturation by acquiring the tegument and the envelope. Too large to fit through the nuclear pores, capsids, instead, use a different, more complex route. *Step 1*: capsids dock and bud at the inner nuclear membrane pinching off into the perinuclear space as the perinuclear enveloped virions (primary envelopment). This process is mediated by the virally encoded nuclear egress complex that, presumably, binds the CATC at the capsid vertices. *Step 2*: perinuclear enveloped virions fuse with the outer nuclear membrane and release the capsid into the cytoplasm (de-envelopment). *Step 3*: cytoplasmic capsids acquire the tegument layer and the envelope by budding at membranes derived from the trans-Golgi network or the early endosomes (secondary envelopment). *Step 4*: the mature virions inside the secretory vesicles fuse with the plasma membrane are released into the extracellular space. Abbreviations: INM, inner nuclear membrane; ONM, outer nuclear membrane; CATC, capsid-associated tegument complex. Figure generated using BioRender (https://biorender.com). Over the years, several models of egress have been proposed. According to the “luminal” egress model,[394] the PEVs instead of fusing with the ONM, acquire a second envelope and

traverse the cytoplasm as double-membrane transport vesicles that fuse with the plasma membrane and release enveloped capsids into the extracellular space. Several lines of evidence argue against this model, however. First, PEVs differ from the mature, extracellular virions in their morphology and protein composition.[286,384] For example, UL31 and UL34, two viral proteins critical for nuclear egress, are found in PEVs but absent from mature HSV-1 or PRV virions.[384] Likewise, the lipid composition of extracellular virions resembles that of cytoplasmic rather than nuclear membranes.[479] Furthermore, unenveloped capsids in the cytoplasm are often found juxtaposed to curved, invaginated vesicles as evidence of envelopment at cytoplasmic membranes,[442] and deletions of particular tegument or envelope proteins, such as HSV-1 UL36 and UL37, or the glycoproteins gD and gE from either HSV-1 or PRV, result in unenveloped capsids accumulating in the cytoplasm.[106,107,133,266,385]

According to an alternative “nuclear pore” egress model, capsids escape the nucleus through enlarged pores. However, other studies have not observed enlargement or other changes in nuclear pores that would allow movement of nucleocapsids to the cytoplasm.[181] Moreover, PEVs in the perinuclear space (PNS) have been observed in many HSV-infected cells[384,442] and accumulate there as the result of some viral gene deletions,[384] which points to budding into the PNS being an intermediate stage in egress. Taken together, these observations argue strongly in favor of the envelopment–de-envelopment–re-envelopment model of egress,[42,93,205,396] in which capsids gain their initial, temporary envelope at the INM, traffic into the cytoplasm as unenveloped capsids, and then acquire their final envelope at cytoplasmic vesicles.

Primary or Nuclear Envelopment

During primary envelopment, the first step in nuclear egress, the mature nucleocapsids acquire an envelope by budding at the INM. This process requires that the capsid be recruited to and dock at the INM, the membrane be deformed around the capsid to form a nascent bud, and the bud be pinched off the INM releasing the PEV into the PNS. However, in the HSV-infected cell nucleus, the marginalized host chromatin and the nuclear lamina present barriers to capsid budding. To overcome these barriers, HSV infection causes both the dispersal of the marginalized host chromatin[430] and the disruption of the nuclear lamina.[383,430]

The nuclear lamina is a dense filamentous protein network of lamins and lamin-associated proteins (LAPs) that underlies the INM and provides shape and mechanical stability to the nuclear envelope. In uninfected cells, the nuclear lamina is completely disassembled during mitosis through phosphorylation of lamins and LAPs by cellular mitotic kinases that disrupt their interactions. However, there is no full disassembly during herpesvirus infection, presumably, to preserve the integrity of the nucleus where viral genome replication and capsid assembly occur. Instead, the lamina is disassembled locally through phosphorylation of lamins and LAPs by the HSV-1 kinase US3 and by cellular kinases that are different from the mitotic kinases,[177,292,396] notably by the protein kinase C that is recruited to the INM, along with the host protein p32 by the HSV-1 ICP34.5 protein.[504,521]

Primary envelopment requires the viral UL31 and UL34 proteins that form the heterodimeric nuclear egress complex (NEC) and are conserved across the *Herpesviridae*. In the absence of either UL31 or UL34, viral replication is reduced by three to five orders of magnitude, and capsids accumulate within the nucleus.[65,398] UL34 has a single-spanning C-terminal

transmembrane region (TM) that anchors the complex to the INM. UL31 is a soluble nuclear phosphoprotein that is retained at the inner nuclear membrane through its interaction with UL34. Crystal structures of NEC homologs from HSV-1, PRV, and HCMV[41,294,495,538] have revealed an elongated cylindrical heterodimer, in which the globular core of UL31 wraps a hook-like extension around the globular UL34 pedestal.

UL31 and UL34 may promote the disruption of the nuclear lamina by binding lamins[383] and by recruitment of the viral US3 kinase and the protein kinase C to the nuclear lamina. UL31 and UL34 are also required for the dispersal of the marginalized cellular chromatin,[430] which may be an indirect effect of disruption of the nuclear lamina, to which cellular chromatin is tethered.

In addition to their roles in clearing the barriers to capsid budding at the INM, UL31 and UL34 are directly involved in the budding process. In PRV, expression of UL31 and UL34 in uninfected cells resulted in the formation of capsid-less perinuclear vesicles, which demonstrated that UL31 and UL34 are the only viral proteins necessary for nuclear budding.[233] Moreover, the NEC has an intrinsic ability to deform and bud membranes, which was established by showing that purified recombinant NEC homologs from HSV-1 or PRV can vesiculate synthetic lipid bilayers *in vitro* without any additional factors or chemical energy.[43,285]

Cryo-EM and tomography (cryo-EM/T) demonstrated that during budding *in vitro*, HSV-1 NEC oligomerizes into hexagonal “honeycomb” coats on the inner surface of lipid vesicles.[43] Coats of similar geometry have been observed on the inner surface of capsid-less perinuclear vesicles formed *in vivo* in uninfected cells expressing PRV NEC.[163] Hexagonal symmetry evident in the coats formed as the result of budding both *in vitro* and *in vivo* suggests that the hexagonal arrangement is biologically relevant. Mutations in U_L31 or U_L34 that would be predicted to disrupt the hexagonal arrangement reduce budding *in vitro*[41,43] and in infected cells,[22,397] which suggests that the hexagonal coat formation is important for the NEC budding activity.

C-capsids preferentially undergo primary envelopment at the INM,[489] implying the existence of a capsid selection mechanism that ensures that only mature, DNA-filled capsids exit the nucleus, which would increase the yield of infectious virions. The nature of this selection mechanism is yet unclear but may involve interactions between UL31 and the CVSC/CATC at the capsid vertices because CVSC/CATC components UL25 and UL17 have been shown to bind UL31[530] and because UL25 mediates interactions between purified HSV-1 nucleocapsids and recombinant NEC.[456] Furthermore, UL25 is required for nuclear egress.[252] Although CVSC/CATC is present on all three capsid types, A- and B-capsids have fewer CVSC/CATC copies on the capsid surface and may differ in the CVSC/CATC conformation.[331] Multiple NEC-binding sites on a C-capsid could thus provide the driving force for creating a PEV through avidity.

In addition to the quality control mechanism(s) that ensure budding of mature C-capsids, another mechanism appears to prevent unproductive budding in the absence of C-capsids, because during infection capsid-less perinuclear vesicles are rarely observed in infected cells. This could be achieved by down-regulating the NEC budding activity prior to the arrival of the capsid, potentially by phosphorylation of UL31 by the alphaherpesviral US3 kinase.[321]

De-envelopment

During this next step in nuclear egress, the PEVs fuse their envelopes with the ONM, which releases the capsids into the cytoplasm (Fig. 9.12). To ensure efficient nuclear egress, PEVs must preferentially fuse with the ONM rather than the INM, but how this selection is achieved is yet unknown. Defects in de-envelopment typically manifest as the accumulation of PEVs in the PNS, with a concomitant reduction in viral titer. Accumulation of PEVs in uninfected cells expressing UL31 and UL34 from HSV-1 or PRV[233] implies the involvement of viral proteins besides UL31 and UL34 in de-envelopment, and several viral proteins have been implicated in this process. Yet, proteins that mediate membrane fusion during de-envelopment have not yet been conclusively identified. The conserved viral glycoproteins gB and gH, which mediate membrane fusion during entry, have been proposed to mediate de-envelopment in HSV-1 because in a gB/gH double mutant virus,[134] PEVs accumulate in the PNS. However, the double deletion has little effect on the extracellular virions. Moreover, single deletions of gB or gH have minimal effects on de-envelopment,[134] which is at odds with both glycoproteins being essential for fusion during HSV-1 entry. Both gB and gH are dispensable for de-envelopment in the closely related PRV.[232] Therefore, other fusion mechanisms independent of these viral glycoproteins must also exist. Overexpression of another viral glycoprotein, gK from HSV-1, which localizes to the ER during infection, results in the accumulation of PEVs, but its precise role in the de-envelopment remains unclear. Elucidation of the de-envelopment mechanism requires identification of proteins on the surface of the PEVs and/or on the perinuclear surface of the ONM that would enable membrane fusion and hence de-envelopment to take place. Membrane fusion is, presumably, accompanied by disassembly of the NEC coats, to allow the naked capsids to be released into the cytoplasm, but the mechanism is yet unknown.

Secondary Envelopment

During this final step in viral morphogenesis, cytoplasmic capsids acquire their tegument and lipid envelope by budding at cytoplasmic vesicles. The identity of the cytoplasmic sites of secondary envelopment have not yet been fully elucidated. HSV has been proposed to undergo secondary envelopment at sites coincident with markers of the trans-Golgi network (TGN)[172,451] or endosomes.[184] HSV infection leads to reorganization of cytoplasmic membranes, blurring the distinction between trans-Golgi and endocytic organelles such that TGN and endosomal markers are spread throughout the cytoplasm. Regardless, both the TGN-derived secretory vesicles and the endocytic pathways contribute to secondary envelopment by mediating trafficking of viral glycoproteins required for efficient secondary envelopment of HSV-1[10,184,204] or trafficking of enveloped particles to the plasma membrane after secondary envelopment.[182,183,204]

At least 12 viral tegument proteins (UL7, UL11, UL14, UL16, UL21, UL36, UL37, UL46, UL47, UL48, UL49, UL51) form a protein interaction network that drives tegument assembly and secondary envelopment.[93,351] However, most individual tegument proteins and protein/protein or protein/membrane interactions are not essential for secondary envelopment. Therefore, this network appears to be functionally redundant.

HSV also recruits components of the cellular ESCRT (endosomal sorting complex required for transport) machinery that mediates membrane budding “away” from the cytoplasm, into either the lumenal or the extracellular space. Only ESCRT-III and Vps4, which function at late stages of the budding process, namely, the scission of the budded vesicle, are required for secondary envelopment of HSV-1 and PRV.[25,226,227,359] This suggests that the budding process

during secondary envelopment utilizes a combination of viral and cellular machinery. The precise mechanism of secondary envelopment is yet to be elucidated.

In addition to infectious virions, in certain cell types, the alphaherpesviruses produce a large number of noninfectious light, or L-particles that contain only viral tegument and envelope proteins. The functions of L-particles in viral infection and pathogenesis are not entirely clear.[38,169,218]

Intracellular Transport and Exocytosis

Secondary envelopment produces an enveloped infectious virion within the lumen of a secretory vesicle. This virion-containing double-membraned vesicle then traffics to the cell periphery along the microtubules where the membrane of the secretory vesicle fuses with the plasma membrane—an SNARE-mediated process called exocytosis—to release the virion to the extracellular space.[182,183] Viral proteins may function as cargo adaptors to recruit microtubule motors to viral secretory vesicles. However, little is known about the identity of viral membrane and tegument proteins present on the cytosolic face of viral secretory vesicles or their function in virion exocytosis.

Targeting of Virus During Egress

In certain specialized cell types, HSV egress can be targeted. In polarized epithelial cells, for viruses that bud through the plasma membrane, targeting of viral glycoprotein(s) to the apical or basolateral surface defines the site of viral release from the cell. HSV glycoproteins target to the basolateral membranes of polarized epithelial cells. For HSV, with the complex pathways of release described above, targeting of viral proteins to specific plasma membrane sites does not direct virus budding to those sites. In fact, HSV egress is targeted to lateral membranes, in particular to cell–cell junctions in polarized epithelial cells, and this process requires the viral gE/gI glycoprotein complex. It is believed that the gE/gI complex accumulates in one domain of the TGN and promotes secondary envelopment there, and this domain targets the sorting of the virion vesicles to the cell–cell junctions and the basolateral membrane.[206] The ability of HSV to spread cell-to-cell is likely to occur via tight junctions in polarized epithelial cells, but the virus can also spread to other cell types in the presence of antibodies, forming the basis of plaque assays conducted in the presence of antiviral antibodies. This allows HSV to spread *in vivo* from one epithelial cell to another without being neutralized by antiviral antibody.

INTRINSIC IMMUNITY, INNATE IMMUNITY, AND ANTI-ANTIVIRAL DEFENSES

Overview

From the initial encounters following entry into the infected cell to the release of progeny virus,

the numerous events and processes required for HSV replication and their impact on cellular physiological process are subject to intense surveillance by an intricate network of host defenses. Detection of conserved viral structural components termed pathogen-associated molecular patterns or PAMPs can interfere with a cell's capacity to support virus replication by inducing a suite of proteins designed to hamper virus replication, including soluble inflammatory mediators like type I interferons that inform neighboring cells of an infectious invader and program them into an antiviral state. Furthermore, the appropriation of critical host processes vital to virus reproduction can trigger responses that restrict virus replication and spread. Included among these latter responses are those that limit viral gene expression in both nuclear and cytoplasmic compartments, result in acute physiological stress, and influence infected cell survival. While such innate, cell-intrinsic responses, if left unchecked, would inhibit virus replication and in fact may be harnessed to in part support latency in neurons, numerous HSV-encoded functions have been identified that subvert host defenses to support virus replication and effectively enable infectious virus production. The cellular factors and processes capable of detecting HSV infection and restricting virus reproduction together with viral countermeasures designed to subvert them are enumerated in the following section. These topics are reviewed in several recent review articles,[8,234,253,289,445] and the reader is referred to these for more detailed discussion.

Receptors that detect HSV infection are located throughout the cell and act to directly restrict viral replication or to initiate signaling pathways that limit viral replication. We will investigate the host cell resistance mechanisms that the virus encounters as it proceeds through the replication cycle.

Receptors at the Plasma Membrane and Endosomes

Toll-like receptor 2 (TLR2) is a cell surface receptor on various antigen-presenting cells that recognizes lipoproteins of various microbes and initiates innate signaling. TLR2 is activated by HSV infection to signal through NF-κB signaling pathways to elicit cytokine production.[149,500] Soluble forms of HSV-1 glycoprotein H and L can activate TLR2 signaling,[149] and the same events likely occur in virus-infected cells. The molecular basis for the TLR2-gH/gL interaction is not understood and could be an important model for TLR2 interaction with viruses. HSV-1 activation of TLR2 leads to MyD88-dependent induction of NF-κB signaling and expression of proinflammatory cytokines such as IL-6 and IL-8. Because of this, TLR2 activation of innate responses and cytokines is an important aspect of HSV-1 encephalitis in murine models. Other factors involved in this signaling process are αvβ3-integrin, which has been reported to act in concert with TLR2 to elicit innate signaling in response to HSV[149] and CD200R1, which increases TLR2 signing on mouse peritoneal macrophages infected with HSV-1.[435]

The HSV-1 IE ICP0 protein reduces the TLR2 signaling pathway by promoting the degradation and/or sequestration of the MyD88 adaptor protein,[480] which would limit the cytokine response in that cell. However, HSV activation of the NF-κB pathway is proviral in the infected cell,[358] and this may be due to NF-κB stimulating IE gene expression or to induction of host genes that protect from apoptosis[301] or other stress. Nevertheless, at face value, these results would seem paradoxical. HSV can activate NF-κB through other mechanisms, including by the tegument protein UL37 binding to TRAF6 and activating NF-κB signaling.[281] Therefore, proteins in incoming virions, including gH/gL and UL37, may activate a limited amount of NF-κB signaling to protect the infected cell, while the IE protein ICP0 and the L US3 protein reduce

NF-κB signaling to limit innate signaling.

Toll-like receptor 9 (TLR9) is a receptor located in endosomes that recognizes unmethylated CpG-rich DNA sequences. TLR9 is important for IFN expression in HSV-1–infected dendritic cells, and TLR9 knockout mice have a reduced type I interferon response to HSV-1 infection. Nevertheless, TLR9 is not required to control HSV-1 infection in mice.[378,500] TLR9, like TLR3, TLR7, and TLR8, requires UNC93b for trafficking to endosomes.[231] Mutations in UNC93b reduce the IFN response to HSV-1 infection,[500] and patients with defects in UNC93b are highly susceptible to herpes simplex encephalitis. Although the UNC93b effect is usually associated with TLR3 deficiency, TLR9 could also play a role in the UNC93b mutation phenotype.

Toll-like receptor 3 (TLR3) is an endosomal receptor that recognizes double-stranded RNA and activates IRF-3 or NF-κB signaling. Human 293 cells expressing TLR3 did not activate NF-κB signaling, but TLR3$^{-/-}$ cells show reduced interferon induction upon HSV-1 infection. Thus, TLR3 is not sufficient for NF-κB signaling in response to HSV-1 infection but is required for optimal IFN responses to HSV-1 infection. Individuals with TLR3-related mutations are susceptible to herpes simplex virus encephalitis (HSE).[17,174,278,406] Furthermore, individuals with UNC93B mutations also show susceptibility to HSE, and as discussed above, UNC93B is involved in transport of TLRs to endosomes. Therefore, there is considerable evidence that TLR3 plays an important role in control of HSV-1 infection in neurons in the central nervous system.

Cytoplasmic Sensing of Viral PAMPS

Cyclic guanylate adenylate synthase (cGAS) is a cytoplasmic sensor that detects DNA, primarily found outside nuclear and mitochondrial subcellular compartments in the cytosol. Upon binding to DNA, cGAS undergoes a conformational change and becomes activated to synthesize cyclic guanosine monophosphate–adenosine monophosphate or cGAMP.[5,111,452] cGAMP then binds to STING to activate it and then IRF-3, which dimerizes and localizes into the nucleus to activate transcription of the *IFNB1* gene, which encodes IFN-β, and other antiviral genes. cGAS is required for induction of type 1 interferons in response to HSV-1 infection in mouse cells[271] and human fibroblasts.[346] Viral DNA is normally transported to the nucleus inside the capsid and thus should not be available for binding by cGAS. However, in macrophages, the capsid is thought to be proteolytically digested and released into the cytosol.[187] Thus, it is not clear how HSV DNA is available for binding to cytoplasmic cGAS in cells other than macrophages, and the role for cGAS in HSV induction of IFNs and its DNA ligand have not been fully defined. cGAS could be involved in sensing of HSV DNA from damaged virions or leaking out of the nucleus or in maintaining tonic or normal physiological levels of DNA sensing machinery in uninfected cells. In addition, HSV infection causes leakage of mitochondrial DNA into the cytoplasm,[514] which could be the ligand for cGAS in HSV-infected cells. Alternatively, there is evidence that some cGAS is nuclear and promotes the stability of IFI16, a nuclear sensor of HSV-1 DNA[346] or acts in cooperation with IFI16 in induction of interferons.[15] Thus, the role of cGAS in induction of interferons during HSV infection remains to be fully defined. Besides its role in controlling interferon production, interferon-independent STING functions have also been reported to promote HSV-1 resistance in mice.[526]

Absent in Melanoma 2 (AIM2). AIM2 is a cytoplasmic DNA sensor that when activated leads to a signaling pathway that activates inflammasome formation and secretion of the

proinflammatory cytokines interleukin 1β (IL-1β) and IL-18. Wild-type HSV-1 does not activate AIM2 signaling,[379] but this is likely due to HSV-1 proteins blocking signaling. A recent study has shown that the HSV-1 VP22 protein blocks multimerization of AIM2 and reduces its signaling.[304]

RNA Sensors in the Cytosol

PKR and OAS. Double-stranded RNA (dsRNA) generated by transcription from primarily late genes encoded on opposing DNA strands in the viral genome is another PAMP indicative of virus infection that accumulates in HSV-infected cells.[101] Following recognition by discrete dsRNA-binding proteins that are subsequently activated by interaction with dsRNA, these host dsRNA PAMP-binding proteins interfere with key functions needed for virus reproduction including protein synthesis and global RNA stability. As discussed in the Gene Expression section above, dsRNA accumulation activates the eIF2α kinase PKR, which can block translation initiation on all mRNAs dependent upon eIF2 to load 40S ribosomes with initiator tRNA and largely inhibit infected cell protein synthesis (Fig. 9.10). Preservation of active, unphosphorylated eIF2 is achieved via the HSV-encoded PP1α-binding subunit ICP34.5 and the PKR antagonist U_S11. The cellular 2′-5′oligoadeylate synthetase (OAS) is another host dsRNA-activated protein that functions as an innate antiviral defense component. Upon activation by dsRNA, OAS catalyzes the *de novo* synthesis of oligoadenylate (OA) chains with a distinctive 2′-5′ linkage.[414] Three major OAS isoforms have been identified as members of a related family and while how they differ functionally is incompletely understood, each exhibits distinctive biochemical properties including their responsiveness to dsRNA concentration, the length of the 2′-5′ OA synthesized, their subcellular localization, and cell type specificity.[414] The resulting OA products bind to the inactive host ribonuclease, RNase L, and stimulate formation of active RNase L homodimers from inactive monomer subunits. By cleaving RNA at the 3′ side of UpXp sequences, activated RNase L promotes both mRNA and rRNA decay within infected cells. OAS activity is inhibited in HSV-1–infected primary human fibroblasts.[405] Furthermore, the HSV-1 U_S11 gene product was sufficient to block OAS activation in extracts from uninfected, interferon-treated cells, and ectopically expressed US11 protein and OAS physically associated in a nuclease-sensitive manner in uninfected cells. The US11 dsRNA-binding domain was required to inhibit OAS, suggesting a mechanism that, in part, could rely on sequestering available dsRNA produced during infection.[405] Like PKR, OAS is one of hundreds of interferon-stimulated genes whose protein products accumulate in uninfected cells and in part contribute to the establishment of an “antiviral” state that is nonpermissive for virus reproduction. In addition, as dsRNA-activated host effectors, the antiviral functions of both PKR and OAS are antagonized by the HSV-encoded dsRNA-binding protein US11.

Retinoic acid–inducible gene I (RIG-I) is a cytoplasmic receptor that recognizes RNA molecules with a 5′ triphosphate or dsRNA molecules. RIG-I–dependent signaling in HSV-infected cells has been described,[72,283,543] but the RNA ligand for RIG-I had not been defined. Viral dsRNA has been reported, and it was hypothesized that small RNAs generated from HSV DNA by RNA pol III released into the cytosol could be ligands for RIG-I.[4,73] Chiang et al.[72] found that a host small RNA, 5S ribosomal RNA pseudogene 141 (RNA5SP141) RNA was the major RNA bound to RIG-I in infected cells. They found that viral inhibition of protein synthesis reduced the abundance of the proteins bound to the pseudogene RNA, exposing the 5S RNA, and

releasing it to the cytoplasm where it is recognized by RIG-I.[72]

Nuclear Defenses

As described in the Gene Expression section, a variety of nuclear molecules serve as restriction factors for HSV-1 replication, including PML, Daxx, ATRX, Sp100, and IFI16. Only IFI16 has been shown to bind preferentially to unchromatinized DNA,[449] but it is believed that that many of these proteins are recruited to the entering viral DNA and promote loading and/or maintenance of heterochromatin. IFI16 has been shown to bind to viral DNA and induce IRF-3 signaling and IFN-β expression,[270,349] in addition to its epigenetic effects.

Evasion and Blunting the Interferon Response

As described above, a number of cellular receptors recognize a number of HSV PAMPs and induce interferon expression, which restricts viral replication in surrounding cells and even in the initial infected cell. However, HSV has evolved a number of viral functions that counter the induction and action of interferon. In fact, the large number of ways by which HSV counters type 1 interferon induction and action demonstrates how important interferons are as an antiviral response for protection against HSV-1. The antiviral gene functions that counter interferons include the following viral genes:

1. *ICP0* degrades IFI16[349] and inhibits and sequesters IRF3[311] to block their action in interferon induction.
2. *US3* phosphorylates a number of host proteins and thereby affects a number of host response pathways. US3 phosphorylates KIF3 (kinesin superfamily protein 3) and thereby down-regulates CD1d expression to inhibit NKT (natural killer T) cell function.[523] US3 reduces type I IFN and ISG induction in HSV-1–infected human monocytes,[362] but the mechanism is not defined. In addition, US3 inhibits TLR2 signaling by reducing TRAF polyubiquitination through a mechanism dependent on the protein's kinase activity.[419] Furthermore, US3 is reported to hyperphosphorylate p65RelA to reduce NF-κB activation in response to TNF-α or IL-1β stimulation,[498] although this effect was not observed for other NF-κB stimuli.[419]
3. *UL37* deamidates the helicase domain of RIG-I to prevent its binding to RNA and induction of interferon expression[543] and deamidates cGAS to reduce its ability to make cGAMP.[540]
4. *ICP27* stimulates the secretion of an infected cell factor that inhibits Stat-1 nuclear accumulation by inhibiting IFN-induced Stat-1 phosphorylation at or upstream of Jak-1.[208] ICP27 also inhibits the cGAS-STING-TBK1 pathway in human macrophages by binding to TBK1 and STING.[76]
5. *ICP34.5* precludes the translational arrest imposed by activated PKR by promoting eIF2α dephosphorylation via an interaction with the PP1α host protein phosphatase. ICP34.5 also overcomes PKR-induced autophagy by binding Beclin-1 and inhibiting its autophagy function.[345] ICP34.5 was reported to reduce ISG expression by blocking the interaction of TBK1 with IRF3 through an interaction with TBK1,[484] but recent data show that this effect may be exerted more indirectly.[300]

6. *UL41/vhs* promotes degradation of host mRNAs and prevents the replenishment of host sensors and response molecules, such as TNF receptor 1, viperin,[421,539] and IFI16.[347]
7. *US11* interacts with a number of host proteins to block innate responses, including PKR to block eIF2 phosphorylation, PACT to prevent PKR activation,[366] OAS to inhibit its activity,[405] and RIG-I or MDA5 to reduce IFN induction.[225]

Catabolic Physiological Stress Responses

HSV infection results in substantial physiological stress that perturbs cellular homeostasis and evokes catabolic responses with antiviral consequences. Cell intrinsic stress responses to virus-induced disturbances, including intensive demands for amino acids and energy, can restrict virus reproduction and spread and thereby contribute to host antiviral defenses. One critical aspect of maintaining homeostasis during virus infection is balancing energy-demanding anabolic processes, including protein synthesis that is absolutely reliant upon host ribosomes, with catabolic processes poised to short circuit the virus lifecycle, prevent infectious virus production, and contain virus spread in a cell intrinsic manner. The multisubunit ser/thr kinase mTORC1 is at the nexus of information-rich cellular signaling networks that integrate physiological and environmental cues and plays essential roles in coordinating fundamental anabolic and catabolic outputs (reviewed by[229]) that profoundly influence host responses to HSV (Fig. 9.9). Moreover, mTORC1 together with virus-encoded functions that subvert mTORC1 signaling impact the proficiency with which the virus replicates during episodes of physiological stress, a defining feature of HSV infection biology.

The HSV US3 ser/thr protein kinase alters the responsiveness of mTORC1 to metabolic stress resulting from either energy or amino acid insufficiency (Fig. 9.9). In contrast to uninfected cells where energy or amino acid insufficiency inhibits mTORC1 activation to tune anabolic processes like protein synthesis to physiological stress,[229,410] mTORC1 remains activated in HSV-1–infected cells deprived of amino acids or under low energy stress. Although US3 did not detectably prevent low energy stress-induced activation of the host AMP-activated protein kinase (AMPK), it enforced mTORC1 activation despite the presence of activated AMPK, and AMPK activity in infected cells was restricted in a US3-dependent manner.[487] Similarly, synergistic action of the HSV-1 UL46 gene product, which stimulates PI 3-kinase and Akt,[123] and US3 supports virus reproduction during amino acid insufficiency.[486] Together, this defines the US3 kinase as an mTORC1 activator that subverts the host cell energy and nutrient-sensing programs to support viral productive growth and overcome cell intrinsic innate responses to metabolic physiological stress that could otherwise restrict virus protein synthesis and reproduction (Fig. 9.9). Uncoupling mTORC1 activation from energy and nutrient availability enables HSV to enforce high-level viral protein synthesis needed for replication during physiological stress and overcome what is likely an evolutionary ancient response that restricts pathogen reproduction within host cells during nutrient and energy insufficiency.

Autophagy

Besides sanctioning survival and adaptation under inauspicious conditions such as starvation and physiological stress, macroautophagy or autophagy enables cells to maintain homeostasis by recycling cytoplasmic components and is a vital innate host defense regulating infection and inflammation.[144,258,531] Cytoplasmic, double-membrane autophagosome accumulation

commences in response to type 3 phosphoinositide 3-kinase (PI3KC3) activation by Beclin1. Delivery of autophagosome contents to lysosomes by fusion results in their proteolytic destruction and catabolic amino acid recycling. Autophagy is regulated in part by mTORC1, which coordinates anabolic and catabolic outcomes in response to changes in homeostasis.[229,410] While activated mTORC1 represses autophagy and stimulates anabolic responses like protein synthesis, insufficiency of nutrients, energy, or growth factors inhibits mTORC1 activation, which limits protein synthesis and promotes autophagy (Fig. 9.9). Host stress-activated eIF2α kinases that limit protein synthesis in response to virus infection, amino acid insufficiency, or ER stress also function as innate defenses and can incite autophagy.[458] By contrast, Beclin1 site–specific phosphorylation by Akt[500] restricts autophagy.

At least three independent functions encoded within the HSV genome antagonize autophagy, illustrating the importance of suppressing this catabolic process. By preventing eIF2 phosphorylation and subsequent inactivation (Fig. 9.10), both ICP34.5 and US11 curb autophagy.[291,458] While US11 also inhibits TANK-binding kinase 1 (TBK1) activation,[282] an N-terminal ICP34.5 domain interacts with and antagonizes Beclin1.[345] Significantly, HSV-1 replication was enhanced in ATG5-deficient mouse sensory neurons unable to undergo autophagy.[533] Furthermore, reduced pathogenesis in adult mice was reported following infection with HSV-1 encoding a Beclin1-binding deficient ICP34.5 mutant protein.[345,518] Greater destruction of viral proteins and/or virions following their delivery to autophagosomes likely accounts in part for this phenotype and was consistent with autophagy functioning as a neuron-specific antiviral defense.[11] In contrast to these findings in adult mice, pathogenesis was not dependent upon the ICP34.5 Beclin1-binding domain in the neonatal mouse CNS,[518] where a greater reliance on ICP34.5 binding to PP1α to preserve unphosphorylated supplies of eIF2 was observed.[517] Thus, age-related and developmental differences in how autophagy is regulated in response to HSV-1 infection likely impact pathogenesis. Recently, however, the HSV-1 US3 ser/thr kinase was shown to be required for virus reproduction in nonneuronal cells during physiological stress, including nutrient deprivation that inhibits mTORC1 activation, and shown to inhibit autophagy.[399] By enforcing constitutive mTORC1 activation, US3 suppresses catabolic responses like autophagy while favoring anabolic responses (including protein synthesis described earlier in Gene Expression and Fig 9.9). Significantly, phosphorylation of cellular autophagy regulators ULK1 and Beclin1 in HSV-1–infected nonneuronal cells was dependent upon US3.[399] Besides preventing mTORC1-dependent autophagy by stimulating ULK1 phosphorylation, US3 was sufficient to also block autophagy in an mTORC1-independent manner and directly phosphorylated the key autophagy regulator Beclin1 on the same site targeted by the cellular kinase Akt,[399] which is known to limit autophagy.[500] Moreover, disabling autophagy by depleting ULK1 and Beclin1 partially rescued US3-deficient virus replication in primary fibroblasts.[399] Thus, autophagy generally limits HSV-1 replication in a cell intrinsic manner in nonneuronal cells, as well as neuronal cells, and is antagonized by multiple, independent virus-encoded functions that act through different mechanisms. Precisely why multiple HSV-encoded functions are needed to counter autophagy remains unknown but could conceivably either increase the probability that autophagy is inhibited in infected cells or enable different functions to predominate in different cell types encountered during the virus lifecycle.

Programmed Cell Death

By activating programmed cell death responses in response to virus infection, virus-infected cells cause their own elimination prior to the completion of the virus reproductive cycle. This cell intrinsic innate immune mechanism that results in death of the infected cell spares surrounding cells and tissues and can effectively limit virus reproduction and spread. Different programmed cell death processes have been identified with distinctive cell biological features and molecular control circuitries and likely have driven the acquisition of virus-encoded countermeasures to disarm them.

Apoptosis

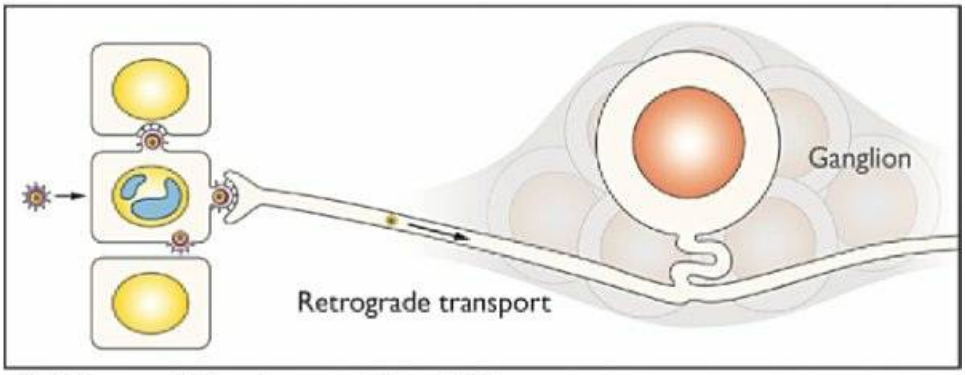
Apoptosis is a developmental process that allows for cell removal via a noninflammatory cell death program characterized by a reduction in cell volume, chromatin condensation and fragmentation, phosphatidylserine exposure in the plasma membrane outer leaflet, and formation of small apoptotic cell bodies that are engulfed by phagocytes.[327] It can be triggered by an extrinsic pathway, which involves extracellular mediators such as signaling by TNF superfamily members (FasL, TNFα, TRAIL) or an intrinsic pathway activated by physiological stressors (ER, genotoxic, survival factor insufficiency, anoikis, inhibition of transcription or translation, cytoskeleton disruption). Activation of cellular pro-apoptotic BCL-2 family members (BAX, BAK, Bid) by the intrinsic pathway stimulates caspase activation, which shapes apoptotic responses by degrading numerous cellular protein substrates and results in mitochondrial outer membrane permeabilization and cytochrome c release.[327] By contrast, the extrinsic pathway requires a caspase 8-containing signaling complex that detects many pathogens including HSV.[317] Apoptosis can also result in response to perturbations in homeostasis induced by HSV-1 infection.

In the context of infection, viruses deficient in key IE regulators ICP4 or ICP27 were unable to suppress apoptosis. Subsequently, discrete HSV-1–encoded gene products whose expression was regulated by ICP4 and ICP27, including glycoproteins (gD, gJ) and the US3 protein kinase, were identified and shown to block apoptosis induced by Fas ligand, sorbitol-induced osmotic shock, virus-dependent lysosomal discharge, overexpression of proapoptotic proteins including Bcl-2 family members and caspase 3, or by viral proteins that provoke apoptotic responses.[31,546] The gD domains needed to block apoptosis induced by HSV-1 are reportedly distinct from those required for binding to the primary receptor nectin 1 or cell-to-cell fusion; however, stimulation of NF-κB activation in response to HSV infection by binding to HVEM on cells that express this TNF receptor family member has been reported.[416] Similarly, the precise mechanism underlying the inhibition of apoptosis by gJ remains unclear, although gJ is widely distributed within infected cells in the endoplasmic reticulum, *trans*-Golgi network, and early endosomes and was found to interact with FoF1 ATP synthase subunit 6.[31] By preventing cleavage of the proapototic BAD BCL-2 family member, the US3 ser/thr kinase blocks BAD-induced caspase 3 activation, and subsequent caspase-dependent cleavage of poly(ADP-ribose) polymerase (PARP), and fragmentation of cellular DNA.[324] While initial studies correlated this activity with US3-dependent BAD phosphorylation on Ser 112 and Ser 136, subsequent work revealed that phosphorylation on these residues was not needed for US3 antiapoptotic activity. Because the US3 ser/thr kinase activity is required to block apoptosis, it remains possible that US3 targets a caspase that cleaves BAX. US3 was also found to block apoptosis induced by overexpression of other proapototic BCL2 family members such as Bid and BAX, and these results suggested that US3 may in fact act to limit apoptosis both upstream and downstream of mitochondrial events. A

conserved C-terminal domain within the large subunit of the ribonucleotide reductase (ICP6) encoded by both HSVs, which also is required for ribonucleotide reductase activity when physically associated with the virus-encoded R2-subunit, interacts with the caspase 8 death effector domain to suppress apoptosis induced via the extrinsic pathways.[121] Finally, a function within the latency-associated transcript (LAT) produced in latently infected neurons reportedly suppresses apoptosis and influences reactivation efficiency in the murine and rabbit models.[120,364]

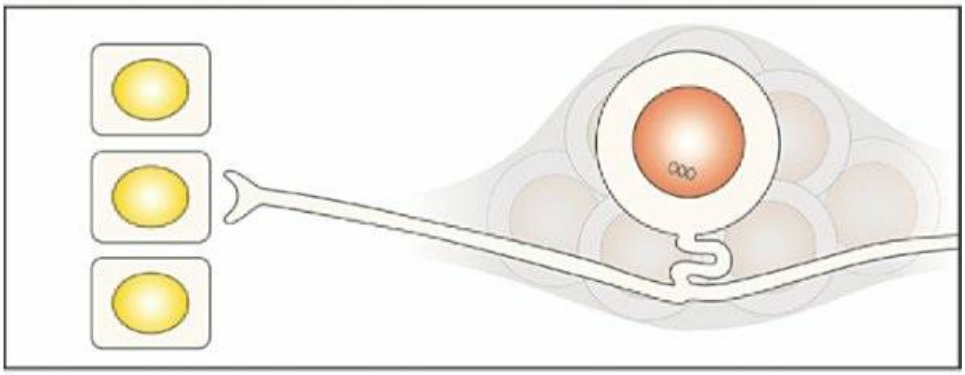
Direct Activation of Programmed Necrosis/Necroptosis

As a consequence of interfering with caspase 8–dependent apoptosis, an alternative programmed cell death (PCD) pathway, necroptosis, can be triggered.[316] Characterized by intracellular organelle swelling, plasma membrane disruption, and inflammation, programmed necrosis or necroptosis is controlled by formation of the necrosome, a complex of receptor-interacting kinases (RIP1 and RIP3) via their RIP homotypic interaction motif (RHIM) domains.[77,482] Following phosphorylation of mixed lineage kinase domain like (MLKL)-protein, a kinase substrate of RIP3, MLKL oligomers trigger membrane pore formation and necrosis.[56,68,496] Besides limiting apoptosis as reviewed in the preceding section, HSV-1 also encodes effectors that disarm host necrotic cell intrinsic responses.[363] Programmed necrosis is antagonized in HSV-infected human cells through the RHIM domain within the multifunctional viral ribonucleotide reductase large subunits (ICP6), which interact with RIP1 and RIP3 to prevent MLKL-dependent necrosis.[161] Thus, the antiviral potential triggered by antagonizing caspase 8–dependent apoptosis is averted in human cells infected with HSV by enlisting the same virus-encoded ribonucleotide reductase large subunits to suppress necroptosis. In mice, however, the physical association of HSV-1 ICP6 with RIP1/3 is unable to restrain necroptosis and necrosis ensues, constraining virus propagation in this nonnatural host species and raising the possibility that necroptosis in part serves as a cross species restriction factor in infection.[191,502] This raises an additional caveat pertaining to the use of mice to model HSV infection biology.



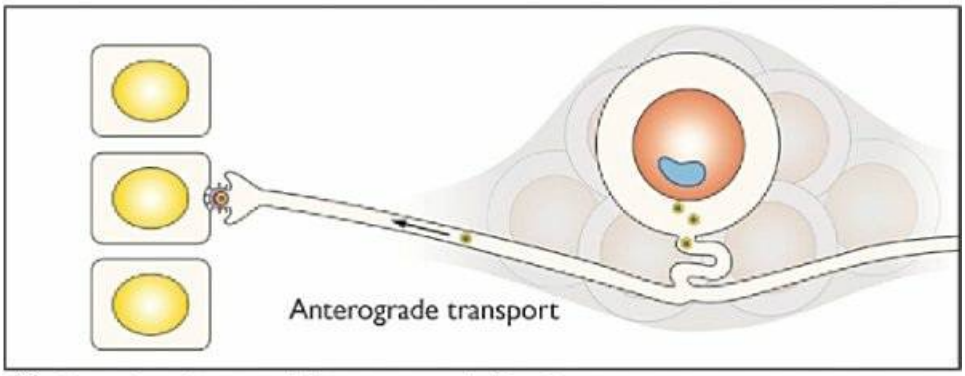
HSV gene products also inhibit other immune responses, including adaptive responses, and these are described in the previous chapter[395] and in the Supplementary Table 9.1 Gene List.

LATENT INFECTION



Overview

Upon entry at oral or genital mucosal sites, HSV replicates and spreads in the tissue at the primary site of infection, and the virus enters sensory or sympathetic neurons by fusion at the axonal termini (Fig. 9.13). The nucleocapsid is carried by retrograde axonal transport to the nucleus in the neuron cell body, and the virus establishes a life-long latent infection in peripheral nervous system (PNS) neurons that innervate the infection site (Fig. 9.14). Viral DNA persists in the nucleus within neuronal cell bodies in a circular episomal form associated with nucleosomes bearing heterochromatin modifications (Fig. 9.7). In contrast to the virus lytic reproductive cycle, genes required for HSV productive replication are largely silenced through host epigenetic



mechanisms during latent infection, and infectious virus may be undetectable or shed subclinically. The predominant viral gene products detected in latently infected neurons are derived from a primary latency-associated transcript (LAT), which is subsequently processed into several non–protein-coding RNA species that include a stable intron and multiple microRNAs (Fig. 9.15). Episodic emergence of the virus from latency, referred to as reactivation, commences with modifications to chromatin structure that support expression of HSV genes needed for productive virus replication. Reactivation results in virus replication within the host neuron culminating in infectious virus production. Viral latent infection is maintained by neurotrophin signaling pathways and epigenetic silencing, as evidenced by perturbations to cellular homeostasis, axonal damage, or epigenetic changes that lead to reactivation of the virus and viral gene expression. Subsequent anterograde axonal transport of virus progeny produced by reactivation to the periphery allows infection of epithelial cells innervating the axon and virus shedding at or near the anatomical site of entry. These reactivation episodes may be asymptomatic or lead to a recurrent lesion, which may vary considerably in severity from punctate lesions that are invisible to the naked eye to severe, debilitating lesions in immunosuppressed individuals. Clearance of lytically infected cells by cellular immunity resolves each recurrent episode in immune competent individuals, but the viral genome reservoir persists within the neuronal nucleus where subsequent reactivation episodes can be triggered. This lifecycle of lifelong latency within peripheral nervous system (PNS) neurons punctuated by episodic reactivation events is a defining characteristic of HSV infections and pathogenesis. While it remains incompletely understood, in part because of the challenges of modeling a human pathogen infection in other species, a powerful assortment of small animal and cell culture models have fueled our understanding of the underlying viral genetics and the cell biological and immune mechanisms that underlie latency as we know it.

A Primary Infection and Establishment

B Latent Infection

C Reactivation and Recurrent Infection

FIGURE 9.13 Stages of HSV infection of the host. A: HSV is introduced onto a mucosal surface or a break in the skin, and it replicates productively in epithelial cells at the site of inoculation and spreads through the tissue. Virus enters sensory neuron axons and is transported to the cell body in a ganglion. **B:** HSV establishes a latent infection in the neuronal cell nucleus. Viral DNA is circular and assembled in chromatin. **C:** Upon neuronal damage or activation, the virus reactivates and undergoes at least a limited productive cycle. Capsids are transported by anterograde transport to the axonal termini, and virions are released. Reactivated virus causes a recurrent infection of the mucosal tissue, causing the shedding of virus. (Copyright, Lynne Chang and David Knipe.)

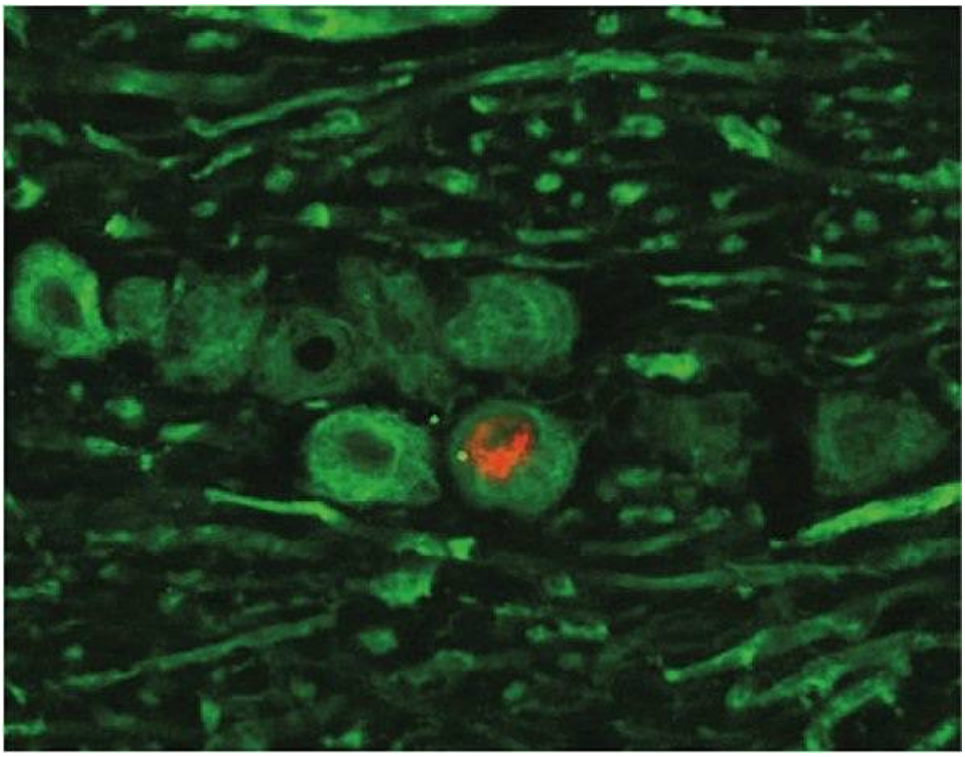


FIGURE 9.14 Detection of HSV stable LAT RNA in latently infected murine trigeminal ganglion neurons by fluorescence *in situ* hybridization (FISH). Mice were infected with HSV-1 following corneal scarification. At 30 days postinfection, the mice were sacrificed, and trigeminal ganglia were frozen and sectioned. The sections were hybridized with a labeled DNA probe detecting the LAT RNA (shown as *red*). Neurons were stained with antibodies detecting neurofilament proteins (*green*). (Copyright, Lynne Chang and David Knipe.)

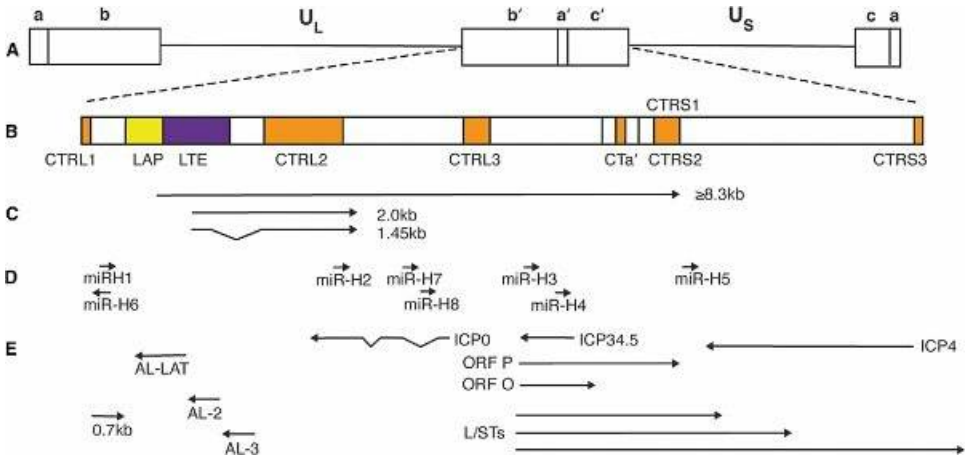

FIGURE 9.15 Map of the LAT transcriptional unit. A: HSV-1 genome in the prototype orientation; U_L and U_S denote the unique sequences of the long (L) and short (S) components of the genome, respectively. *Boxes* denote repeated sequences. **B:** Expanded view of the L–S junction of the HSV-1 genome showing the regulatory

elements, including the latency-associated transcript promoter (LAP), long-term enhancer element (LTE), CTCF (CCCTC-binding factor) motifs, and putative insulator sites labeled as CTRL1, CTRL2, CTRL3, CTa' and CTRS1, CTRS2, CTRS3. The primary LAT initiates at bp 118,802 on the HSV-1 genome based on RNase mapping of the primary transcript or at 118,803 using *in vitro* transcription. The 5′ exon extends from bp 118,803 to 119,465, and the major intron extends from bp 119,465 to 121,417. The LAT promoter is from bp 118,003 to 118,878. A second promoter, sometimes referred to as the LAP2 promoter, has been identified in transient assays and extends from bp 118,867 to 119,461. An enhancer allowing long-term expression of LAT (long-term enhancer element or LTE) extends from bp 118,077 to 119,461 and is located downstream from the LAT gene transcriptional start site. LAP2 extends from bp 118,867 to 119,461. CTCF elements containing CCTC factor (CTCF) binding sites at the U_L/c boundary (bp 120,503–120,635), and in the LAT intron (bp 117,158–117,342). **C:** LAT transcripts including the ≥ 8.3-kb LAT primary transcript; 2- and 1.5-kb LAT stable introns. **D:** Major microRNAs encoded by the LAT region: miR-H1, miR-H2, miR-H7, miR-H3, miR-H5 and miR-H4, miR-H6, miR-H8. **E:** Locations and orientations of transcripts including infected cell protein (ICP) 0, ICP4, ICP34.5,[74] open reading frame (ORF) P and ORF O, L/STs, 0.7-kb LAT (only in strain 17 and McKrae, not KOS), antisense to LAT transcripts AL-LAT, AL-2, AL-3.[196] (Copyright, Catherine Sodroski and David Knipe.)

Latent infection was first detected experimentally by cocultivation of explanted sensory ganglia tissue from experimentally infected mice with permissive cells and observation of cytopathic effect owing to reactivated virus. Infectious virus was not detected in homogenized ganglia tissue; therefore, the virus was considered to be latent in the tissue at the time of explant. This led to the original definition of latency: the virus must be able to reactivate from the latent state under appropriate experimental conditions. Operationally, this meant that virus could be detected after axotomy of intact ganglionic tissue and cocultivation of explanted ganglia with suitable susceptible cells in culture but not by inoculation of the susceptible cells with homogenized cell-free ganglia. The definition of latency was later extended to include viruses that can be detected in sensory ganglia several weeks after infection of experimental animals by *in situ* hybridization with probes for the latency-associated transcripts (LATs) or by assays to detect viral DNA in ganglia.[267] At the present time, the only technique for demonstrating that a virus is deficient in establishing latent infections in small animal models is the inability to detect HSV DNA by polymerase chain reaction (PCR) in total DNA isolated from whole ganglia. This more expansive definition of latent infection has enabled an assessment of the roles of specific HSV genes in the establishment and maintenance of latency, separate from their roles in reactivation. Nevertheless, it does equate the presence of viral DNA with a bona fide latent state defined biologically as capable of reactivation.

Central questions regarding the nature, control, and underlying molecular mechanisms governing HSV latency remain unanswered or incompletely understood. These include how can HSV undergo a productive infection in epithelial and other nonneuronal cells but undergo a latent infection in sensory and sympathetic PNS neurons? What intrinsic restrictive features of neurons allow the latent infection? Does the virus play an active or passive role in the latent infection? Does the host immune response control the latent infection or just the lytic infection?

While our current understanding of the molecular and cellular mechanisms of HSV latency illustrates progress toward ultimately deciphering these significant gaps in knowledge, many unknowns remain.

Experimental Systems for the Study of HSV Latent Infection

Small Animal Models

The most utilized small animal model systems are laboratory mice and rabbits for HSV-1 infection and guinea pigs for genital infection by HSV-2. In all three species, inoculation of wild-type virus results in viral replication at the peripheral site and retrograde transport of virus to the nucleus of a dorsal root or trigeminal ganglion neuron, followed ultimately by establishment of latency. While the virus replicates in a fraction of sensory neurons following entry in all three animal model systems, several key features distinguish these models from each other and from infections in the natural human host. Both HSV-1 and HSV-2 reactivate spontaneously in the rabbit eye model, where the virus is readily detected in lacrimal secretions. While HSV-2 also reactivates spontaneously following genital infection of the guinea pig resulting in lesions containing small amounts of virus, the acute and recurrent phases are not always well separated. By contrast, detection of spontaneous virus reactivation in mice resulting in the appearance of infectious virus either in ganglia or at peripheral sites is exceptionally rare. Inducible reactivation has been studied in murine systems primarily following axotomy and subsequent explant of ganglia and coculture with permissive rabbit kidney cells in culture. Nevertheless, reactivation can be induced to a certain level in latently infected mice *in vivo* with peripheral tissue trauma, transient hyperthermia, UV irradiation, or epinephrine iontophoresis in the eye. Knockout mouse strains differing with respect to their susceptibility to infection have been particularly useful in studies of immune responses to acute and latent infection.

Cultured Neuron Systems

To understand molecular mechanisms underlying latency at the cell autonomous level, several cell culture models have been established to investigate virus–host interactions in the neuron itself in the absence of other cell types, including glial cells and lymphocytes that are present in ganglia. By investigating molecular interactions involving HSV-1 and the host neuron, the nuanced relationship that has evolved between the virus with this specialized host cell type can be delineated and an understanding of underlying neuronal cell intrinsic mechanisms controlling latency and reactivation at its most fundamental level can be achieved. Given that authentic, isogenic, uniform populations of human sensory or sympathetic peripheral neurons, representing archetypal host cells, are not readily available, several model systems have been developed. These include using bona fide PNS neurons harvested from rodents,[60,79,528] neuronal-like human cells differentiated from transformed, established cell lines,[125,425,467] and neurons experimentally derived from human stem cells.[96,340,368] While imperfections are associated with each of these experimental model systems, including species differences, ease of manipulation, culture purity, and the extent to which differentiated neuronal cells derived from cell lines or stem cells represent bona fide adult human sensory neurons, they continue to inform and shape our understanding of latency and reactivation despite their unavoidable strengths and weaknesses. At present, it is not possible to favor one over the other nor predict which most accurately models a

natural infection in an authentic human sensory or sympathetic neuron.

To model latency in neurons, Wilcox and Johnson were among the first to utilize cultured primary sympathetic neurons isolated from the superior cervical ganglia (SCGs) of unborn rat pups and infect them with HSV-1 for latent infection.[516] Compared to sensory ganglia composed of heterogeneous neuronal types, neurons from sympathetic ganglia have an advantage in being simpler to isolate and resulted in more homogenous neuronal cultures following treatment with antimitotic agents to purge nonneuronal, dividing cells. As HSV-1 also replicates productively in neurons and cultured neurons prepared from dissociated ganglia, which are largely deficient for innate immune cells important for generating innate antiviral responses, the antiviral drug acyclovir was enlisted to uniformly suppress productive virus growth. Following removal of acyclovir, infectious virus was not detected, and a state displaying the canonical hallmarks of HSV latency defined in small animal models was reproducibly observed. Notably, productive cycle gene expression is repressed, infectious virus production is not detected, and LAT accumulation is observed in the neuronal nucleus. These pioneering studies using rat SCG sympathetic neurons latently infected with HSV-1 established that withdrawal of the neurotrophic growth factor NGF stimulated reactivation from latency[516] and first implicated NGF with a role in preserving latency in neurons. While prescient, methods for selectively manipulating host cell gene expression in neurons had not yet been developed and the molecular basis and complexity underlying NGF signaling had not yet been deciphered. Thus, these initial studies were limited to evaluating how application of varied chemical inhibitors, many of which were broadly acting, and applied physiological stresses influenced reactivation, severely limiting the utility, impact, and widespread implementation of the model.

More than 20 years later, these findings were revisited with modern methods incorporating a reporter eGFP-expressing recombinant HSV-1 enabling real-time readouts of virus reproduction in living neurons, a detailed molecular understanding of NGF-signaling, gene-specific silencing techniques capable of effectively creating hypomorphic alleles of essential host genes, and gene delivery techniques enabling ectopic expression of dominant gain of function alleles into neurons.[60,79,240]

Studies of neurons in culture have identified a defined, neuron cell autonomous relationship whereby HSV-1 persists in a nonreplicating state that is regulated by and responsive to specific cellular signaling pathways vital for neuronal homeostasis and survival. Specifically, they have revealed that (a) the virus–host neuron relationship reflects a fundamental interaction where latency can be modeled using cultured neurons and its underlying molecular circuitry dissected in the absence of an acquired immune component and (b) HSV-1 latency in cultured neurons reflects an active process maintained through continuous cell surface receptor–mediated neurotrophic factor—PI3-kinase—Akt signaling (Fig. 9.16), which maintains the viral genome in an epigenetically silenced state capable of episodic, inducible reactivation in response to defined physiological stresses.[60,79,240,305]

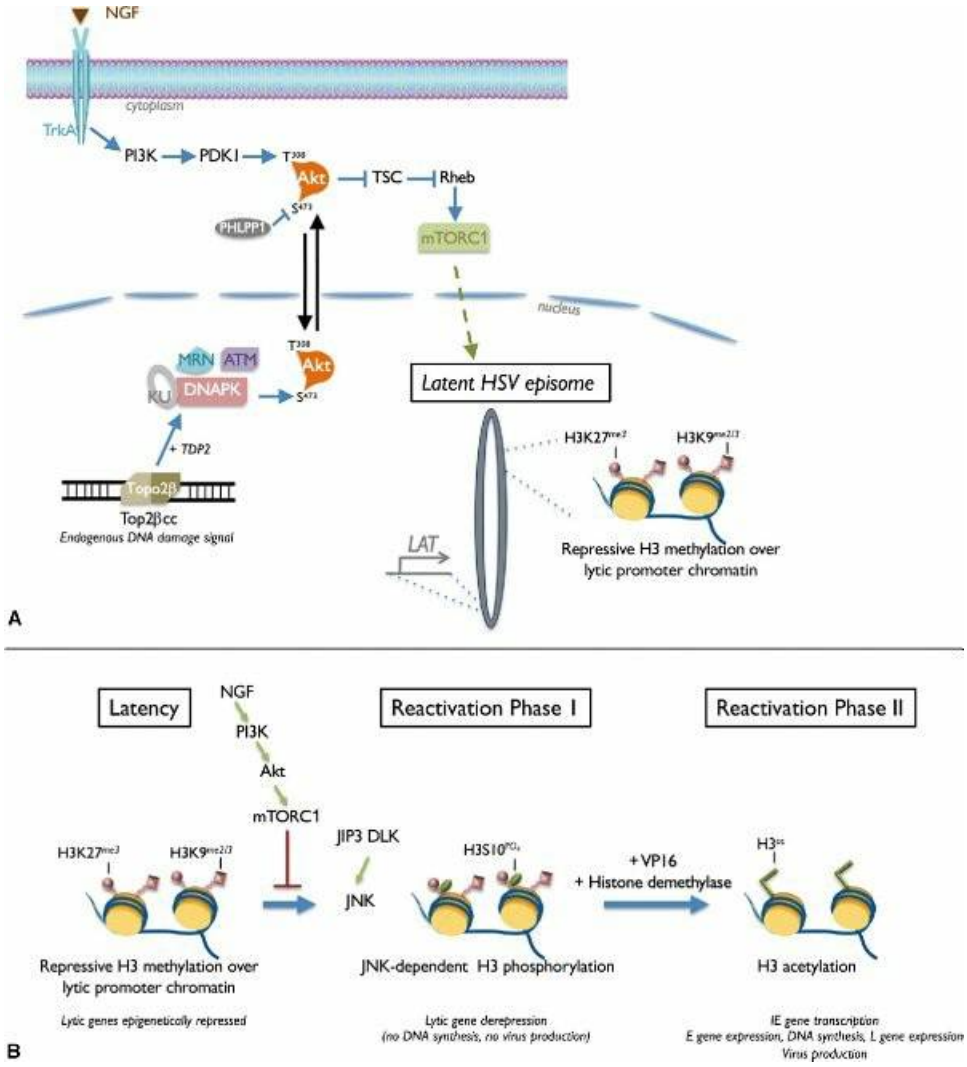

FIGURE 9.16 Regulation of HSV1 latency in cultured neurons by Akt-mTORC1 signaling and the DNA damage response. A: Model illustrating how activation of cellular AKT-mTORC1 signaling by extracellular NGF and cell intrinsic TOP2β-mediated nuclear DNA damage signaling maintain HSV-1 latency in cultured neurons. Binding of NGF to its high-affinity receptor TrkA stimulates PI-3 kinase (PI3K) signaling and sustained AKT Thr308 phosphorylation by PDK1. Full Akt activation in cultured sympathetic rodent neurons requires AKT to be phosphorylated on Ser473 by DNA-PK. MRN also activates ATM at DSB sites on chromatin, and ATM also promotes Akt S473 phosphorylation. DNA-PK activation results from transient DNA double-strand breaks (DSBs) generated by an endogenous DNA damage signal within the nucleus. These endogenous DSBs at promoter elements result from naturally occurring expression of host early response genes during normal neuronal activity[296] and are produced by the host topoisomerase 2β-DNA cleavage complex (TOP2βcc) intermediates acted on by TDP2. Subsequent TOP2βcc processing for both DNA repair[180] and activation of DNA-PK[190] requires the MRN complex. Presumed translocation of Akt into the nucleus allows phosphorylation by DNA-PK, and subsequent nuclear export of S473 phosphorylated Akt allows activation of

cytoplasmic AKT-mTORC1 signaling. The Ser473 phosphatase PHLPP1 negatively regulates Akt activation and downstream mTORC1 signaling. Thus, sustained activation of the AKT-mTORC1 signaling axis in neurons requires consolidating at least two independent signals generated from potentially different subcellular compartments (nuclear and plasma membrane/cytoplasm). During latency, LAT is expressed from the latent genome and histones at HSV-1 lytic promoters remain in a repressed state. **B:** Neuronal stress stimuli that trigger DLK/JIP3-mediated activation of JNK contribute to a histone methyl/phospho switch[79] and subsequent replacement by euchromatin-associated marks. Interfering with continuous Akt-mTORC1 signaling results in JNK activation. The resulting histone H3 phosphorylation on residue S10 is dependent upon JNK together with JIP3/DLK and provides the trigger to initiate reactivation phase 1, which is characterized by virus genome-wide lytic gene derepression without viral DNA synthesis or infectious virus production. Subsequent expression and stochastic nuclear accumulation of VP16 in a limited cell population allows removal of repressive histone methylation marks by a histone demethylase, which coincides with the commencement of the ordered lytic gene expression program (IE genes, E genes, DNA synthesis, L genes) that culminates in infectious virus production (reactivation phase 2).

While neuronal latency in the natural human host and small experimental animals is established following virus infection at a peripheral nonneuronal site, available cultured neuron models are largely reliant on transient acyclovir treatment to limit virus productive growth and spread. This is not surprising, as neurons effectively support HSV productive replication and should a latently infected subpopulation stochastically form at some level following acute infection of cultured neurons, it would likely be overcome by the spread of a productive infection from neighboring cells within the culture. Nevertheless, conclusions derived from cultured neurons where latency was established using transient acyclovir administration approximate the experimental observations made without acyclovir in laboratory-infected animals. Significantly, NGF retarded whereas anti-NGF antibody accelerated the accumulation of viral mRNAs following explant-induced reactivation of sensory ganglia from experimentally infected mice.[119] Together with *in vivo* data from latently infected rabbits showing that anti-NGF administration stimulates HSV shedding,[177a] this demonstrates that HSV gene expression and reactivation are responsive to NGF in experimental latency models that do not utilize acyclovir to limit productive virus growth. Furthermore, reactivation induced by PI-3K inhibition has been reported using whole, nondissociated embryonic mouse DRG three-dimensional cultures where latency was established following *in vitro* infection without acyclovir.[305] Compartmentalized cultures that physical and fluidically separate axons from cell bodies (microfluidic or Campenot type chambers) have also been used to establish latency by infecting axons at relatively low MOI with pseudorabies virus, a related porcine α-herpesvirus, without acyclovir.[244,245] Obtaining sufficient material for biochemical analysis, however, from neurons grown in compartmentalized chambers that separate axons and soma remains a major challenge, as do studies in whole ganglia that are far from uniform and composed of varied neuronal and nonneuronal cell types. Significantly, results obtained in neuronal culture models without acyclovir are consistent with findings in models that employ acyclovir. Thus, acyclovir remains a powerful tool enabling high efficiency nonproductive infections modeling latency to be effectively established in cultured

neuron models. Its use allows greater numbers of mostly homogenous populations of latently infected neurons to be made available for gene silencing, gene delivery, and biochemical analysis of neuronal cell intrinsic signaling pathways and responses.

The combination of latency studies in animal and neuron systems has yielded special insight into the mechanisms of latent infection and reactivation. Animal studies had shown the importance of epigenetic silencing of the viral genome to maintain latency,[499] and neuronal studies had shown the importance of neurotrophin signaling in maintaining latency.[60,119,240] The important connection between these two was made in neuronal studies showing that stress or signals that can arise from interruption of neurotrophin signaling leads to an epigenetic change linked to induction of viral gene expression.[79] Thus, the combination of animal studies and neuronal studies provides a powerful approach to the investigation of HSV latency, as detailed below.

Description of the Latent Infection State of HSV

The HSV-1 genome during latent infection of sensory neurons is in a covalently closed, dsDNA circle wrapped in heterochromatin. We will discuss the state of the viral latent genomes, their chromatin, and viral gene expression during latent infection. We will then describe the events of establishment, maintenance, and reactivation from latent infection.

Form and Copy Number of Viral DNA

In latently infected neurons, viral genomes are in the form of endless or circular DNA[387] assembled in nucleosomal chromatin.[108] Early studies on HSV DNA in latently infected neurons using animal models determined that there are between 0.1 and 1 viral genome equivalents per cell genome.[387] In calculations based on neurons accounting for only about 10% of the total cells in a sensory ganglion, it was obvious that each latently infected neuron must contain more than one viral genome. This was shown more directly in studies showing that approximately 20% of single purified murine trigeminal ganglion neurons contain viral DNA with an average of 20 to 30 HSV DNA molecules per cell and a range from less than 10 to greater than 1,000 molecules per cell. In studies of human neurons obtained by laser capture microdissection of trigeminal tissue, 2% to 10% of the neurons contain viral DNA with a median value of 11 genomes per cell and a range of 5 to 3,955 copies per cell. The range of DNA copy numbers raises the issue of heterogeneity of latent infection in different cells. Furthermore, only 0.2% to 1.5% of the human TG neurons express LAT, as detected by *in situ* hybridization. Thus, there are many more neurons containing DNA than expressing LAT, at least as detected by *in situ* hybridization. This extends the issue of latent infection heterogeneity by demonstrating that some latently infected neurons have all viral genes but LAT silenced, whereas other neurons have the entire viral genome silenced.

How the copy number of viral DNA molecules is established in individual neurons is not understood. High HSV genome copy numbers in latently infected cells could result in part from multiple viruses infecting each neuron. Alternatively, the viral DNA could be replicated by viral or cellular mechanisms. Studies using HSV mutant strains that do not replicate viral DNA in neurons, such as TK-negative viruses, do show lower levels of latent viral DNA per cell, supporting the idea that viral DNA replication contributes to HSV genome copy number in latently infected neurons. Nevertheless, even ganglia infected with TK-negative mutant viruses

contain multiple genomes per cell, and this could be due to the slow accumulation of viral DNA from the periphery or low level viral DNA replication.

Viral Chromatin

Histone modifications, particularly methylation and acetylation, play important roles in defining the type of regulation imposed on eukaryotic genes by nucleosomes, with particular modifications resulting in chromatin-mediated gene activation (active or euchromatin) or repression (inactive or heterochromatin). During latent infection, the LAT promoter and 5′ exon are associated with acetylated histones or active chromatin, whereas lytic gene promoters are not associated with acetylated histone H3. In contrast, viral lytic gene promoters are associated with heterochromatin forms of histones during latent infection.[499] The heterochromatin modifications include histone H3 lysine 9 dimethylation (H3K9me2),[499] histone H3 lysine 27 trimethylation (H3K27me3),[81,255] and H3K9 trimethylation (H3K9me3),[81] but little or none of the constitutive heterochromatin marker H3K20me3.[81] Recent studies have shown that the latent genomes in murine trigeminal ganglia[376] and in iPSC-derived sensory neurons[340] also have histones with euchromatic H3K4me3 modifications. The combination of the facultative heterochromatin mark H3K27me3 and the euchromatin mark H3K4me3 defines bivalent chromatin, a form of chromatin that is on developmentally regulated genes so they can be readily turned on at the appropriate time. Bivalent chromatin on the latent HSV genome would help it to be in a poised latency state,[265] which can reactivate with the appropriate stimulus to the latently infected neuron.

HSV DNA is not detectably methylated during latent infection in mice. The mechanism by which HSV DNA escapes methylation is a fundamental issue that remains to be defined. Current models for maintenance of HSV latent infection therefore involve the epigenetic silencing of all viral lytic genes except for the *LAT* gene and microRNAs by heterochromatin.

The three-dimensional structure of chromatin is also important for gene control. One cellular function important for higher-order structure of chromatin is CCCTC-binding factor (CTCF). CTCF promotes chromatin loop formation by two molecules of CTCF binding to separate sites and dimerization, which anchors cohesin onto the loops.[373] The loops could then define domains that are epigenetically silenced or active with the CTCF/cohesion complexes acting as chromatin insulators.

Amelio et al.[16] identified seven candidate CTCF elements containing CTCF sites, including ones at the U_L/c boundary, and in the LAT intron, and they proposed that these insulators keep the LAT enhancer activity within that boundary and heterochromatin outside of those boundaries. CTCF bound on the viral genome has also been shown to recruit polycomb repressive complex 2 (PRC2 component) Suz12,[506] which could lead to H3K27me3 modification of histones on either side of the site.

The *CTRL2*-binding site between the *ICP0* gene promoter and the *LAT* transcriptional unit (Fig. 9.15) is of particular interest because the *ICP0* gene promoter is associated with more heterochromatin and the LAT promoter is associated with more euchromatin, so *CTRL2* is a candidate insulator element between these two promoters. Comparison of an HSV-1 KOS deletion mutant virus lacking both copies of *CTRL2* with its marker rescued counterpart revealed that the $CTRL2^{-}$ virus replicated normally in cultured cells and established equal viral latent

DNA loads in murine trigeminal ganglia.[265] A statistically significant increase in heterochromatin on the *LAT* promoter and increased LAT expression but reduced reactivation were also observed.[265] To explain these findings, the *CTRL2* insulator was proposed to form an additional loop with a different site on the virus genome, which subsequently stimulated VP16 expression and triggered reactivation.[265] However, an independently constructed *CTRL2* deletion in the HSV-1 strain 17 genetic background resulted in a virus that replicated less well in cultured cells, and fivefold less latent DNA was detected in rabbits compared to wild-type virus. The strain 17 *CTRL2* deletion mutant also displayed reduced lytic gene transcription during latent infection and decreased H3K27me3 repressive chromatin marks over the ICP0 gene as well as other lytic genes and LAT,[507] leading the authors' to postulate that CTCF bound at the *CTRL2* site increased H3K27me3 on the viral genome. Adding to the complexity, knockdown of CTCF in rabbits latently infected with HSV-1 in the trigeminal ganglia increased ocular shedding of HSV-1.[505] Thus, at this time, we still have a complex picture with some evidence that CTCF binding to *CTRL2* serves as an insulator to prevent heterochromatin spreading,[265] while others have found that CTCF acts as an insulator to prevent spreading of chromatin from the LAT enhancer.[507]

Latent Viral Gene Expression

During latent infection, there is abundant expression of viral noncoding RNAs but very limited amounts of lytic transcripts. The major transcripts observed during latent infection are a family of noncoding RNAs known as the latency-associated transcripts (LATs)[447] and microRNAs[213,476,477] from the two copies of the R_L component of the HSV-1 genome (Fig. 9.15).

LAT

The *LAT* transcriptional unit yields a family of transcripts arising from the R_L repeat sequence (Fig. 9.15) by splicing and processing. The full-length 8.3- to 9-kb transcript accumulates at low levels in latently infected neurons, whereas the 2- and 1.5-kb introns processed from the full-length transcript are abundant and accumulate in the nucleus. These introns are highly stable as a result of unusual lariat structures. LAT was originally detected by *in situ* hybridization analysis of latently infected murine ganglia[447]and subsequently found in latently infected rabbit and human ganglia. The 2-kb LAT is the major species detected in neuronal nuclei by *in situ* hybridization[447] (Fig. 9.14).

LATs are transcribed in sensory neurons from a promoter/enhancer sequence (*LAP*; Fig. 9.15) bearing neuron-specific elements (Fig. 9.8). Although the 2-kb LAT can be detected in productively infected cells at late times postinfection, this is likely the result of splicing of read-through transcripts that are common at late times postinfection[155] or another promoter and not transcription from the true *LAT* promoter. Despite a very limited number of reports of proteins potentially encoded by LATs, most investigations have not found evidence for expression of proteins by the LATs.

A second promoter, sometimes referred to as the *LAP2* promoter, has been identified in transient assays only and is located downstream from the *in vivo LAT* gene transcriptional start site. An enhancer allowing long-term expression of LAT (long-term enhancer element or LTE) is

located downstream from the *LAT* gene transcriptional start site.

Additional Transcripts

There are several additional transcripts near or overlapping the *LAT* gene or its promoter that could conceivably play a role in LAT function or contribute to the phenotypes of *LAT* gene mutant viruses (see Fig. 9.15). As a first example, a 0.7-kb transcript encoded on the same DNA strand as LAT but upstream of LAT is expressed by HSV-1 strains 17 and McKrae but not by strains KOS and F. Second, transcripts that are complementary to the *ICP4* gene transcripts, called *anti-4 transcripts*, were detected by reverse transcriptase (RT) PCR. The anti-4 transcript(s) may be expressed from a new transcriptional unit downstream of the primary LAT transcriptional unit or expressed as a read-through transcript from LAT; however, in any case, anti-4 transcription is promoted by LAT expression. Third, a transcript that is antisense to the 5′ end of LAT has been identified as encoded by HSV-1 strain McKrae and reported to express a protein in infected rabbits.

microRNAs. A number of HSV-encoded microRNAs are expressed during latent infection, as first detected in latently infected murine[476] and human ganglia.[477,478] In latently infected murine trigeminal ganglia, these include miR-H1,[248] miR-H2, miR-H3, miR-H4, miR-H5, and miR-H6,[476] as well as miR-H7, miR-H8, miR-H17, miR-H18, and miR-H24.[213] In guinea pig ganglia latently infected with HSV-2, the microRNAs shown to be expressed are miR-I (miR-H3), miR-II (miR-H4), and miR-III (miR-H2). In human trigeminal ganglia infected with HSV-1, these include miR-H1-8[477]; in human sacral ganglia infected with HSV-2, they include miR-H3, 4, 7, 9, and 10.[461,478] Of note, a subset of HSV-encoded microRNAs, while only detected at low levels during lytic infection or in latently infected samples, accumulated to higher levels upon reactivation in murine ganglia, including miR-H8, miR-H28, and miR-H29.[118,165] Many of the HSV microRNAs relevant to latency are likely to be processed from the primary LAT because their expression depends on the LAT promoter.[248,460] Interestingly, miR-H6 expression is reduced in a *LAT* promoter mutant virus,[248] despite this microRNA being encoded upstream of the *LAT* promoter, suggesting that the *LAT* promoter is bidirectional. Expression of HSV-2 miR-H3 by transfection reduced ICP34.5 expression in transfected or infected cells,[460] as did transfection of miR-H4,[462] and expression of HSV-1 miR-H2 reduced ICP0 expression.[476] Although HSV-2 miR-H6 had no effect on ICP4 expression, transfection of HSV-1 miR-H6 also reduced ICP4 expression.[476] It was thus hypothesized that these microRNAs could contribute to latent infection by down-regulating critical viral gene products needed for lytic infection.

In addition to encoding microRNAs, the HSV genome contains cis-acting elements responsive to host microRNAs that can influence latency. Two target sites for the neuron-specific microRNA, miR-138, were identified in the 3′-UTR of the mRNA encoding the HSV-1 transactivator ICP0, and one was found in the corresponding mRNA encoded by HSV-2. ICP0 and lytic gene expression in cultured cells was directly repressed by miR-138. Furthermore, disrupted miR-138–binding sites in ICP0 mRNA not only enhanced lytic gene expression in murine TGs but also enhanced virulence in mice.[352] Thus, a cell type–specific neuronal microRNA can promote latency by directly targeting ICP0 expression.

Lytic Transcripts

In murine models of HSV-1 latent infection, there is low-level expression of lytic transcripts,[246]

and this may be due to abortive or nonproductive reactivation events[246] or to a limited number of cells undergoing a more complete reactivation.[170] The relatively lower levels of late viral transcripts such as *gC* gene transcripts argues that the lytic gene expression is due to abortive reactivation events in at least this murine system.[295] Single-cell RNA sequencing of dorsal root ganglia latently infected with HSV-1 showed frequent lytic gene transcription in this system.[295]

Events of Latent Infection and Reactivation

HSV latency and reactivation are complex biological processes that can be subdivided into discrete stages. Following entry into axonal termini of sensory or sympathetic neurons, HSV must reach the nucleus in the neuronal cell body to establish a permanent latent infection. Having established a latent infection by delivering its genome and effectively colonizing a postmitotic, nondividing neuron, the infection is maintained in a nonreplicating state for the life of the infected individual. Finally, in response to dynamic physiological and/or environmental cues, the virus changes its relationship with the host neuron and activates a complex gene expression program that results in the assembly and release of infectious virus particles capable of shedding at the anatomical entry portal and subsequently spreading to new hosts. In the following sections, we examine these defined stages of latency and review what is known regarding the underlying genetic and cell biological regulatory mechanisms.

Establishment of Latency

Electron microscopic studies indicate that in neurons infected in cell culture, the viral particle transported by retrograde transport along microtubules in the axon is the unenveloped nucleocapsid or nucleocapsid–tegument structure. Viral gene expression, including IE, E, L, and LAT RNAs, is observed in ganglia of infected animals over the first 24 to 72 hours. Several host immune response effectors in experimental animal models are postulated to play a role in control of early viral replication, including IFN-γ, macrophages, γδ T cells, and $CD8^+$ T cells. $CD8^+$ T cells infiltrate the ganglia starting around 5 to 7 days postinfection, coincident with the time at which virus starts to decrease around day 7. $CD8^+$ T cells have been shown to play an essential role in control of HSV replication in the murine nervous system and in controlling viral replication in the ganglia during acute times of infection. Cytokine and chemokine expression increases in the acutely infected murine sensory ganglia. Silencing of HSV genes in sensory neurons in animal models appears to be a slow and multistep process.

Further evidence that entry through the axon is critical for the normal process of establishment of latent infection has come from culture systems. Studies using isolated chicken TGs cultured in a double chambered system to create an axon-only compartment showed that application of virus to distal axons resulted in nonproductive infections where LAT accumulated and lytic genes were repressed.[162] This raises the possibility that axonal entry, the natural route of virus entry from the periphery, may be a critical determinant in the lytic/latent decision in neurons.

Although the events occurring during the first few hours after entry of viral DNA into dorsal root ganglia have not been defined, a key factor is likely to be the reduced expression of IE genes. The reduced IE gene expression is likely explained by several mechanisms either as part of a common pathway or acting in a combination of pathways.

1. *Neuronal repressors.* Several neuronal repressors have been proposed to repress IE gene expression in neurons. First, the Oct-2 factor was postulated to repress IE gene expression through its interaction with TAATGARATT DNA-containing sites blocking Oct-1 activation. Oct-2 expression was not detected in sensory neurons nor was expression from a complete IE-promoter/enhancer-bearing reporter gene detectably repressed when Oct-2 was overexpressed. The neuron-specific Zhangfei/CREBZF factor has also been postulated to block activation of IE gene promoters through interaction at Oct-1–binding sites. Perhaps more significantly, expression of a dominant-negative form of the host repressor REST reduced viral replication in neurons,[119] indicating that REST could be part of the mechanism of silencing of the viral genome in neurons.
2. *Neurotrophin-regulated repression of viral gene expression.* Neurotrophins, including nerve growth factor (NGF), are host-encoded polypeptides that function in the nervous system as growth factors that promote survival, differentiation, axonal growth, and synaptic plasticity. By engaging cell surface receptors on the surface of sensory and sympathetic neurons, NGF generates signals that travel to the nucleus where they influence gene expression. NGF treatment of sensory neurons has been shown to restrict viral lytic gene expression,[516] and anti-NGF treatment of latently infected neurons increases viral lytic gene expression.[60,119] Furthermore, ocular administration of anti-NGF antibodies to latently infected rabbits resulted in virus shedding, consistent with increased reactivation *in vivo*.
3. *Lack of viral and cellular factors necessary to overcome host silencing and allow IE gene transcription.* Several studies have raised the idea that sensory neurons lack essential factors for expression of HSV IE genes, thereby explaining the latent infection in these cells. In studies using *in situ* hybridization to detect Oct-1 mRNA, Oct-1 expression was initially not detected in cells of the sensory ganglia, but more sensitive assays showed Oct-1 and GABPα/β are present but at low levels in sensory neurons. Kristie et al.[250] first showed that HCF-1, or C1, the cellular cofactor required to stimulate IE gene expression along with Oct-1 and VP16, resides in the cytoplasm in mouse trigeminal ganglion neurons and is translocated into the nucleus only under conditions of reactivation such as axotomy followed by culture of explanted ganglia. Thus, while HCF-1 is predominately nuclear in most dividing nonneuronal cells, it may not be capable of localizing to the nucleus in HSV-infected neurons, and this prevents IE gene transcription. In addition, VP16 does not contain a nuclear localization signal and is dependent upon HCF-1 for transport into the cell nucleus. VP16 in the incoming virion therefore would not accumulate in the neuronal nucleus within cell bodies and transactive IE genes. Finally, VP16 does not bind mouse Oct-1 as well as human Oct-1, potentially limiting its capacity to activate IE gene expression in neurons. The viral genome may also be localized to or near ND-10 structures, which aids in repression of the lytic gene expression.[302]
4. *Viral RNA–mediated repression of IE gene expression.* LAT-negative mutant viruses show elevated lytic gene expression in trigeminal ganglion neurons during acute infection of mice at 3 to 5 days postinfection (dpi).[145] Therefore, LAT or one of its products seems to exert some of its repressive effects at early times following infection of neurons.

Kinetics of Chromatin Silencing of Viral Lytic Genes

Chromatin assembly with incoming viral DNA is very rapid during lytic infection of cells in

culture.[82] By contrast, histone H3 association with HSV DNA in murine trigeminal ganglia seems slower, possibly due to lower histone pools in resting neurons, and is apparent by 7 dpi, while the H3K9me2 modification is apparent by 15 dpi.[499] Whereas viral lytic gene promoters are associated with H3 histone by 7 dpi, further studies found that the H3K27me3 heterochromatin modification was not detected on HSV lytic gene chromatin until later, at 14 dpi,[80] arguing that the earliest chromatin effect is association of unmodified chromatin followed by the H3K27me3 modification. In this murine infection model, acute viral replication in the trigeminal ganglia has largely declined by 7 dpi; therefore, H3K27 methylation appears to occur after resolution of the infection. This is significant as it suggests that events earlier than heterochromatin modifications of histones are responsible for the initial silencing of the viral genome.

In addition to being composed of nonneuronal and neuronal cells, sensory ganglia including the trigeminal ganglia contain different neuronal subtypes. Studies on the neuronal subtype in which latent infection is established in murine model systems have shed light on the mechanisms of establishment of latent infection. In mice infected by the ocular route with HSV-1 strain KOS virus, latent infection is preferentially established in a subset of neurons identified with the A5 antibody recognizing a specific lacto-series glycoconjugate marker. Further studies showed that HSV-2 preferentially established latent infection in KH10 monoclonal antibody-reactive sensory neurons in either trigeminal or dorsal root ganglia. A recombinant HSV-2 that expresses the HSV-1 LAT showed an HSV-1 phenotype (i.e., preferential establishment of latency in A5-positive neurons), and a recombinant HSV-1 expressing the HSV-2 LAT showed an HSV-2 phenotype (i.e., preferential establishment of latency in KH10-positive neurons).[194] These studies showed that LAT influenced establishment of latent infection in discrete neuronal subtypes in mice. Furthermore, studies of infection of murine adult sensory ganglion neurons *in vitro* have shown that A5-positive sensory neurons are nonpermissive for HSV-1 strains KOS and 17 *in vitro* but are permissive for HSV-2.[39] Although the LAT recombinant viruses were not examined in the latter study, the results, in total, raise the general model of LAT controlling productive infection in specific neuronal subtypes. Therefore, these studies support the idea that both viral and host factors contribute to establishment of latent infection.

The question of whether viral infection leads directly to latent infection versus lytic infection and/or whether lytic infection can convert to latent infection has been debated extensively. Studies using viruses that express CRE recombinase from viral lytic gene promoters to activate cellular reporters and mark cells in which viral lytic gene transcription has occurred found that approximately one-third of the latently infected murine neurons have experienced IE promoter activation prior to establishment of latent infection but have not experienced TK or VP16 promoter activation.[370,371] This argues that at least some IE gene expression can precede latent infection and raises that possibility that these gene products could affect the host responses or viral chromatin and affect the type of latent infection that ensues. Furthermore, ICP0 nonsense mutant viruses show reduced H3K27me3 and LAT expression during latent infection,[377] arguing that the ICP0 protein itself increases LAT expression and indirectly increases facultative heterochromatin, during establishment and/or maintenance of latency. This raises the possibility that ICP0 could be a target for antiviral drugs during establishment and/or latency.

Maintenance Phase of Latency

The HSV-1 latent state, characterized by circular viral genomes expressing LATs and miRNAs while lytic genes are epigenetically silenced by heterochromatin, is maintained by a number of signaling pathways within the sensory neuron. Cultured neuron model systems have enabled progress toward elucidating the molecular signals that lead to viral genome repression and by extension, upon their perturbation, the earliest events resulting in inducible reactivation that are simply not possible to observe in live animal models.

By integrating numerous fundamental physiological inputs including growth factor, nutrient, energy, and oxygen sufficiency, local signaling by the mechanistic target of rapamycin complex 1 (mTORC1) in axons provides a critical signal to maintain viral genome repression and repress reactivation of HSV genomes in the nuclear compartment.[240] This defines how changes in homeostasis detected within axons can trigger genome repression or activation in spatially segregated nuclear compartments and identified how regulating neuronal gene expression posttranscriptionally at the level of mRNA translation (Fig 9.9) controls latency and reactivation (Fig. 9.16). The cellular repressor of cap-dependent translation, the eIF4E-binding protein 4E-BP1, is a key target of mTORC1 (Fig 9.9) that controls latency and reactivation, consistent with a role for differential translation of 4E-BP1–regulated neuronal mRNAs in regulating latency.[240]

Changes in genome integrity within neurons also regulate mTORC1 activation by Akt. This is significant because endogenous, cell intrinsic, double-stranded DNA (dsDNA) breaks generated by topoisomerase 2β-DNA cleavage complex (TOP2βcc) intermediates accumulate as a result of normal processes stimulating gene activation in neurons in the absence of exogenous DNA damaging agents.[297] Continued activation of the neuronal DNA damage response and DNA repair proteins is required to ensure full activation of Akt, which involves Akt S473 phosphorylation dependent upon balancing opposing activities of the cellular DNA-dependent protein kinase DNA-PK, which is required for DNA repair, and the Akt S473 phosphatase PHLPP1.[190] This provides a mechanism whereby extracellular cues in the form of neurotrophic factor signaling and nuclear genome integrity can be harnessed and integrated to control activation of neuronal Akt-mTORC1 signaling to maintain latency and repress reactivation (Fig. 9.16).

Host responses in ganglia also can contribute to the maintenance of latency. There is prolonged expression of cytokines and chemokines and $CD8^+$ T-cell infiltration[280] in the latently infected murine ganglia and prolonged expression of cytokines and chemokines in human latently infected ganglia. This indicates that there is continued antigenic stimulation of dendritic cells (DCs) and macrophages and continued T-cell activation in the ganglionic tissue both in experimental animal models and likely in the natural human host. As described elsewhere in this chapter, the ongoing immune surveillance is likely in response to the presence of viral antigens in the ganglion owing to low-level reactivation.

Latent HSV infection also leads to perturbation of neuronal host cell gene expression. Using microarrays, Kramer et al.[247] showed that numerous cellular genes were up-regulated or down-regulated in latently infected murine trigeminal ganglia. Little is known about the effects of these gene expression changes on the host neuron or whether they influence either latency or reactivation. More recent application of single-cell RNA-seq and single-molecule fluorescent *in situ* hybridization technologies using neurons prepared from rat sympathetic ganglia and latently infected with HSV-1 *in vitro* revealed that HSV-1 elicits a host gene expression signature to counteract viral reactivation in a cell type–specific manner.[189]

Reactivation of Virus from the Latent State

In humans, latent virus is reactivated after local stimuli such as injury to tissues innervated by neurons harboring latent virus or by systemic stimuli such as physical or emotional stress, hyperthermia, exposure to UV light, menstruation, and hormonal imbalance, which may reactivate virus simultaneously in neurons of various ganglia (e.g., trigeminal and sacral). Thus, injury or stimulation of cells innervated by dorsal root neurons harboring latent virus is a common trigger of recrudescence of lesions caused by reactivated virus.

The ability of sensitive PCR tests to measure HSV DNA in human genital secretions has led to the detection of frequent viral DNA shedding in the genital tract of both asymptomatic and symptomatic individuals. This raises questions about whether HSV latency is actually a low-level chronic infection producing constant virus shedding rather than a true latent infection.[411] However, the amount of virus shed by many individuals is very low, potentially representing virus DNA within desquamated epithelial cells rather than virions. Even if the limited amount of DNA detected were to result from reactivation of a small number of neurons reactivating at any one time, it seems likely that the vast majority of infected neurons are undergoing a latent infection. Nevertheless, the possibility of low-level chronic infection, especially with HSV-2, remains.

As described earlier, there are several experimental model systems for studying *in vitro* and *in vivo* reactivation of HSV. Upon induction of reactivation by *in vitro* explant of murine latently infected ganglia, LAT and microRNA transcript levels decrease, lytic gene transcripts increase,[119] and the histones associated with the *LAT* gene become deacetylated consistent with their repression. Similarly, lytic genes such as *ICP0* become associated with acetylated histones, which support epigenetic stimulation of virus gene expression and lytic gene transcripts accumulate. HSV-1 reactivates spontaneously in the rabbit ocular infection model, and HSV-2 reactivates spontaneously in the guinea pig vaginal infection model.

In cultured neuron latency models, reactivation can be induced by perturbing specific signaling pathways required to maintain latency by using chemical inhibitors, removing neuronal trophic support factors, interfering with host gene expression by RNAi, or expressing mutant alleles of signaling components. These include nerve growth factor deprivation,[60,79,516] PI-3 kinase inhibitors,[60,79,230] histone deacetylase inhibitors,[239,368] and adenyl cyclase activators.[95] Similar to reactivation induced by interfering with PI-3 kinase signaling, activation of adenyl cyclase by forskolin or cAMP mimetic treatment induced HSV reactivation in a DLK/JNK-dependent manner that involves a histone phospho/methyl switch (H3K9me3/S10p, discussed in detail later).[95] However, forskolin-induced reactivation was also dependent on neuronal activity, consistent with a role for neuronal hyperexcitability or repeated action potential firing in controlling HSV reactivation. Finally, IL-1β, a known mediator of prolonged stress inflammation and neuronal hyperexcitability, was identified as a physiological stimulus that triggers HSV reactivation in mature neurons.[95]

It was initially assumed that viral gene expression during reactivation follows the lytic gene cascade regulatory program (IE genes followed by E genes, DNA replication, and L genes) originally defined in an established, human tumor cell line,[186] and this was supported by some experimental evidence. However, Tal-Singer et al.[457] reportedly detected E gene expression prior to IE gene expression during explant-induced reactivation. While they used RT-PCR to detect viral transcripts, they did not show that the assays for each of the transcripts was equally

sensitive. Thus, it remains conceivable that differences in the kinetics of observed transcript appearance reflected sensitivity of the detection assay rather than the true order of accumulation. Other *in vivo* and cell culture studies have suggested that optimal viral gene expression in neurons depends on viral DNA replication, although viral spread was not ruled out in the *in vivo* and *ex vivo* studies. However, when viral spread is prevented during ganglion explant, there is no apparent role for viral DNA synthesis in stimulation of IE and E gene expression. One study using infected rat sensory neurons in culture, however, does support the idea that viral gene expression in neurons is affected by viral DNA synthesis and found that viral DNA synthesis stimulates IE and E gene expression.

The events leading to viral gene expression during reactivation have been examined in various systems, and some understanding of the underlying mechanisms has been achieved. From studies in animal models, Thompson and Sawtell proposed defining the exit from latency as the expression of viral lytic proteins as detected by immunohistochemistry using anti-HSV antiserum, and they defined full reactivation as the production of infectious virus. Using a mouse model where reactivation is induced by transient hyperthermia, they observed an average of one cell per trigeminal ganglion in which virus has escaped latency and approximately 70% of the ganglia reactivated with an average yield of 10 pfu of virus per ganglion. An ICP0 mutant showed similar escape from latency, but infectious virus was not detected. These investigators concluded that ICP0 does not initiate reactivation from latency *in vivo*; however, the process of latency exit in this model system is of very low efficiency and could have minimized the differences between wild-type and mutant viruses.

Reactivation requires the action of LSD1, which demethylates H3Kme2 and H3Kme1 to reduce heterochromatin on viral chromatin.[273,274] LSD1 inhibitors block reactivation in explanted ganglia[273,274] or in the rabbit eye model and guinea pig infection model.[178] Thus, LSD1 inhibitors could conceivably serve as a herpes antiviral drug that prevents HSV reactivation by locking in viral latency. Antiviral targeting of a host function, however, carries toxicity risks, but this could be a useful strategy if drugs can be identified that preferentially inhibit the capacity of LSD1 to affect viral gene expression compared to gene expression in uninfected cells.

In cultured neurons, a critical role for the neuronal-specific c-Jun N-terminal kinase (JNK) stress pathway has been defined (Fig. 9.16) whereby viral genome derepression requires JNK-dependent histone H3S10 phosphorylation.[79] This comprises a histone methyl/phospho switch that allows histone H3 phosphorylation to override repressive epigenetic K9me3 methylation marks that are normally associated with gene silencing. Moreover, it defines how activation of a fundamental neuronal stress response associated with axonal damage, injury, and regeneration is subverted to overcome epigenetic repression associated with HSV genome silencing during latency. More work is required to understand how JNK activation, which is likely a near final step in modifying viral genome chromatin to overcome genome silencing, integrates with signals downstream of mTORC1 and 4E-BP1. Whether this involves the direct action of a single 4E-BP1 translationally regulated mRNA, multiple mRNAs, or a complex regulatory process with numerous molecular steps is unknown, but at least has become a tractable problem addressable with known methodologies. The molecular basis underlying how other inducers of reactivation function is also now approachable using cultured neuron models. Are other neuronal signaling pathways capable of regulating latency and reactivation? Do they all converge on a common set of downstream effectors involving PI-3K-Akt and/or mTORC1 and JNK, or are other pathways

with discrete effectors involved? Can multiple pathways synergize and produce context-dependent outcomes with respect to maintaining latency and triggering reactivation? While these outcomes are presently unknown, neuronal cell culture models of HSV latency and reactivation provide a powerful opportunity to investigate these critical questions using genetic, biochemical, and cell biological methods in a quantifiable manner.

In contrast to the ordered program where IE gene products stimulate E followed by L gene expression in a cascade-like manner that characterizes acute infection and HSV productive growth, viral gene expression during reactivation is distinctively regulated. Using the mouse model, the first detectable HSV-1 gene product detected upon inducible reactivation was unexpectedly found to be VP16, a late protein. Significantly, while reactivation of the VP16 mutant virus *in*1814 was readily detected upon *in vitro* explant and coculture of ganglia with permissive cells, reactivation was not detected following induction by transient hyperthermia.[468] This suggested that VP16 was required for *in vivo* exit from latency but not for *in vitro* explant-induced reactivation. Consistent with this proposal, the *VP16* promoter, which normally is transcribed late in infection, was shown to direct VP16 expression following hyperthermia-induced reactivation in mice.[468] This led to a model where VP16 is expressed prior to IE proteins and stimulates reactivation by triggering IE gene expression to advance the lytic program much in the way that VP16 delivery by the incoming tegument functions during acute infection to initiate HSV IE gene transcription.[468] Further support for a reactivation-specific viral gene expression program was provided by experiments using *ex vivo* and *in vitro* cell culture models. Following explant of sensory ganglia from latently infected mice and incubation with NGF-neutralizing antibody in the presence or absence of cycloheximide, viral genes of IE, E, and L kinetic classes, including VP16, were found to be expressed simultaneously and not sequentially ordered.[119] A similar disordered pattern of HSV mRNA accumulation with simultaneous expression of IE, E, and L mRNAs was observed upon inducible reactivation of latently infected cultured rat and mouse SCG neurons.[79,230] These results argue that reactivation from a genome epigenetically silenced by heterochromatin occurs via cellular mechanisms affecting the entire genome uniformly and emphasize the differences in the mechanisms of reactivation versus initial acute infection of neurons and other cell types.

Two distinct reactivation-specific phases of viral gene expression were observed following inducible reactivation of rat and mouse neurons latently infected in culture. Global, simultaneous derepression of all kinetic classes of HSV-1 mRNA was observed during the initial phase, termed phase 1.[230] Neuronal JNK-dependent phosphorylation of histone H3S10, which rapidly overrides repressive methylation chromatin marks, was shown to be associated with this genome-wide burst of HSV-1 gene expression.[79] Histone demethylase inhibitors were unable to block phase 1, demonstrating that removal of repressive histone epigenetic methylation marks is not required.[79] In agreement with *in vivo* mouse models,[468] VP16 protein accumulation was detected during phase 1 as one of the earliest events following inducible reactivation.[230] However, while IE, E, and late mRNAs and proteins were readily observed in phase 1, nuclear accumulation of VP16 protein and its critical cellular cofactor HCF, viral DNA synthesis, and infectious virus were not detected.[230] Significantly, this initial widespread derepression of viral genes preceded a second phase of VP16-dependent HSV-1 gene transcription

A second discrete reactivation-specific gene expression program termed phase 2 followed the initial genome-wide phase 1 burst of HSV-1 gene expression.[79,230] The onset of phase 2 was

VP16-dependent and correlated with the nuclear accumulation of VP16 and HCF-1 proteins followed by VP16-dependent viral gene transcription, HSV-1 genome amplification, and infectious virus production.[230] Thus, the production and subcellular localization of VP16 plays a critical role in enabling reactivation from latency in sympathetic neuron culture models. Unlike phase 1, cellular H3K27 demethylases (UTX/KDM6A and JMJD3/KDM6B) and the H3K9 demethylase (LSD1/KDM1) are required for full reactivation and infectious virus production in phase 2.[79] In addition, phase 2 HSV-1 gene expression more closely resembled the cascade pattern of viral gene expression during acute, productive replication.[230] The underlying mechanisms restricting virus genome amplification to phase 2 are unknown and could provide a platform to investigate and ultimately reveal unexpected nuances of viral gene expression. For example, at the single-cell level, what are the determinants of whether the genome-wide viral gene expression burst defining phase 1 will in fact progress to phase 2? Are there stochastic combinations of phase 1 gene expression more likely to progress to phase 2 or is phase 1 gene expression relatively homogenous following inducible reactivation? Does phase 1 always progress to phase 2, or are there restriction factors (perhaps including LAT products like virus microRNAs) that act as molecular hurdles that could prevent or limit the onset of phase 2 and in fact reestablish genome silencing, in effect reversing reactivation and reestablishing latency? Continued exploitation of these powerful cultured neuron models will help answer these mechanistic questions and undoubtedly raise additional new exciting questions along the way.

Role of Viral Gene Functions in Latency

Genetic analysis of mutant viruses has attempted to define the role of viral gene products in establishment of latent infection. HSV must have access to the nerve endings in order to establish latency; therefore, *in vivo* it could be expected that the greater the number of peripheral cells that become infected and support virus multiplication, the larger the number of neurons that will harbor latent virus. Indeed, replication-defective viruses show reduced levels of latent infection in animal models, although they can establish and maintain latent infections but not reactivate. In essence, no deletion mutant has totally failed to establish latent infection in mice or rabbit models, indicating an inability to identify a single viral gene product absolutely required to support latency in nonhuman animal models. Thus far, no viral gene function is essential for latent infection of neurons in culture either. Whether this reflects an intrinsic limitation of nonhuman animal models in responding to LAT function or is also true in the natural human host remains unknown.

LAT

During the establishment of latency, LAT and HSV-encoded microRNAs accumulate and contribute to silencing virus gene expression. LAT expression is detected by 26 hpi in murine trigeminal ganglia and continues to increase for at least 3 to 9 dpi.[119] Similar levels and kinetics of LAT expression are observed for a TK-negative mutant virus, which does not replicate in TG neurons, indicating that LAT expression at these times largely occurs from input viral genomes. Several studies support the possibility that LATs and HSV microRNAs could be expressed early enough to add to or synergize with the repressive effects of preexisting host repressors.[119,248]

LAT-negative mutant viruses show elevated lytic viral gene expression in murine trigeminal sensory neurons during acute infection[145] and during latent infection.[337] Consistent with these *in vivo* results, expression of LAT has been shown to reduce viral gene expression and replication

in cultured cells. One study did report that LAT increases lytic gene expression during latent infection of rabbit trigeminal ganglia with the HSV-1 strain 17ΔPst mutant virus versus HSV-1 17syn$^+$ wild-type virus.[153] However, some stocks of the HSV-1 17 ΔPst mutant used in this paper have a lytic growth defect and a rescued virus was not used.[153] Thus, the bulk of the literature documents that LAT decreases lytic gene expression with the exception of one study.

Consistent with its gene expression effects, LAT has been shown to increase H3K9me2 heterochromatin marks and decrease H3K4me2 euchromatin marks on latent HSV-1 chromatin in murine trigeminal ganglia.[499] Further analysis of the structure of the viral heterochromatin demonstrated that LAT expression shows statistically significant increases of H3K27me3 and H3K9me3 on latent viral chromatin in murine trigeminal ganglia.[81] With the exception of a single study where wild type and LAT mutants were not rigorously compared in a side-by-side experiment,[255] the bulk of the literature supports the idea that expression of LAT increases facultative heterochromatin on the latent viral genome.

LAT has been reported to have several other effects on latent infection. With regard to establishment, some studies reported that viruses deleted in various domains of *LAT* establish latency at normal levels, whereas others reported that the number of neurons harboring LAT-negative viruses is decreased by three- to fivefold.[365] It is conceivable that assaying numbers of latently infected cells is a more quantitative or accurate assay of latent infection than measurement of total viral DNA molecules. With regard to reactivation, some observed reduced explant reactivation of virus from ganglia latently infected with LAT-negative mutant viruses, although in some cases LAT-negative mutant viruses show reduced replicative ability. The region of the LATs associated with increased reactivation has been mapped to a 348-bp sequence in the 5′ end of LAT.

Consistent with increased viral gene expression, infection of mice with LAT-negative mutant viruses has been shown to result in greater cell destruction in trigeminal tissue, to cause neuronal death, and to cause higher mortality.[503] By using recombinant viruses that express reporter proteins to mark infected cells,[370] latently infected cells were shown to be lost faster with an LAT-negative mutant virus,[337] and lytic reporter gene expression during latent infection of murine decreased faster with LAT-negative mutant viruses.[338] Consistent with these findings, LATs may protect neurons from apoptosis. Thus, an LAT-deficient virus was reported to induce apoptosis in rabbit trigeminal ganglia at slightly higher levels than the wild-type virus. The effect of LAT on apoptosis in mice, however, was observed in some studies but not others. LAT expressed from a plasmid vector can protect cells of human and monkey continuous lines from cell death induced by etoposide, ceramide, or other agents.[365] Although the original hypothesis was that the LATs protected sensory neurons from apoptosis during acute infection,[365] others have argued that the effect of LATs on establishment of latent infection may be minimal and that it is more likely that the LATs play a role in blocking apoptosis during reactivation.

A role for HSV-1 LAT RNA in reactivation distinct from its function in latency establishment was recently demonstrated by depleting LAT after the establishment of HSV-1 latency in rabbits. This was accomplished by delivering an adeno-associated virus (AAV) vector to deliver a LAT-targeting hammer-head ribozyme after latency was established followed by inducible reactivation. LAT depletion in latently infected neurons with adenovirus-associated vectors expressing the ribozyme prevented reactivation in 60% of the rabbit eyes.[508] This study is also notable in that it demonstrated that AAV can be delivered to trigeminal ganglia by the

corneal route.

LATs have also been reported to protect neuronal-derived cells from $CD8^+$ T-cell killing[202] and to promote $CD8^+$ T-cell exhaustion in trigeminal ganglia.[14,69] Overall, despite differences in the experimental models utilized, a common theme of LAT studies has been that LATs protect neurons from death, either by reducing viral gene expression, by protecting against apoptosis, or by other mechanisms. Studies of latent infection in human neurons, the natural host of the virus, should be very important in further defining the role of LAT in HSV-1 latent infection.

miRNAs

Although miR-H2-3p is complementary to ICP0 mRNA and could reduce ICP0 expression when coexpressed in transfected cells and miR-H6 is able to reduce ICP4 in transfected cells,[476] there have been few alterations in phenotype displayed by recombinant viruses harboring deletions of the sequences encoding these miRNAs.[248,460] Findings from studies using miR-H2 mutant viruses differ as to the impact of endogenous miR-H2 on ICP0 expression and virus replication.[139,353] While a miR-H2 mutant virus produced in a 17syn+ background displayed increased ICP0 expression in 293 cells, a miR-H2 mutant in a KOS background had no effect on ICP0 expression in Vero or Neuro2A cells or in latently infected mouse trigeminal ganglia. Furthermore, while the 17syn+ mutant virus had a reduced rate of replication following low-multiplicity infection in the Neuro2A mouse neuroblastoma cell line, there was no difference in latency establishment, maintenance, or reactivation from latency in mouse trigeminal ganglia following infection with the KOS-background miR-H2 mutant virus. The basis for this strain-specific behavior of miR-H2 mutant alleles remains unknown. Besides the miR-H2 mutant virus, miR-H3 and miR-H4 mutant viruses were produced in a 17syn+ background. Both mutant viruses had slightly increased rates of replication in Neuro2A cells following low-multiplicity infection but, while the miR-H4 mutant had increased ICP34.5 expression, there was no observed effect of miR-H3 on ICP34.5 expression in 293 cells after transfection or HSV-1 infection.[139]

Expression of a subset of these microRNAs in latently infected mouse ganglia is dependent on LAT. Because *LAT* deletion mutants can efficiently establish and maintain latency in mouse trigeminal ganglia, this indicates that LAT-encoded microRNAs are not essential for the establishment or maintenance of latency.[248] A similar dependency on LAT for expression of miR-H6 was observed in HSV-2 infection models, suggesting HSV-2 LAT-encoded microRNAs are similarly not required for latency establishment or maintenance.[460] A recent paper reported that an HSV mutant with the miR-H1 and miR-H6 sequences deleted showed slower reactivation than the wild-type parental virus.[34] The phenotype of a rescued virus remains to be explored. The limited phenotypic changes of the miRNA mutant viruses may be due to the fact that the effects of miRNAs are often subtle or human neuron specific. These miRNAs are conserved in HSV; thus, they must play a biological role, although their individual effects may be small.

ICP0

HSV-1 ICP0 increases the levels of LAT in latently infected murine ganglia and thereby increases the levels of H3K27me3 facultative heterochromatin.[377] This phenotype was observed with an *ICP0* gene nonsense mutant virus, so the effect is likely to be due to the protein itself. The mechanism could be direct or indirect but raises the possibility that viral lytic proteins could

also influence latency.

Assembly of Progeny Virus in Neurons

As described earlier, reactivation leads to expression of sufficient viral proteins and viral DNA replication to produce some progeny virions. These are ultimately released at the axonal termini to initiate the recurrent infection at the site of innervation of the nerve. The mechanisms of assembly of HSV progeny virions in neurons has been controversial, as there has been evidence of intact viral particles undergoing anterograde transport ("married" model) as well as evidence of independent transport of capsids and vesicles ("separate" model) containing the viral glycoproteins.[20,519] New components of the virion move by anterograde transport to both peripheral and central branches of the neuron. Virion assembly and/or release have been reported along the axon shaft and at the axon tip.[342] The question is how virions or virion components are transported by anterograde transport to these sites of virion release. Early studies of HSV infection of human fetal neurons followed by electron microscopy, immunoelectron microscopy, and immunofluorescence analyses concluded that capsids are transported independently from vesicles containing viral glycoproteins. Immunofluorescence and live cell imaging of human neuroblastoma cells infected with HSV also showed separate sites of staining or localization for glycoproteins relative to capsid proteins.[434] A further study using high-resolution electron microscopy has shown that 75% of the capsids in the axons of rat neurons were in virion particles.[328] More recent studies of "two-color" HSV recombinants expressing fluorescent capsid proteins and a fluorescent glycoprotein have continued to find different results, in that one study found that 64% to 70% of the capsids were associated with glycoproteins while undergoing anterograde transport,[20] although another found that 80% and 67% of the capsids in two neuronal systems were independent of glycoproteins.[519] Thus, there is the potential that either of two mechanisms of transport could occur to different extents in different neuronal cells under different conditions. Genetic studies have provided some insight in this area. One study has shown a defect in transport of envelope proteins, VP22 tegument, and VP5 capsid proteins into the optic nerve in mice infected with a glycoprotein E–negative virus, implying that axonal localization of certain glycoproteins and capsid and teguments may be linked.

Role of the Host Immune Response in Latency

While the role of the host immune response in controlling acute lytic infection is clear as is the role of cellular immunity in containing reactivation events, the extent to which the host immune response is a primary component that controls latency in the neuron itself has been intensively investigated and debated. The models positing immune control as a primary regulator of latency originate with observations that immune cells are found infiltrating latently infected ganglia in naturally infected human sensory ganglia and experimentally infected mice. It has been reported that antagonizing $CD8^+$ T cells and/or IFN-γ remaining within explanted murine trigeminal ganglia at 14 days postinfection promotes viral gene expression and reactivation.[280] However, $CD8^+$ T cells remaining within TGs explanted after 34 days, a time point more consistently associated with latency in the mouse model, were unable to block reactivation. Indeed, T cells resident in infected ganglia in mice and rabbits reportedly have an exhausted phenotype and exhibit reduced function.[14,201,441] Although some studies have attempted to correlate T-cell infiltrates with LAT-positive neurons, most LAT^+ neurons in latently infected mice sensory

ganglia are devoid of detectable associated inflammatory cells and T cells were only observed clustered around spontaneously reactivating neurons.[170] Additional studies observed that $CD8^+$ T cells nonspecifically traffic into latently infected murine sensory ganglia, although only the HSV-specific $CD8^+$ T cells are activated and specifically retained in the ganglia. Moreover, in authentic human TG, the neurons that were surrounded by T cells were not detectably positive for LAT or HSV DNA.[170] Finally, latency can be established in immunodeficient mice lacking innate and adaptive immune systems. Taken together, these studies i) imply that the role of cellular immunity is one of surveillance and control once reactivation at the molecular level has commenced within the neuron and ii) are consistent with the existence of neuronal cell-intrinsic mechanisms that are primarily responsible for controlling the lytic/latent switch in the viral lifecycle within the host neuron. This includes neuronal and viral factors including LAT and microRNAs working in concert, whereas $CD8^+$ T cells are activated and retained in the ganglia in response to low-level expression of viral antigens.

To model how latently infected neurons might respond to antiviral cytokines produced by immune cells infiltrates within ganglia, latently infected cultured rat sympathetic neurons were exposed to extrinsic interferon. Type I and type II interferon both induced neuron-specific transcriptional responses that prevented reactivation phase 1.[279] Furthermore, sensitivity to interferon action was lost once phase 1 commenced and ICP0 expression prior to phase 1 could protect neurons from type II interferon action.[279] The surprising finding that IFN acts within a limited temporal window and is antagonized by a reactivation phase 1 viral protein exemplified by ICP0 implicates the viral products produced within phase 1 in the establishment of an IFN-resistant state that allows reactivating virus to proceed into active replication during reactivation phase 2.[279] Thus, in addition to allowing immediate production of VP16,[230] the reactivation phase 1 HSV genome-wide burst of expression enables production of numerous viral functions that subvert host defenses regardless of their classification as IE, E, or L genes. Moreover, it provides a potential mechanism for reactivation events initiating from latent HSV DNA genomes to access tegument functions, which are normally expressed as late genes and delivered in the context of infecting virions where they function at times that precede viral gene expression during acute infection.

The fate of the neurons after viral reactivation has been a topic of long debate. In support of survival of the neurons is that loss of sensory perception due to virus-induced sensory neuron loss is not a common sequela in patients suffering from frequent recurrences at the same site. A formal rebuttal of this argument is that nerve endings from adjacent unaffected neurons could grow into the healed area and reestablish a network. The second and more significant observation is that women with recurrent genital lesions shed virus in the interim between clinically manifest lesions. If each local lesion arises from a reactivated neuron, there would not be enough neurons to support viral reactivation over many years if the neurons die as a consequence of this process. The fate of the infected neuron may depend on the latent viral load and the strength of the inducing signal; thus, there may be a continuum of effects of reactivation on the host neuron. A recent study evaluating reactivation in mice in response to hyperthermic stress found that fragmented viral protein–positive neurons morphologically consistent with apoptotic bodies and containing cleaved caspase-3 were detected.[114] While evidence for direct T-cell–mediated antigen recognition was not detected, inhibition of viral DNA replication with acyclovir surprisingly blocked neuronal fragmentation. Thus, at least some neurons supporting HSV-1 reactivation following hyperthermia in mice do not survive this event, and acyclovir

therapy can reduce fragmentation associated with hyperthermia-induced reactivation.

PERSPECTIVES

We have considerable knowledge of the mechanisms of viral replication in cells, and future studies on the role of human host factors and how the virus interacts with those human cell factors will be important for understanding the virus and our human cells. Powerful new methods for studying the structure and function of viral and host gene products will define the molecular basis for viral pathogenesis. Exciting new applications of neuronal cell culture and human stem cell culture technology are providing us with powerful new approaches to study the interaction of HSV with human neurons and organoids in culture. These will be important for the design of new antivirals that target latent infection as well as lytic infection. HSV infections have been associated with neurodegenerative diseases,[167] and a recent study of maternal immunization of female mice with an HSV vaccine was recently shown to prevent behavioral changes due to neonatal infection.[358a] These results further raise the potential for a direct role for HSV infection on long-term neurological disease and the potential for antiviral interventions. Detailed studies of the effects of HSV infection in the neuronal systems for lytic and latent infection may provide the mechanistic basis for this and other forms of viral neuropathogenesis.
