KSHV vFLIP, the product of ORF 71, also referred to as K13, is the viral homolog of cellular FLIP (FLICE [protein FADD-like interleukin-1 beta-converting enzyme, now called caspase-8] inhibitory protein). KSHV vFLIP is composed of two death effector domains (DEDs) one right next to the other, which mediate homotypic protein–protein interactions with other DED-containing proteins. DEDs are present in the adaptor protein FADD, which binds the death receptor, FasR. Initiator caspases, including caspase 8 and 10 in humans, also contain two tandem DEDs, and caspase 8 is a critical player in Fas-mediated death induction. Among the cellular FLIPs, the two predominant forms are the long form ($FLIP_L$) and the short form ($FLIP_S$). vFLIP is structurally more similar to $FLIP_S$, as they both lack a caspase-like domain present in $FLIP_L$. After FasR is bound by Fas ligand present outside the cell, FasR binds FADD, which in turn recruits and activates procaspase 8, via interactions between the DED domains of FADD and the caspase, generating the death-inducing signaling complex (DISC). Caspase activation subsequently triggers the apoptotic cell death program. This process can be blocked by competitive binding by the cellular FLIP proteins.

Virally encoded FLIPs were first discovered in poxviruses and other herpesviruses, where they blunted Fas-mediated killing by preventing caspase 8 recruitment to the DISC.[592] Procaspase 8 can also be bound and inhibited. Several early studies have supported a mechanism for KSHV vFLIP.[28,39] However, the ability of vFLIP to block Fas-mediated killing has been questioned[128]; consistently observed in all studies is the observation that KSHV vFLIP up-regulates the antiapoptotic transcription factor, NFκB,[112] and that vFLIP can be found bound to NEMO (also called IKKγ) in PEL cells.[229,380,593] This complex activates IKK, leading to IkB phosphorylation and the release of active p65-p50 NFκB heterodimers. In addition, vFLIP also increases accumulation of the p52 subunit of NFκB, indicating that vFLIP can activate the alternate pathway of NFκB, which involves the proteolysis of p100 to p52.[416] These findings are concordant with the observations that (a) PEL cells exhibit high levels of NFκB activity, and

inhibition of this pathway induces cell death[308]; and (b) siRNA-mediated knockdown of vFLIP promotes apoptosis in PEL.[212,228] It therefore appears that the key role of vFLIP during PEL latency is the activation of an antiapoptotic program through the up-regulation of NFkB activity. Notably, among the cellular genes that are clearly regulated by NFκB, and therefore by vFLIP, are the cellular inhibitor of apoptosis 1 and 2 proteins, as well as cellular FLIP,[228] making studies to determine whether vFLIP can inhibit FAS-mediated apoptosis complicated as the effect might be direct or indirect. vFLIP has also been demonstrated to suppress glycolysis by activating the NFκB pathway in rat mesenchymal stem cells (MSCs).[697] vFLIP itself is stabilized by Hsp90[461] and the MAVS signaling complex in peroxisomes.[127]

Several transgenic mouse models for vFLIP have been made. In one of these, where vFLIP was expressed in all B and T cells, mice showed enhanced responses to mitogenic stimuli and not surprisingly, an increased incidence of lymphoma in a small proportion of mice, but in a much higher proportion when bred with cMyc transgenic mice.[4,128] In the second report, a conditional knock-in system was used to express vFLIP in all B cells, or specifically in germinal center B cells.[28] These mice developed lymphadenopathy with increased numbers of lambda light chain–expressing plasmablasts, reminiscent of MCD, as well as tumors of B-cell origin with high frequency, albeit with an abnormal immunophenotype and histiocytic transdifferentiation. The same conditional model was used to induce vFLIP expression in endothelial cells, which led to vascular proliferation, increased circulating IL6 and IL10, and increased myeloid cells with a suppressive phenotype.[29] Expression of vFLIP in intestinal epithelial cells also led to inflammation.[521]

The proteasome inhibitor, bortezomib, blocks IkB proteolysis, impairs NFkB activation and triggers apoptosis of PEL cell lines[12,417] and in a xenograft mouse model of PEL. These data suggest that this drug might have therapeutic efficacy in PEL.

We have discussed the antiapoptotic effects of NFκB, which likely provides the selective force for maintaining KSHV vFLIP. However, NFκB is a key positive regulator of inflammatory responses. It seems paradoxical that a latency program in herpesviruses, designed for cryptic persistence, would call attention to itself by activating inflammation; but vFLIP has additional effects, which may at least partially explain this paradox. In addition to the antiapoptotic function that is thought to be mediated mainly by NFκB-regulated genes, vFLIP has been shown to protect B cells from autophagy by binding to Atg3.[352] In endothelial cells, it is required for the spindling seen after infection with KSHV.[222] It contributes to prevention of detachment-induced apoptosis (anoikis) in endothelial cells.[178] Moreover, NFκB activation may not be the only function of KSHV vFLIP. The protein also binds to RIP and TRAF2 upstream of IKK, and TRAF binding results in JNK activation.[11,229] It has also been shown that activation of NFkB hinders lytic gene expression, and inhibition of NFκB activation induces lytic reactivation. Thus, vFLIP may play an important role in maintaining stable KSHV latency.

Kaposins

The locus for kaposin was initially identified by a screen for genes that were expressed during latency in PEL cell cultures.[691] *In situ* hybridization using probes for kaposin mRNA revealed that kaposin is expressed at low levels in both uninduced BCBL-1 cells and to some degree in latent KS spindle cells.[569,577] Like several other latent loci, kaposin is also highly up-regulated

during lytic replication.[524]

Kaposin mRNA encodes for three proteins due to differential translation initiation (Fig. 15.7).[524] At their 3′ end, all kaposin messages contain a small ORF (ORF K12) encoding a highly hydrophobic 60 amino acid polypeptide called *kaposin A*. Kaposin A is found in intracellular membranes and the plasma membrane.[594] Kaposin A is capable of transforming Rat-1 fibroblasts, and the resulting cell lines form tumors (fibrosarcomas) in nude mice.[445] Kaposin A binds cytohesin-1, a guanine nucleotide exchange factor (GEF) for ARF GTPases, and a regulator of cell adhesion mediated by integrins. This interaction allows for GTP binding to ARF1. Since expression of a cytohesin-1 mutant deficient in guanine nucleotide exchange reverses transformation,[314] this activity is likely to be important for transformation. Immediately upstream of the K12 ORF is a series of tandemly repeated 23-nt GC-rich elements, termed DR (*d*irect *r*epeat) 1 and DR2. This region lacks AUG codons; however, multiple proteins are generated from this region by initiation at variant CUG codons. One of these initiates upstream of the DR2 repeat cluster and terminates after the DR1 repeats and encodes a nuclear protein named kaposin B that lacks the ORF K12 polypeptide region because of a stop codon in the reading frame. Another protein, kaposin C, similarly begins 5′ to DR2 but in an alternative reading frame compared to kaposin B. Translation proceeds through the DR regions and ORF K12. This generates a transmembrane protein that contains the amino acid repeats (encoded by the DRs) fused to K12. Although the kaposins B and C DR sequences are in different frames, they share a common segment of repetitive sequence. Translation of an individual repeat induces the ribosome to enter the next repeat one nucleotide out of frame; after traversing three such repetitive sequences, the ribosome reverts back to the initial frame (Fig. 15.7). Thus, the repeat regions of kaposin B and C share two sets of common 23 amino acid repeats, flanked on both sides by sequences unique to each protein. Consequently, kaposin C is partly a membrane-bound kaposin B isoform.

Kaposin B can bind and activate MAP kinase–associated protein kinase 2 (MK2) as well as the upstream kinase, p38 MAP kinase.[420] MK2 is the major target of p38, which is a stress-inducible kinase. MK2 regulates the stability of cytoplasmic mRNAs that contain AU-rich elements (AREs) in their 3′UTRs. AREs are found in many cytokine mRNA transcripts, for example, IL-1, -3, -4, -6, TNF-alpha, GM-CSF, as well as other growth factors like VEGF, and oncogenes, for example, MYC. AU-rich mRNAs are highly unstable, but activation of the MK2/p38 kinases inhibits their turnover and thereby enhances the levels of these cytokine mRNAs. Thus, by up-regulating MK2, kaposin B prolongs the half-lives of ARE-bearing reporter transcripts and increases cytokine production[420] (Fig. 15.8). Both the DR1 and DR2 repeat regions are essential for kaposin B's function.[421] It was shown that kaposin B also enhanced stability of PROX1, a regulator of lymphatic endothelial differentiation that is up-regulated upon KSHV infection of endothelial cells. The PROX1 mRNA transcript also contains an ARE, and kaposin B enhances its stability.[678]

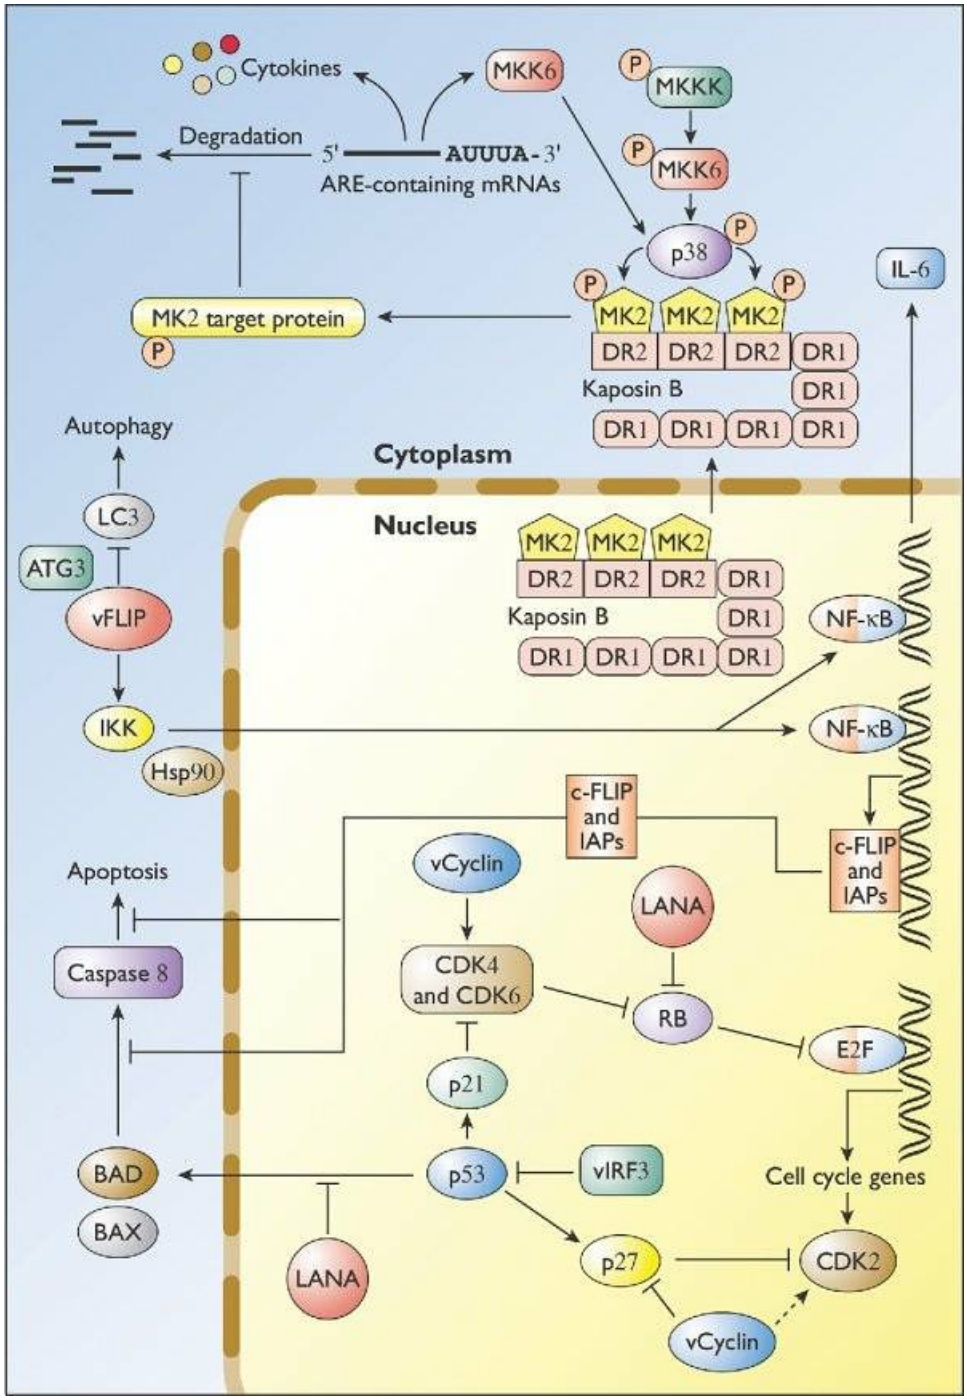

FIGURE 15.8 Functions and interactions of latent viral proteins. LANA, vCyclin, vFLIP, kaposin, and vIRF3/LANA act in concert to inhibit apoptosis and enhance cell survival and proliferative loops.

K10.5/vIRF3/LANA2

The KSHV genome has four genes that encode proteins of the IRF (*i*nterferon *r*egulatory *f*actor) family. IRFs are cellular transcription factors and several members, including IRF3 and IRF7,

transcriptionally activate type I interferons and interferon-stimulated genes (ISGs). The viral IRF homologs (vIRFs) are encoded by ORFs K9-11 (Fig. 15.3), suggestive of the fact that they arose by duplication of one or more ancestral genes, plausibly obtained from the cellular genome. All the vIRFs are lytic proteins except for one, vIRF3 (ORF K10.5), which encodes a nuclear protein that is expressed in latent PEL but not in KS spindle cells.[162,389,516] For this reason, vIRF3 is also called latency-associated nuclear antigen 2 or LANA-2.

vIRF3 expression inhibits the IRF3/7-mediated induction of the IFN-A4 promoter in murine cells and hinders the ability of these cells to mount an IFN response to RNA virus infection.[389] KSHV vIRF3 can also bind and inactivate the function of cellular IRF7.[293] This leads to the suppression of IFN-alpha-related activities.[293]

vIRF3 also inhibits cellular IRF5 function[651] preventing its ability to induce p53-independent apoptosis and p21-mediated cell cycle arrest.[651] In concordance, vIRF3 has also been shown to bind and inactivate p53.[516] Central to its expression in PEL, a critical finding was that vIRF3 expression was required for PEL survival.[650] Knockdown of vIRF3 expression in PEL hampered cell proliferation and increased activity of caspase-3 and -7.[650] Additionally, these effects were seen even in the context of dually infected, EBV-positive, and KSHV-positive PEL lines.[650] In endothelial cells, vIRF3 appears to play a role in angiogenesis. Hypoxia-inducible factor-1 (HIF-1), a regulator of angiogenesis, is composed of an oxygen-sensitive alpha-subunit and a constitutively expressed beta-subunit. vIRF3 can bind the HIF-1 alpha subunit to stabilize it under normoxic conditions and increase the expression of VEGF and angiogenesis in endothelial cells.[549] vIRF3 together with vIRF1 can also interact with the cellular USP7 deubiquitinase to impact the KSHV life cycle.[664] Additionally, vIRF3's interaction with HDAC5 contributes to virus-induced lymphangiogenesis.[354] vIRF3 has also been shown to interact with the host sumoylation machinery to inhibit sumoylation of tumor suppressors.[341]

Thus, vIRF3 appears to play a key role in cell survival and angiogenesis in the context of viral latency, and perhaps angiogenesis in KS lesions.

Viral microRNAs, lncRNAs, and Circular RNAs

MicroRNAs are 21 to 23 nucleotide long RNAs that regulate gene expression via base pairing to their mRNA targets. MicroRNAs (miRNAs) are generated from the cleavage of larger transcripts named pri-miRNAs, via a processing pathway involving a RNAse III-like endonuclease named Drosha located in the nucleus. These pri-miRNAs contain an imperfect inverted repeat that is cleaved by Drosha into a 65-nucleotide hairpin called a pre-miRNA, which is then transported to the cytoplasm where it is recognized by another RNAse III-like endonuclease named Dicer. Dicer cleaves off the loop of the hairpin thereby generating a partial duplex RNA molecule, which can bind to its target mRNAs. One strand of the RNA duplex is transferred to a cytoplasmic complex named RISC (RNA-induced silencing complex). In general, if base pairing of the miRNA to the target is perfect, RISC cleaves the target mRNA. However, if base pairing of the miRNA to the target is imperfect, RISC modulates translational repression of the target mRNA either through inhibiting translational initiation or elongation or through deadenylation.

Following the seminal discovery of viral microRNAs (miRNAs),[489] KSHV was found to encode eleven pre-miRNAs that arose from transcripts in the latency region (Fig. 15.5).[78,227,489,527] The miRNAs derived from these hairpins are designated as miR-K1 through

miR-K11. Some of these pre-miRNAs, for example, miR-K3, 4, 6, 9, donate each of the 2 arms of the hairpin to RISC, thereby giving rise to two mature miRNAs from each pre-miRNA. Each member of the pair is referred to as “5p” or “3p” to indicate its origin from the 5′ or 3′ segment of the hairpin. Additionally, the miR-K10 miRNA undergoes RNA editing at a single site in the seed sequence generating two different miRNAs (miR-K10a and miR-K10b). Thus, although there are 12 pre-miRNA transcripts arising from the KSHV genome, these lead to the generation of 17 mature miRNAs. These miRNAs are present in KS and PEL.[470,471] There is strong sequence conservation in the genomic sequences that encode for these miRNAs and only a subset of pre-miRNAs displayed single nucleotide polymorphisms (SNPs) that could affect their biogenesis.[409]

There are many publications identifying functions for the KSHV miRNAs since their discovery. miR-K11 was found to contain an identical seed sequence to that of a cellular miRNA, miR-155.[216] Viral miR-K11 was found to suppress known targets of cellular miR-155, including the transcriptional repressor BACH1, the pro-apoptotic protein, BIRC4BP/XAF1, and the cell cycle regulator, FOS.[216] Using a transcriptional profiling approach, another group identified that the target for miR-K5 was a pro-apoptotic Bcl2-associated factor, named BCLAF1. Moreover, additional KSHV miRNAs including miRs K9, K10a and K10b were also found to target BCLAF1. Repression of BCLAF1 expression by the KSHV miRNAs was found to be important for cell survival to apoptotic stimuli[700] as was the down-regulation of tumor necrosis factor–like weak inducer of apoptosis (TWEAK) receptor, a pro-apoptotic protein that is targeted by miR-K12-10a (also known as miR-K10a).[1] miR-K1 has been shown to down-regulate p21, a protein that induces cell cycle arrest[215] and also to target IkBα.[356] Moreover, miR-K12-3 and miR-K12-7 (also called miR-K3 and miR-K7, respectively) down modulate C/EBPbeta p20 (LIP), an isoform of C/EBP that represses IL-6 and IL-10 expression. This results in up-regulation of these cytokines in cells from the myeloid lineage.[499]

One study also looked at gene expression profiling in cells stably expressing all KSHV-encoded miRNAs.[528] They found that 81 genes were changed in the presence of the viral miRNAs. One of these proteins is the anti–tumor suppressor protein, thrombospondin 1 (THBS1), whose protein levels were decreased over tenfold.[528] Reduced THBS1 expression in the presence of viral miRNAs led to decreased TGF-beta activity suggesting that the viral miRNAs contribute to tumorigenesis and angiogenesis.[528] Many of the KSHV viral miRNAs target genes regulating glycolysis, cell cycle, and apoptosis.[204]

It is known that KS is composed of poorly differentiated endothelial cells, expressing markers of both lymphatic endothelial cells (LECs) and blood vessel endothelial cells (BECs). KSHV-encoded miRNAs appear to contribute to transcriptional reprogramming by silencing the cellular transcription factor, musculoaponeurotic fibrosarcoma oncogene homolog (MAF).[243] MAF is expressed in LECs but not in BECs, where it functions as a transcriptional repressor of BEC-specific genes to maintain the differentiation status of LECs. KSHV-infected LECs show an up-regulation of BEC-specific genes through miRNA-dependent down-regulation of MAF.[243] In summary, KSHV-encoded miRNAs can influence the differentiation status of a cell in a manner similar to certain cellular miRNAs and this suggests that the viral miRNAs may contribute to the development of viral malignancies via reprogramming the differentiation pathway of the infected cell. The entire KSHV miRNA cluster impacts the cellular metabolic response by suppressing heat shock protein A9 (HSPA9), HIF and prolyl hydroxylase

EGLN2.[676] KSHV miRNAs also up-regulate argininosuccinate synthase 1 (ASS1) and modulate the generation of nitric oxide (NO), which is important for the survival of KSHV infected cells.[369] KSHV viral miRNAs have also been demonstrated to target enzymes in the mevalonate pathway to repress cholesterol levels in infected cells.[542]

The viral miRNAs are also incorporated into extracellular vesicales (exosomes) that can shape the extracellular tumor environment.[424,677] The KSHV miRNAs have also been shown to suppress CASTOR1-mediated mTORC1 inhibition to promote tumorigenesis.[368]

In addition to their roles in cell survival and oncogenesis, the KSHV viral miRNAs also play a key role in regulating the lytic–latent switch. Several studies have examined the role of viral miRNAs in controlling this switch, and although all these studies find that the miRNAs enhance latency and suppress lytic replication, the mechanism by which this occurs is different in each case. For example, miR-K9* has been reported to target the 3′ UTR of the ORF50 transcript thereby enhancing latency and preventing viral reactivation.[40] Consistent with this finding, a KSHV BAC with 10 of the 12 viral miRNAs deleted displayed elevated levels of viral lytic genes, including ORF50.[387] Additionally, miR-K12-4-5p (also called miR-K4-5p) was found to target Rb-like protein 2 (Rbl2), a known repressor of DNA methyl transferase 3a and 3b (DNMT3a/b). miR-K12-4-5p reduced Rbl2 protein expression and increased DNMT1, -3a, and -3b mRNA levels to regulate genome-wide epigenetic reprogramming.[387] In further confirmation of the role of the viral miRNAs in suppressing lytic replication, deletion of 14 microRNAs from the KSHV genome also significantly enhanced viral lytic replication as a result of reduced NFκB activity.[356] The viral miRNAs were also found to decrease expression of lytic genes by targeting host transcription factors.[492]

Circular RNAs (circRNAs) encoded by KSHV were recently discovered. Multiple circRNAs were detected in cells infected individually with KSHV, as well as cells dually infected with KSHV and EBV.[587,598,606] KSHV encodes multiple circRNAs, which are located within ORFs of viral lytic genes and are induced during the lytic phase of the viral life cycle.[587,606] KSHV circRNAs were also found in KSHV-associated tumors, suggestive of the fact that these viral circRNAs may play a role in KSHV pathogenesis. Additionally, it was reported that a human circRNA, hsa_circ_0001400, is induced upon KSHV infection and can inhibit the expression of several KSHV genes.[587]

Genes Expressed at Low Levels During Latency but Highly Up-Regulated During Lytic Replication

Although K1 and vIL-6 are considered to be lytic proteins, several publications demonstrate that these proteins are expressed at low levels during latency, yet are highly up-regulated during lytic replication.[59,104,483,570,633] Using tightly latent cell lines that displayed very low levels of spontaneous lytic reactivation to perform array-based transcript profiling and limiting dilution reverse transcription PCR (RT-PCR), Chandriani et al. found that both K1 and K2/vIL-6 genes were expressed under latent conditions.[104] Additionally, the K1 promoter is active in multiple cell types in the absence of ORF50/RTA protein.[59,60,104,633] It is likely that due to their potent signaling properties, both K1 and vIL-6 need to be expressed at low levels in infected cells. Since these two genes show a distinct latent/lytic expression profile compared to other viral genes, we discuss them in a separate section below. It is likely that the K15 gene also falls in this

same category[2].

K1

ORF K1 is situated at the left end of the genome and encodes for a type I transmembrane protein whose signaling function is analogous to the B cell antigen receptor complex. K1 is found in the ER and also on the plasma membrane. It contains a highly variable and glycosylated N-terminal ectodomain, a transmembrane region, and a cytoplasmic tail that sports an immunoreceptor tyrosine-based activation motif (ITAM).[346] This structure, also found in BCR and TCR signaling complexes, contains two tyrosine residues separated by characteristic spacing. Activation of the B-cell receptor by antibody binding results in phosphorylation of tyrosines by Src kinases. Phosphorylation creates binding sites for Syk kinase, which upon activation mediates downstream signaling, including PLCγ activation, calcium release, and NFATc activation, among other events. The K1 protein signals in a similar fashion, but its activity appears to be constitutive, since it signals in the absence of a ligand.[333,346] While it is possible that the K1 ectodomain binds to a ubiquitously expressed cell surface protein, constitutive activation is more likely due to self-oligomerization mediated by cysteine residues in the K1 ectodomain. K1 aggregation leads to ITAM phosphorylation, Syk kinase recruitment, and increased NFATc and AP-1 activity similar to what occurs upon BCR activation. Moreover, the activated K1 tail can interact with other signaling proteins besides Syk, including PI3-kinase (via its p85 regulatory subunit), Lyn, RAS-GAP, PLC-γ 2, vav, and Cbl.[333,350,595] PI3K activation results in phosphorylation and activation of Akt kinase.[595] Activated Akt phosphorylates the forkhead (now known as FOXO) transcription factors, sequestering them in the cytoplasm (Fig. 15.9). Since FOXOs induce apoptosis, this phosphorylation is an antiapoptotic event, and K1 expressing cells exhibit greater resistance to apoptosis induced by both Fas ligand and by the expression of FOXO proteins.[595] K1's effect on apoptosis may also be linked to its ability to bind to chaperones. K1 was shown to interact with heat shock protein 90-beta (Hsp90beta) and endoplasmic reticulum–associated Hsp40 (Erdj3/DnaJB11) by tandem affinity purification.[643] K1 expression and antiapoptotic function was highly dependent on Hsp90 and Hsp40/Erdj3 since knockdown of these proteins, as well as pharmacological inhibitors of Hsp90, dramatically reduced K1 expression.[643] Interestingly, Hsp90 inhibitors were efficacious against KS by also targeting LANA[120] and vFLIP in PEL.[461] Furthermore, in B cells, K1 expression hinders the surface transport of the BCR[348] and this may be a means by which KSHV puts the infected B cell under the control of the virus rather than the control of the BCR. In this manner, stimulation of BCR signaling does not jeopardize the viral life cycle. K1 signaling function in B cells has been shown to be regulated by its endocytosis, and these two events are intertwined.[596]

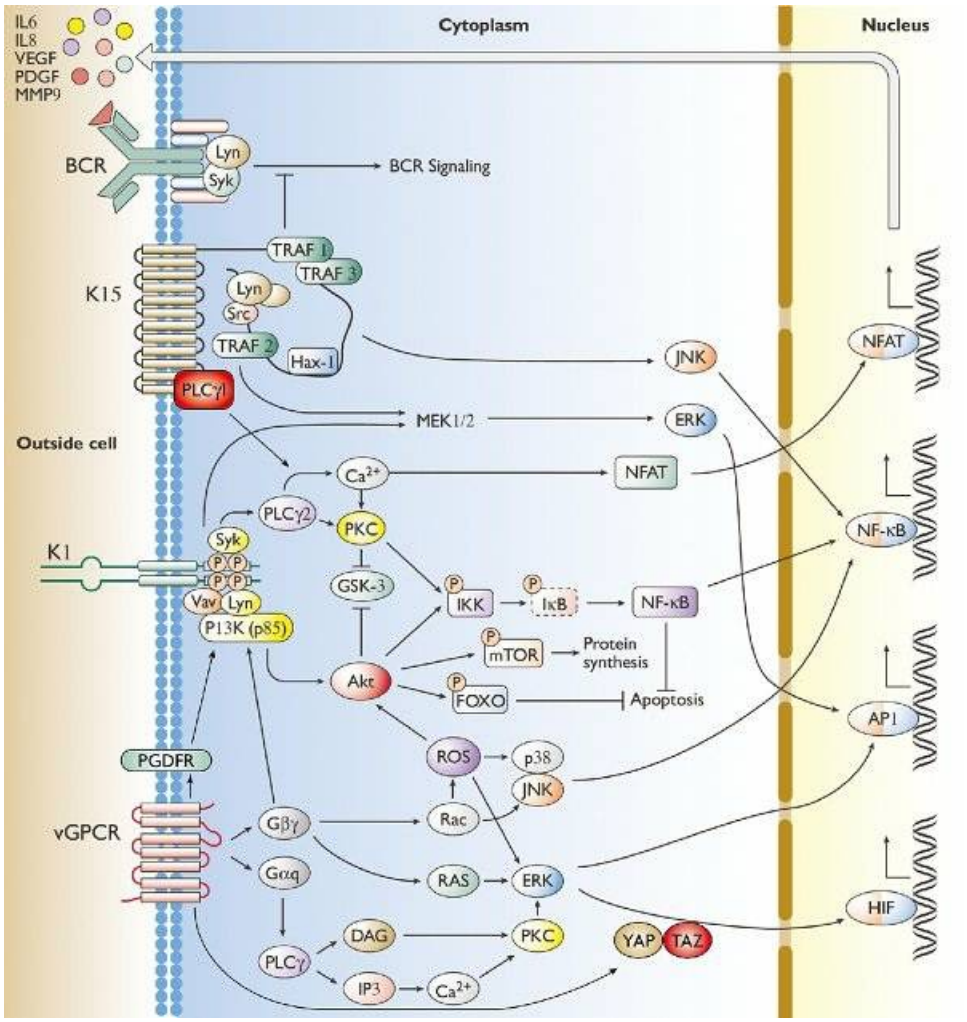

FIGURE 15.9 Signal transduction pathways activated by KSHV-encoded transmembrane proteins, K1, K15, and vGPCR. Activation of the PI3K and MAPK pathways by viral signaling proteins leads to enhanced production of cytokines and growth factors, cell proliferation, and inhibition of cell death.

K1 is capable of transforming rodent fibroblasts and substituting for the STP oncogene in the context of HVS-mediated transformation of T cells.[347] Lymphomas and sarcomas are known to develop in K1 transgenic mice, and the lymphomas show activated Lyn kinase and are refractory to Fas-mediated apoptosis.[635] In epithelial and endothelial cells, K1 expression has been reported to induce the secretion of angiogenic factors, including vascular endothelial growth factor (VEGF) and matrix metalloproteinase-9.[630] K1 can activate the PI3K/Akt/mTOR pathway in endothelial cells and can immortalize and extend the life span of primary human umbilical vein endothelial cells (HUVECs) in culture[633] (Fig. 15.9). K1 ITAM expression was needed to activate both the VEGF/VEGFR-2 and the PI3K/Akt signaling pathways in these cells. Additionally, K1 was shown to modulate 5′ adenosine monophosphate-activated protein (AMPK) to enhance cell survival.[15] Thus, K1 appears to be important in KSHV-associated tumorigenesis and angiogenesis.

In the context of lytic replication, the ITAM of K1 has been shown to augment lytic reactivation from latency.[334] However, others have shown that the K1 ITAM is needed to suppress TPA-mediated viral reactivation in the context of PEL cells and this suppression may contribute to the establishment and/or maintenance of KSHV latency *in vivo*.[349] These differences may be explained by the experimental conditions used in each model system. A study with recombinant viruses showed that K1 deletion viruses displayed reduced lytic replication compared to WT KSHV and also yielded smaller numbers of infectious progeny. Cells infected with a K1 deleted virus showed reduced phosphorylation and activation of Akt kinase.[687]

Recently, it was demonstrated that K1 proteins from AIDS-related KS had greater transformation potential versus K1 sequences from classic KS and that this corresponded with the aggressiveness of KS seen in AIDS patients with KS versus classic KS patients.[588]

vIL-6

Cellular human IL-6 (hIL-6) signals through a heterodimeric receptor composed of a signaling subunit (gp130) and a high-affinity ligand-binding subunit (gp80/IL-6Rα). Following hIL-6 binding to this receptor complex, STATs 1 and 3 are activated. The signaling mechanism of the viral homolog, vIL-6, differs from hIL-6 in that it does not need the gp80 subunit; rather, it binds directly to gp130 to trigger signal transduction (Fig. 15.10). Although vIL-6 does not need gp80 to activate signaling, it can still interact with this subunit of the receptor complex, which appears to modulate vIL-6's activity.[266,360]

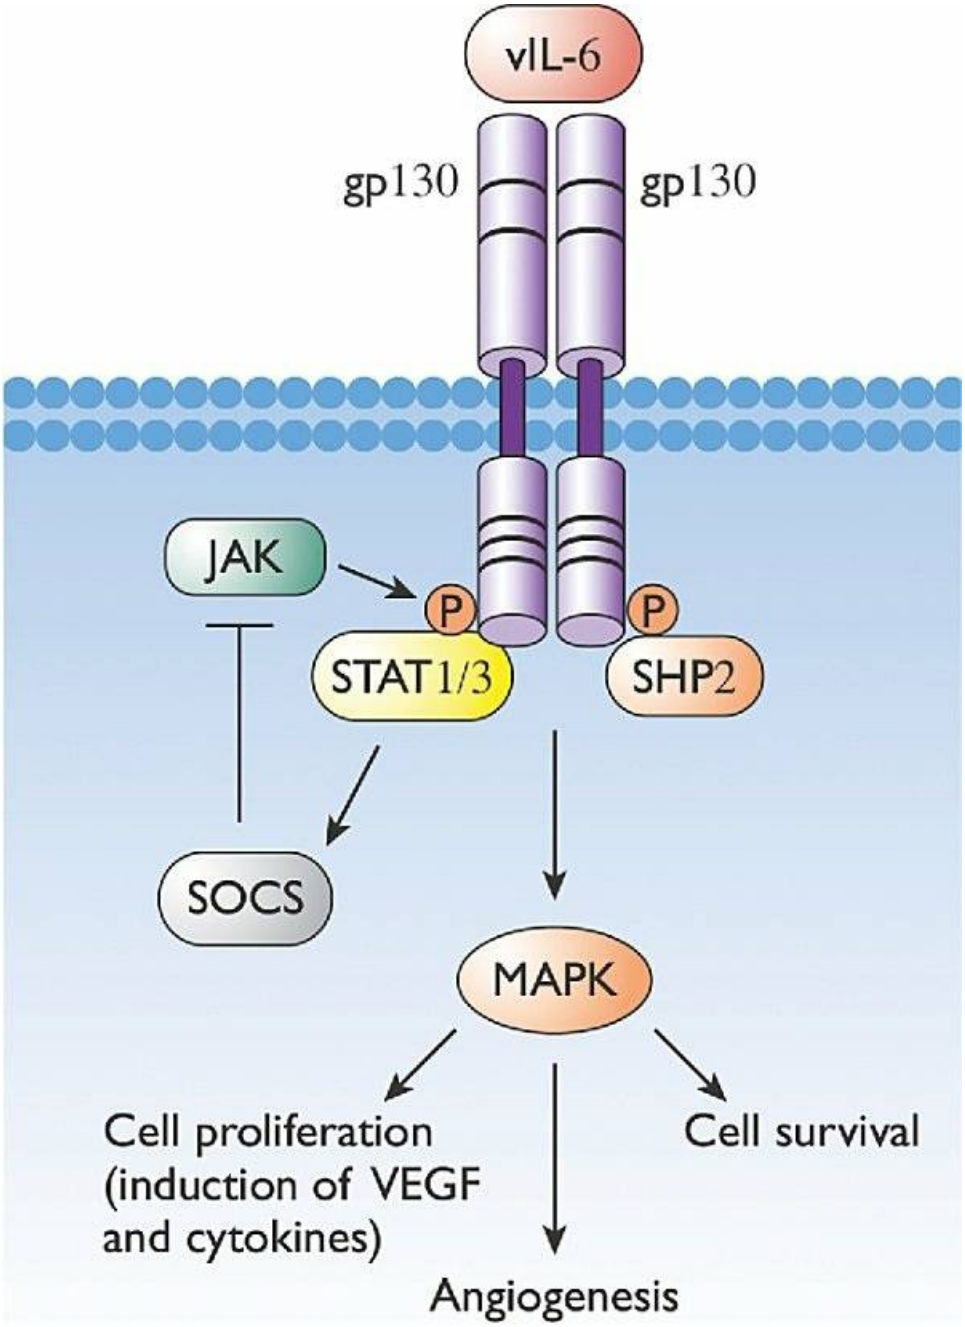

FIGURE 15.10 KSHV vIL-6 activates IL6 receptor signaling by directly binding and activating the gp130 subunits of the IL-6 receptor complex. This leads to increased cell survival, proliferation, and induction of pro-angiogenic factors.

IL-6 promotes B-cell differentiation to plasma cells and also impairs B cell apoptosis in response to apoptotic-inducing signals. vIL-6 shares the antiapoptotic activities of cellular IL-6 on B cells (including PEL cells),[291] thus implicating vIL-6 in PEL and MCD pathogenesis.

Ectopic expression of vIL-6 in immortalized mouse fibroblast lines is linked to increased

angiogenesis in the fibrosarcomas when these lines are transplanted into nude mice.[18] Increased angiogenesis due to VEGF induction by vIL-6 is an activity shared with cellular IL-6.[18] In PEL, vIL-6 expression was shown to be selectively activated by IFNα in the absence of full lytic replication, indicating that the virus can use vIL-6 to detect an early innate immune response. vIL-6 was also shown to blunt IFN signaling in these cells. In endothelial cells, vIL-6 expression caused an induction of Angiopoietin 2, a proangiogenic and lymphangiogenic factor[607] as well as integrin β3 (ITGB3).[517]

Several groups have shown that vIL-6 can be localized to the endoplasmic reticulum (ER)[117,118,426] where it still retains "intracrine" signaling activity by interacting with gp130 intracellularly. The ER-resident chaperone protein, calnexin, plays a role in ER localization of vIL-6.[117] Intracellular vIL-6 appears to be functional in the autocrine promotion of proliferation and survival of PEL. Additionally, secreted vIL-6 is completely N-glycosylated, and this glycosylation is required for optimal conformation of the protein and optimal signaling.[155,426]

Although a vIL-6 deletion mutant of KSHV did not affect viral latency or reactivation,[114] knockdown of vIL-6 expression in PEL led to reduced cell growth[118] suggesting that vIL-6 likely plays an important role in PEL proliferation. Taken altogether, vIL-6 can contribute to KSHV pathogenesis through an autocrine manner during latency by augmenting survival and proliferation (Fig. 15.10). During lytic replication, vIL-6 may function in a paracrine manner to promote survival of uninfected cells.

The Lytic Phase

The default pathway for KSHV is latency. Hence, lytic infection, in cell culture, is most often studied by using compounds to induce reactivation from latency. In PEL cell lines, this is achieved by treatment with phorbol esters (TPA) or histone deacetylase (HDAC) inhibitors (sodium butyrate, valproic acid) which will induce lytic reactivation in approximately 30% of PEL cells as judged by lytic protein expression. Transfected RTA expression plasmids or chemically induced RTA can also be used to induce more uniform reactivation. When immunofluorescence assays (IFA) for late lytic proteins (e.g., ORF K8.1) are utilized, only half of the cells are positive, even at very late times. Thus, not every entry into lytic infection is completed successfully, and abortive lytic infection occurs some or most of the time. We currently do not comprehend why many of these reactivated PEL cells fail to enter the lytic cycle when treated with HDAC inhibitors or TPA, and why only a fraction of cells in culture undergo lytic replication. One possibility is that many cells do not support the transmission of the inducing signal, or that the signal itself is ineffective or inhibitory in cells that do not support replication. Additionally, when PEL cell lines are cultured for many weeks in tissue culture, they lose efficient inducibility by TPA and HDAC inhibitors. Similarly, passage of stable PEL cell lines with drugs such as hygromycin, neomycin etc. also hinders induction by TPA and HDAC inhibitors. Again, although it is not clear why this happens, it is important to work with cells at low passage.

In addition to PEL, other latently infected cell lines including 293, Vero, human foreskin fibroblasts (HFF), and TIME cells[335] can be induced sufficiently, while other lines (e.g., HeLa, SLK) into which a KSHV genome was transfected are only transiently inducible by chemical means.[14,36] However, inducible or forced expression of the lytic switch protein, RTA, can induce reactivation in a much wider array of lines than chemical activation.[36,448]

Epigenetic Regulation of the Latent–Lytic Switch

Several groups reported the presence of genome-wide epigenetic marks on the viral episome and their involvement in the regulation of the switch between latency and lytic replication. These epigenetic modifications occur early following primary infection.[289] Histone modifications associated with the KSHV latent genome are involved in the regulation of latency and also control the temporal and sequential expression of genes during the viral lytic life cycle. Activating histone modifications include acetylated H3 (AcH3) and H3K4me3 while repressive histone modifications include H3K9me3 and H3K27me3. The latent viral genome contains both activating and repressive histone modifications. These marks are mutually exclusive across the latent genome.[233,599] For example, under latent conditions, the genomic region encoding the lytic gene, ORF50/RTA, contains activating H3K4me3 and repressive H3K27me3 marks that rapidly change to increasing AcH3 and H3K4me3 activating modifications and decreasing H3K27me3 modifications upon viral reactivation.[233,599] Additionally, latency-specific histone modification patterns were established following *de novo* infection, and there was rapid and widespread deposition of H3K27-me3 marks across latent genomes.[233] H3K27-me3 can be a bivalent modification that can repress transcription despite the simultaneous presence of activating marks on the genome, leaving these genes in a poised state for expression.[233] It was also observed that EZH2, the H3K27me3 histone methyltransferase, was present on the entire KSHV genome during latency, but was dissociated from the genome during ORF50-mediated reactivation. EZH2 inhibition or knockdown and expression of H3K27me3-specific histone demethylases all induced the lytic life cycle in PEL.[599] Chromatin immunoprecipitation (ChIP) assays revealed that KSHV genomes are highly methylated at CpG residues (except for the LANA promoter[116]), leading to the establishment of characteristic global DNA methylation patterns. These types of studies are still in their infancy, but thus far they revealed that the viral genome is epigenetically modified in the latent state so that transcription is generally repressed. At the same time, parts of the genome also contain activating histone modifications and the virus may therefore be poised to enter the lytic cycle once reactivation is triggered. Additionally, ORF50/RTA lytic transcription is actively repressed by LANA during latency, which is relieved upon lysine acetylation of the LANA protein.[386] BET inhibitors were shown to disrupt KSHV latency,[121] and it was also reported that Bmi regulates latency and inhibition of Bmi induces KSHV reactivation.[262]

Immediate Early (IE) Gene Expression

A single viral protein named RTA encoded by ORF50 controls reactivation from latency and the induction of lytic replication. The fact that RTA is the key lytic switch protein was derived from two types of experiments: (a) expression of ectopic RTA by itself is sufficient to induce reactivation from latency[390,579]; and (b) knocking out ORF50 function, either by dominant negative ORF50 mutants,[391] or by removal of ORF50 from the viral genome[668] prevents reactivation from latency. Thus, ORF50/RTA is the critical protein required for the induction of lytic replication. Several experiments show that (a) ORF50 is the first transcript to appear following chemical induction with TPA of PEL[390,580]; (b) the RTA/ORF50 promoter is inducible by TPA and knockdown of tousled-like kinase (TLK),[161] and (c) lytic induction is linked to demethylation of the ORF50 promoter.[116,385] ORF50 is a canonical immediate-early protein as it

is transcribed in the presence of cycloheximide.[579,693] ORF50 is part of a polycistronic transcript encoding for both K8 and K8.1 genes (Fig. 15.11).

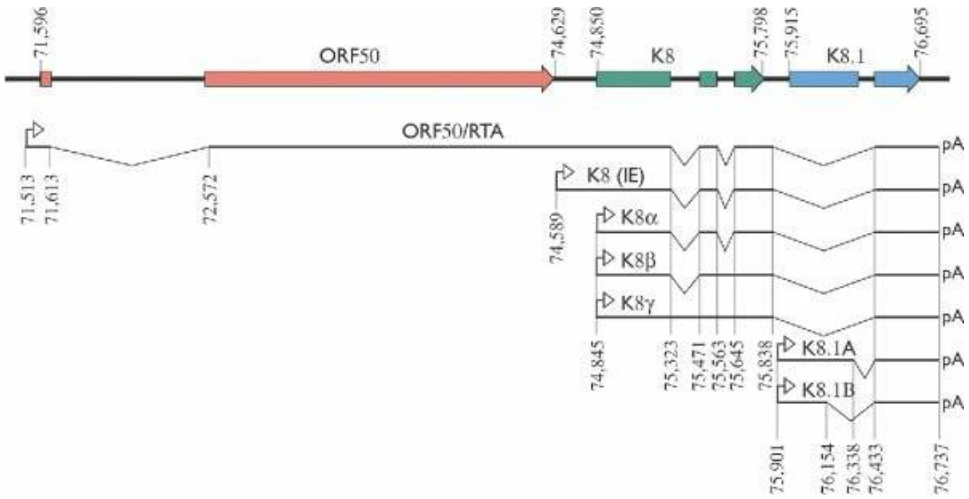

FIGURE 15.11 Map of known transcripts emanating from the main lytic region of KSHV. *Top line* shows map of the major genomic ORFs (*arrows*). ORF50, K8, and K8.1 are encoded on a polycistronic transcript. All mRNAs are polyadenylated at the indicated positions. (Modified by permission from Yuan Y, Renne R. ORF50/RTA

ORF50/RTA is a viral transcription factor. Its sequence and function is highly conserved among the rhadinoviruses.[148] KSHV RTA has an amino-terminal DBD and a carboxy-terminal activation domain. A fusion of the ORF50 activation domain with a GAL4 DBD results in robust activation of GAL4 responsive promoter elements. ORF50 is phosphorylated on its C-terminal activation domain during viral replication. Moreover, phosphatase-treated ORF50 runs at a higher mobility than its predicted molecular weight, suggesting that additional, posttranslational modifications must exist.[391] ORF50 forms tetramers and higher-order multimers in solution and the amino-terminal proline-rich, leucine heptapeptide repeat (LR) of ORF50 is necessary, but not sufficient, for oligomerization. Mutagenesis of this LR region revealed that ORF50 tetramers are sufficient for transactivation and viral reactivation and that ORF50 mutants that are unable to form tetramers, but can still form higher-order multimers, are either nonfunctional or reduced in function.[71]

ORF50 has been shown to bind to at least 19 sites in the KSHV viral genome.[119] These include regions of promoters, introns, and exons of KSHV genes including ORF8, K4.1, K5, PAN, ORF16, ORF29, ORF45, ORF50, K8, K10.1, ORF59, K12, LANA, K14/vGPCR, and K15, the two origins of lytic replication OriLyt-L and OriLyt-R, and the microRNA cluster.[119] ORF50 expression leads to a strong activation of delayed early (DE) promoters (8- to 300-fold depending upon the DE promoter). The highest activation by ORF50 is of the PAN (nut-1)

promoter, which drives the transcription of a very abundant noncoding *p*oly*a*denylated *n*uclear transcript (PAN RNA). Several mutagenesis experiments demonstrated that the ORF50-responsive site in the PAN promoter is the sequence AAATGGGTGGCTAACCTGTCCAAAA upstream of the PAN RNA cap site. ORF50 has been shown to bind to this site *in vitro*.[108,564] A similar sequence is located just upstream of the lytic kaposin transcript.[524,565] Many other RTA-response elements (RREs) have been identified using promoter–reporter cotransfection assays in the promoters of DE viral genes (e.g., TK, ORF57/MTA, K8/RAP, K2, K9, K14, DBP), and in one late promoter (gB).[232] ORF50 can also up-regulate its own promoter. Many of the RREs share little sequence homology to the PAN/kaposin site or to each other. The RREs display low-affinity interactions with purified ORF50 protein in *in vitro* ORF50 binding assays.[565,699] Although ORF50 binds to these sites with low affinity, many of these sites are very strongly induced by ORF50 in transient transfection cell–based assays, for example, the ORF57/MTA and K14 promoters.[571]

Direct DNA binding by ORF50 is not the sole mechanism by which this protein can transcriptionally activate promoters. Two-hybrid screens of ORF50 binding cellular partners revealed that ORF50 can efficiently bind to the transcription factor, RBP-Jκ[370] (also called CBF-1 or CSL). Indeed, RBP-Jκ recognition sites are found in many promoters of ORF50-responsive genes (e.g., K8/RAP, TK, PAN, ORF57/MTA, K14, LANA, and gB).[232] In many of these promoters, RBP-Jκ sites lie adjacent to low-affinity ORF50 binding sites, suggesting that cooperative interactions may exist to enhance or stabilize the binding of ORF50 at these sites. Even reporter genes that harbor synthetic RBP-Jκ elements can be strongly activated by ORF50. This suggests that in addition to binding promoters through its sequence-specific DNA binding activity, ORF50 is also targeted to promoters through protein–protein interactions with RBP-Jκ (as well as other transcription factors) bound at the promoter. RBP-Jκ deleted fibroblasts are not supportive of ORF50-transactivation of many reporter genes, and when infected with KSHV, they show defective reactivation upon transfection of ORF50.

RBP-Jκ protein normally functions as a transcriptional repressor. ORF50 binding to RBP-Jκ converts it from a repressor to an activator via ORF50's activation domain. In uninfected cells, RBP-Jκ-directed repression is controlled by the Notch pathway. Notch is a transmembrane receptor, and activation by extracellular ligands leads to the cleavage of its juxtamembrane domain, liberating its intracellular domain (ICD). The Notch ICD moves to the nucleus, where it can bind RBP-Jκ, converting it from a repressor of transcription to an activator of transcription. This phenomenon is similar to what happens with RBP-Jκ and ORF50. Thus, KSHV has co-opted the Notch-RBP-Jκ pathway to transactivate ORF50-responsive, RBP-Jκ binding site containing promoters.

Interestingly, ORF50 binds to RBP-Jκ at two sites, and one of these is identical to the site bound by Notch ICD and EBNA2. The human Notch ICD that constitutively activates RBP-Jκ was expressed in PEL and gene expression profiling showed that this domain robustly induced expression of a number of lytic viral genes but could not evoke the full repertoire of lytic viral gene expression normally induced by ORF50 expression.[109] These results indicate that the control of viral gene expression by cellular Notch signal transduction only partially overlaps with ORF50[109] suggesting that RTA does more than merely mimic notch and that some RBP-Jκ elements in the viral genome have completely diverged from Notch signaling. This result is not surprising given that ORF50 has additional mechanisms of promoter targeting besides RBP-Jκ sites (see below). However, these results suggest that certain lytic genes can be activated in an

ORF50-independent manner and under conditions when ORF50 is not expressed.

ORF50 can also interact with the transcription factor C/EBPα in the K8/RAP, ORF57/MTA and PAN promoters and with Oct-1 in the ORF50 promoter.[628] These interactions are important for ORF50 recruitment to these sites. Additionally, the binding of ORF50 to both Oct-1 and the K8 promoter leads to transactivation and viral reactivation and the ORF50/Oct-1 interaction is necessary for optimal KSHV reactivation.[91] ORF50 can also interact with STAT-3, inducing it to move to the nucleus to activate STAT-responsive genes.[237] ORF50 also binds proteins involved in histone acetylation (CBP and histone deacetylase 1)[236] and the chromatin remodeling complex, SWI/SNF and the TRAP/Mediator complex, that enables interaction of RNA pol II with many transcription factors.[238] Interactions with the histone modeling proteins occur via the C-terminal activation domain of ORF50. Mutational studies show that blocking these interactions prevents both transcriptional activation and lytic induction, confirming their importance for ORF50 function.

The spliced isoform of plasma cell transcription factor X box binding protein 1 (XBP-1s) can regulate the latency to lytic switch for KSHV.[654,682] XBP-1s is normally absent in PEL, but the induction of endoplasmic reticulum stress or hypoxia leads to production of XBP-1s and induction of the lytic cycle.[147,682] XBP-1s binds to ORF50 and activates the ORF50 promoter in a synergistic manner.[654] This interaction links lytic reactivation to plasma cell differentiation, which may be a mechanism whereby virus is produced in sites where immunoglobulin production is occurring, which include lymphoid tissues in the oral mucosa allowing virus to be shed into saliva.[654]

While most research has focused on ORF50 transactivation, several reports show that ORF50 can also bind transcriptional repressors. As mentioned above, ORF50 binds HDAC1 resulting in repression of ORF50-mediated transactivation.[236] ORF50 also binds to and is inhibited by poly(ADP-ribose) polymerase 1 (PARP-1) and Ste20-like kinase hKFC.[239] It has also been shown that ORF50 can bind a cellular zinc-finger protein named K-RBP (for KSHV RTA binding protein). K-RBP is a transcriptional repressor that was shown to repress ORF50-mediated transactivation in an HDAC-independent manner. K-RBP could also suppress ORF50-mediated lytic reactivation. In a subsequent study, it was found that ORF50 could induce ubiquitin-mediated degradation of K-RBP and ORF50 mutants that were defective in mediating K-RBP degradation were not as transcriptionally active as wild-type ORF50.[670] Interestingly, the HSV-1 ICP0 transactivator and the HCMV pp71 transactivator also induce degradation of transcriptional repressors suggesting that this may be a common mechanism by which many herpesviral lytic transactivators function.[670] Additionally, transducin-like enhancer of split 2 (TLE2) is another repressor that interacts with ORF50 and inhibits its transactivation activity and ability to induce the lytic life cycle.[252] TLE2 appears to interact with the Pro-rich domain of ORF50, which is the same site that interacts with RBP-Jκ.[252]

Finally, ORF50 has also been shown to target IRF7 through ubiquitin-mediated degradation. The degradation is mediated through ORF50's recruitment of a E3 ubiquitin ligase, RAUL, which normally imparts K48-linked ubiquitins on IRF3 and IRF7.[680] It has also been shown to down-regulate MHC II[583] and promote the degradation of TRIF thereby blocking TLR3 signaling.[429] Through down-regulation of myeloid differentiation primary response 88 (MyD88), RTA is also able to block TLR4 signaling.[377] A summary of ORF50's interactions and functions

is shown in Figure 15.12.

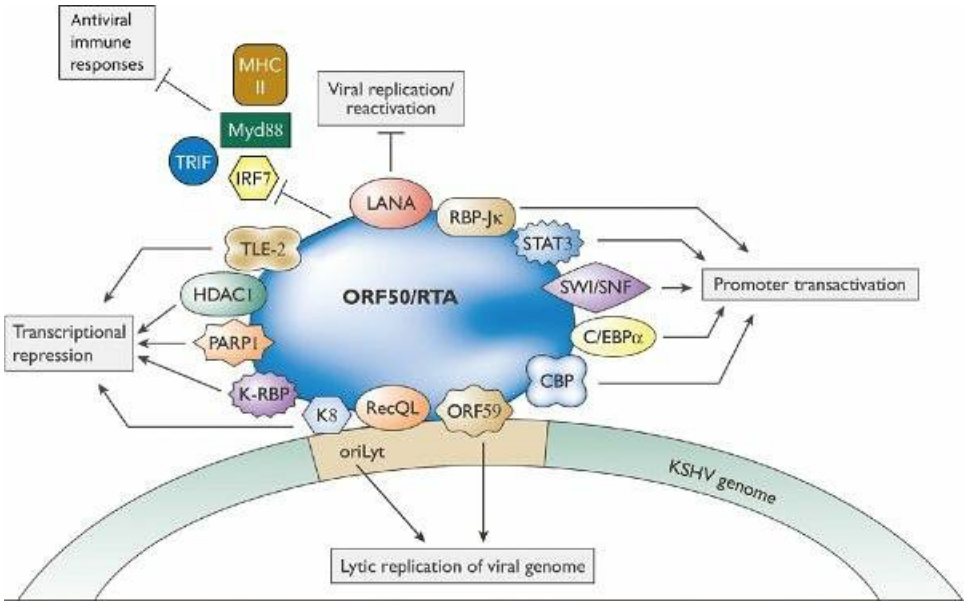

FIGURE 15.12 ORF50/RTA domains and interaction partners. Functional consequences of the interaction of ORF50 with other cellular and viral proteins.

Other Immediate-Early Genes

Detailing the kinetics of viral gene expression in the presence of cycloheximide led to the identification of several other IE genes.[693] Additional IE mRNAs encode for the products of ORF45 and K4.2, as well as a 4.5-kb RNA with partial complementarity to ORF 29. (Note: some reports refer to ORF45 and K8 as DE genes). Moreover, several transcripts antisense to ORF50 have been identified; however, their biological function is not known.[390,693] The K8 gene has two promoters, one of which is activated in the IE phase and a second promoter that is activated as a DE promoter through an ORF50-responsive RBP-Jκ site in the promoter.[631] Interestingly, the gene for KSHV ORF57/MTA, the homolog of HSV ICP27, is transcribed in the DE phase. The IE ORF45 protein functions to evade host innate immunity and is discussed separately (see below).

K8/RAP

ORFK8 is a DE protein that is member of the bZIP family of proteins, including EBV Zta and cellular transcription factors, c-jun and c-fos. K8 is also called RAP (*r*eplication-*a*ssociated *p*rotein) or K-bZIP. ORF K8 and EBV Zta share some sequence similarity[223] although unlike EBV Zta, K8 does not induce viral reactivation of KSHV or enhance ORF50-mediated reactivation from latency.

Unlike ORF50, K8 does not appear to affect promoter activity to a great extent. However, together with other proteins, K8 contributes to KSHV lytic replication and gene expression. For example, it binds to cellular bZIP proteins such as C/EBP-α, a transactivator that is involved in

the induction of differentiation and cell cycle arrest.[658] K8 binding to C/EBP-α prolongs the half-life of C/EBP-α, thereby augmenting its function. The K8 promoter itself contains C/EBP-α binding sites and there is a positive feedback loop for both K8 and C/EBP-α during viral replication. Further, since ORF50 also binds C/EBP-α, ORF50-driven transactivation of K8 is increased by K8. Stabilization of C/EBP-α also helps ORF50 activate other viral lytic promoters with C/EBP-α binding sites such as the ORF50 and ORF57 promoters.[628] Although K8 augments C/EBP-α function, K8's effect on most other transcription factors appears to be of a repressive nature. For example, K8 hinders CBP[274] transactivation, and direct binding of K8 to ORF50 hinders its transactivation function on some promoters like those of ORF57 and ORF50, although PAN promoter activity is not affected.[280,371] RTA/ORF50 and K8 together have been reported to bind to cellular and viral genomes to modulate gene expression.[302] It is also involved in the regulation of viral DNA replication.[383]

K8 induces a prominent G1 arrest. Many herpesviruses exhibit cell cycle arrest during lytic replication, including KSHV. This is thought to occur in order to prevent cellular DNA synthesis from ensuing thereby reducing the competition for energy and nucleotide pools. K8 induces cell cycle arrest by enhancing C/EBP-α accumulation through inhibition of E2F expression and increased expression of the CDK inhibitor, p21.[658] Moreover, K8 can directly bind CDK2 complexed to cyclins A and E, and this interaction leads to impaired kinase activity.

Finally, K8 also plays important roles in viral lytic replication as it is thought to bind the lytic replication origins of KSHV. These roles will be discussed below in the lytic replication section.

Delayed-Early (DE) Gene Expression

KSHV proteins belonging to the DE class are genes whose transcription is sensitive to the effects of cycloheximide since their expression depends on the transactivation of their promoters by IE proteins. However, their expression is independent of viral DNA synthesis inhibitors. Many DE proteins, for example, DNA polymerase, thymidine kinase, ribonucleotide reductase, etc. have enzymatic functions or serve as accessory proteins (ssDNA binding protein, polymerase processivity factor, etc.). The DE proteins prepare the infected cell for viral DNA replication. Other DE proteins are involved in immune evasion (K3/MIR1, K5/MIR2, and K14), host shutoff (ORF37/SOX), nuclear–cytoplasmic transport of viral RNAs (ORF57), or modulation of signal transduction (vGPCR, K1, K15). At least two noncoding RNAs have been identified as DE transcripts—the polyadenylated nuclear (PAN) RNAs. Please note that the term delayed early (DE) is borrowed from the alpha herpesvirus literature and may not be as strictly applicable to the various environments that trigger KSHV reactivation. In most cases, the time delay is minimal.

ORF57/MTA

ORF57 also known as MTA (*m*RNA *t*ranscript *a*ccumulation) is a posttranscriptional regulator and a homolog of HSV ICP27 and EBV ORF57/MTA proteins. ORF57 moves between the nucleus and cytoplasm and enables the cytosolic accumulation of unspliced mRNAs.[312] A crystal structure of the C-terminus of ORF57 has been reported[684] and its stability has been shown to be regulated by phosphorylation and homodimerization.[401]

ORF57 interacts with Aly/REF, an export factor, to promote nuclear mRNA export.[402] ORF57 binds to intronless viral mRNAs and functions to recruit the hTREX complex (through interactions with the export adapter protein, Aly), but not the EJC, and assemble a viral ribonucleoprotein particle termed vRNP.[61,538] Aly subsequently binds the DEAD-box protein UAP56, which recruits the remaining hTREX components to the complex.[61] It has also been shown that ORF57 associates with PYM, a protein that recruits the 48S preinitiation complex to newly exported mRNAs through binding EJC. This ORF57-PYM interaction allows this complex to associate with intronless KSHV transcripts to initiate translation of viral mRNAs.[62] ORF57 also inhibits the ARS2-mediated RNA decay pathway.[522]

Unlike HSV ICP27, ORF57 does not hinder the expression of intron-containing transcripts[312] since unlike HSV, many lytic cycle KSHV genes are efficiently spliced (e.g., K8, K14, K15, ORF50, ORF57, the vIRFs, ORF29 etc.). During lytic replication, ORF57 partially colocalizes with the cellular splicing machinery in nuclear speckles and assembles into spliceosomal complexes in association with viral pre-mRNAs and essential splicing components. ORF57 binds Sm protein and interacts with snRNAs. Thus, ORF57 appears to function as a novel factor in the spliceosome-mediated splicing of viral RNA transcripts.[400]

ORF57 can bind ORF50 and augment ORF50's transactivation function on several viral promoters.[312,480] ORF57 can also promote the accumulation of nuclear PAN RNA[134,312] in an export-independent manner. ORF57 binds PAN RNA directly at an ORF57-responsive element (ORE) thereby protecting it from the cellular RNA decay pathway.[525] Another mechanism by which ORF57 has been shown to stabilize mRNAs is through inhibition of microRNA modulation of viral transcripts.[297] The vIL-6 transcript contains an MRE (ORF57/MTA-responsive element) analogous to the ORE reported previously.[525] Binding of ORF57 to the MREs in vIL-6 stabilized its message and enhanced its translation.[297] One of the MRE sites was also a binding site for miR-1293 and hence, ORF57 competes with miR-1293 for binding to vIL-6 thereby preventing its RISC-mediated degradation. ORF57 also interacts with a miR-608 binding site in the cellular human IL-6 transcript and prevents miR-608 repression of this message as well.[297] Finally, ORF57 interacts directly with the cellular protein RNA Binding Motif Protein 15 (RBM15), thereby stabilizing the ORF59 RNA transcript in the cytoplasm.[401] A genome-wide analysis of viral RNA targets of ORF57 performed by a UV cross-linking and immunoprecipitation (CLIP) assay revealed eleven viral transcripts that were targeted by ORF57 including vIL-6.[297] ORF57 has also been shown to block PKR activation and inhibit stress granule formation.[543]

Additionally, two groups have shown that the disruption of ORF57 in a KSHV BACmid resulted in the lack of expression of several lytic genes including ORF57, ORF59, K8alpha, K8.1, and PAN RNA during the viral lytic cycle and yielded no virion production.[399] It has been reported that ORF57 is cleaved by caspase-7 during reactivation. The cleaved ORF57 was hampered in aiding the expression of viral lytic genes suggesting that caspase-7 displays antiviral activity against KSHV lytic proteins.[401] ORF57 is also involved in lytic replication through the inhibition of P-bodies.[544]

Lytic Viral Replication

The delayed early phase is followed by lytic cycle DNA replication. Similar to the case with

other herpesviruses, multisubunit complexes containing the core replication machinery are directed to a cis-acting replication origin called oriLyt, by an ori-specific DNA binding protein. Replication complexes are nuclear substructures where viral replication occurs and are in proximity to host ND10 domains. Replication utilizes a rolling circle mechanism, whereby linear genomes are processed and packaged into nascent capsids.

KSHV encodes 6 catalytic and accessory proteins similar to other herpesviruses, including the viral DNA polymerase (POL, encoded by ORF 9), helicase (HEL, ORF 44), polymerase processivity factor (PPF, ORF 59), primase (PRI, ORF 56), primase associated factor (PAF, ORF 40/41), and single-strand binding protein (SSB, ORF 6). When coexpressed in cells, these proteins form stable multi-subunit nuclear structures.[657] The KSHV genome contains two oriLyt regions: the left-hand origin (oriLyt L) is situated between ORFs K4.2 and K5, while the right-hand element (oriLyt R) lies between ORFs K12 and 71.[21,375] These elements promote semiconservative replication, which is suppressed by viral DNA polymerase inhibitors (e.g., phosphonoacetic acid). These two ~1.7 kb regions share striking sequence homology with one another; the right-hand element seems to be an imperfect inverted repeat of the left-hand element. Each lytic origin is composed of two subdomains: (a) a 1.1-kb region with multiple AT-rich palindrome sequences, TATA boxes, and transcription factor binding sites and (b) an adjacent region (~600 bp) composed of multiple GC-rich tandem repeats. Genetic studies have identified four critical elements required for oriLyt-L function. These include (a) a high-affinity ORF50 binding site and nearby TATA box, (b) four pairs of C/EBPα sites, (c) an 18 bp AT-rich palindrome, and (d) a 32 bp sequence of unknown function.[21,632] The RRE and TATA box are components of a promoter that drives expression of a 1.4-kb transcript. Similar features are also present in oriLyt R where the RRE and TATA element drive expression of kaposin mRNA.[524] These similarities are schematized in Figure 15.13, in which oriLytL and oriLyt R have been superimposed to highlight their commonalities. Among these motifs, the K8, C/EBP, and RREs function as key cis-acting elements.[634]

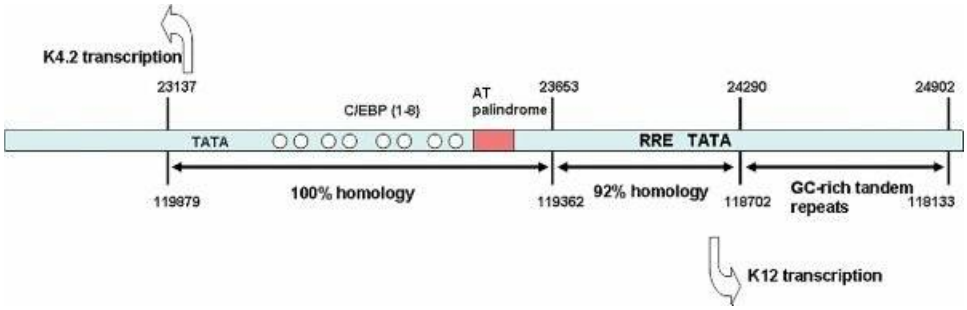

FIGURE 15.13 The structure of KSHV lytic replication origins. OriLyt-R and OriLyt-L are superimposed to reveal their commonalities. The *central bar* depicts important common sequence features. *Arrows* above the bar depict the transcripts from this region in OriLyt-L; *arrows* below the *bar* denote RNAs transcribed in oriLyt-R. Numbers refer to nucleotide sequence of each region. Degree of conservation of each domain between the two origins is indicated by percent homology. (Modified from Wang Y, Li H, Chan MY, et al. Kaposi's sarcoma-associated herpesvirus ori-Lyt-dependent DNA replication: cis-acting requirements for replication and ori-Lyt-associated RNA transcription. *J Virol* 2004;78(16):8615–8629. Copyright © 2004

American Society for Microbiology. Amended with permission from American Society for Microbiology.)

The oriLyt regions can bind K8 indirectly through the C/EBPα sites.[375] The 18 bp AT-rich palindrome is thought to be the place where initial strand unwinding occurs during the start of DNA replication. ORF50 activates the RRE-containing ori-Lyt promoter by binding to it and initiating transcription across the GC-rich tandem repeats.[634] The prereplication complex, of which ORF50 is a component, is recruited to ori-Lyt through the ORF50-RRE and the K8-C/EBP interactions with the ori-Lyt.[634]

Consistent with its function as a repressor of viral genes, a K8 deleted KSHV BAC displayed an enhanced growth phenotype in terms of virion production and the expression of lytic genes in the context of ORF50/RTA induction.[301] However, reactivation by chemical induction (TPA and sodium butyrate) yielded no virion production and an aberrant lytic profile compared to wild-type KSHV BAC.[301] Curiously, immunofluorescence staining revealed that in the absence of K8 there was a disruption of LANA subcellular localization suggesting that K8 can influence LANA localization.[301] However, another group showed that a different K8 deleted KSHV BAC displayed no difference in overall viral gene expression during lytic reactivation with TPA in epithelial cells, fibroblasts, and endothelial cells.[637] However, the K8 mutant virus–infected cells displayed lower copy numbers of latent KSHV genomes compared to wild-type KSHV–infected cells. These data suggest two possibilities—(a) K8 may be involved in abortive viral replication (leading to viral genome replication but not virion production) or (b) K8 may be involved in the maintenance of latent viral genomes[637] through modulation of LANA function as discussed above.[301,637] The former is likely to be the case since it was shown that LANA represses origin-dependent lytic DNA replication in a dose-dependent manner and that this suppression was overcome by increasing amounts of K8.[519] Additionally, LANA alone was shown to interact with oriLyt by chromatin immunoprecipitation (ChIP) implying that the inhibition of lytic replication by LANA was mediated by direct binding.[519] This suggests a model where LANA interacts with K8 to negatively modulate the switch from latency to lytic replication. Conversely, K8 positively modulates lytic replication by relieving the LANA-mediated suppression of lytic replication.

Late Gene Expression

As with other herpesviruses, late gene transcription starts subsequent to the onset of DNA replication. The transcription of many (but not all) late genes is hindered by viral DNA synthesis inhibitors, for example, phosphonoacetic acid, ganciclovir, foscarnet, and cidofovir. Most late genes encode for structural proteins, for example, capsid and envelope proteins.[181,285,534] Late templates must either be actively replicating or have undergone a chromatin structure change that is dependent on viral replication to be activated. The KSHV ORF24 encodes for a protein that binds RNA polymerase II and recruits this polymerase to the late promoters of viral genes thereby mimicking the host TATA-box-binding protein (TBP). It was reported that ORF24 was necessary for late gene expression.[152]

FUNCTIONS OF LYTIC VIRAL PROTEINS

Modulation of Antigen Presentation by K3/MIR1 and K5/MIR2

The observation that diseases associated with KSHV infection are substantially more severe in hosts with T-cell impairment (e.g., AIDS) indicates that T cells are critical for the control of viral infection. Immune surveillance and clearance by cytotoxic T (CTL) cells is likely an important selective pressure in driving KSHV evolution with the host; therefore, it is no surprise that KSHV possesses an arsenal of proteins that evade the host's immune system.

The infected cell usually presents antigenic peptides from the virus in complex with class I major histocompatibility complex (MHC I) to CTLs. Two proteins (ORFs K3 and K5) prevent MHC-I display.[137] K3 and K5 encode for proteins called MIR1 and MIR2, respectively, for *m*odulators of *i*mmune *r*ecognition. K5/MIR2 down-regulates only HLA-A and HLA-B, while K3/MIR 1 down-regulates all four HLA allotypes (HLA-A, -B, -C, and -E)[279,575] (Fig. 15.14).

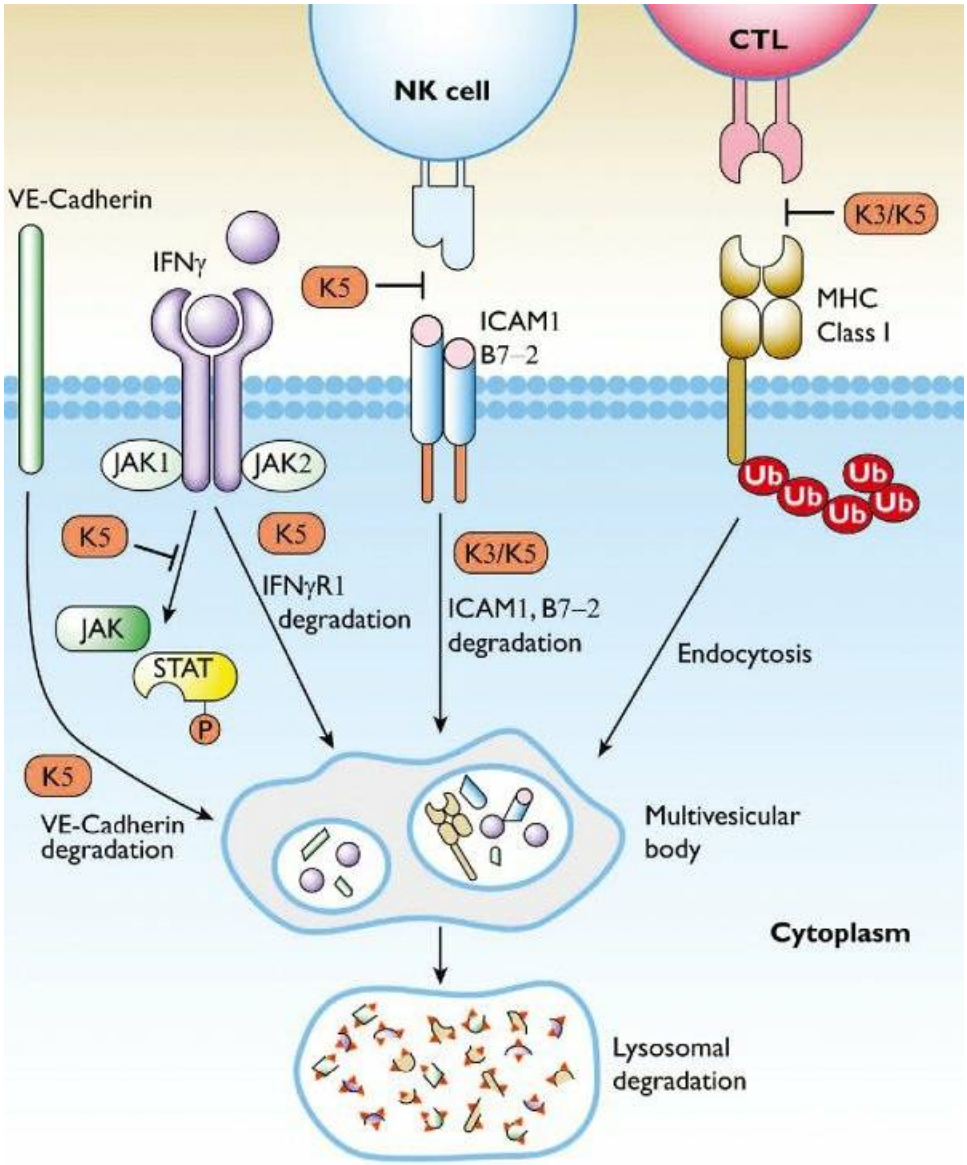

FIGURE 15.14 Ubiquitination and degradation of cell receptors by K3/MIR1 and K5/MIR2. The MIRs are able to induce the ubiquitination and degradation of a number of these receptors including MHC class I, ICAM-1, B7-2, and IFNγR1.

K3 and K5 are transmembrane proteins that resemble each other suggesting that they may have arisen from duplication of an ancestral gene. Each protein contains an amino-terminal variant RING finger with cysteine and histidine residues that vaguely resemble those found in PHD domain proteins. The zinc finger structure is on the cytosolic face of the membrane.[529] The KSHV MIR proteins show functional similarity to the cellular MARCH protein family, which was discovered after K3 and K5. MARCH proteins are transmembrane ubiquitin ligases that ubiquitinate and target cellular glycoproteins for lysosomal destruction[34] (Fig. 15.14). K3 and K5 appear to act during different stages of the viral life cycle. While K5 acts during viral entry into the lytic phase, K3-mediated down-regulation of MHC-I occurred during later stages of lytic

replication.[70]

The MIR proteins reside in the ER membrane and augment the endocytosis of MHC-I chains that reach the cell surface[137,279] through MIR-mediated ubiquitination.[529] Ubiquitination directs these chains to the endosomes and subsequently the multivesicular body (MVB), a sorting organelle from which the MHC-I chains can be targeted for lysosomal degradation.[384,427,529] Interestingly, K3 induces lysine-63-linked polyubiquitination (instead of K48-linked polyubiquitination) of MHC class I chains, which leads to endocytosis and endolysosomal degradation.[172] This lysine-63-linked polyubiquitination required the activities of UbcH5b/c and Ubc13-conjugating enzymes.[172]

The MIR RING finger recruits E2 ubiquitin conjugases. K3 and K5 target recognition maps to the transmembrane regions of both effector and target molecules[529] Subsequently, transfer of the ubiquitin chain to lysines in the cytoplasmic tail can occur. Strikingly, K3/MIR 1 can also ubiquitinate cytosolic cysteine residues.[76]

The MIRs can also down-regulate CD1d, an MHC-related protein that presents lipids and glycolipids to classical and nonclassical natural killer (NK) T cells, which respond with the release of interferon.[376] This observation suggests that CD1d-restricted T cells likely play a role in host immunity against KSHV, but the lipid presentation and antiviral immunity is not well understood. K5/MIR2 (but not K3) also down-regulates ICAM-1 and the costimulatory molecule B7-2 (CD86).[138,278] These two proteins, which are expressed on antigen presenting cells, can bind and activate CD4-positive T cells. K5-mediated down-regulation of these proteins reduces helper T-cell costimulation[138] and impairs susceptibility to NK-cell cytotoxicity.[278] K3 and K5 also down-regulate the interferon gamma receptor 1 (IFN-gammaR1),[364] thereby preventing it from binding IFNγ released from activated T and NK cells. KSHV K5 reduces cell surface expression of the NKG2D ligands, MHC class I–related chain A (MICA), MICB, and activation-induced C-type lectin (AICL), which is a ligand for NKp80.

Although K3 and K5 appear to be functionally homologous in most cases, there are instances when K5 appears to encode additional functions not performed by K3. For instance, unlike K3, which induces ubiquitin-dependent endocytosis and degradation, K5 can induce the down-regulation of its targets through multiple pathways, including endocytosis-dependent and -independent as well as ubiquitination-dependent and -independent pathways.[428] K5 induces the degradation of nonclassical MHC class I-related (MHC-I) HFE via a polyubiquitination-mediated ESCRT1/TSG101-dependent pathway.[515] A proteomic screen performed with K5 revealed that it also targets bone marrow stromal antigen 2 (BST-2, CD316) also known as tetherin, activated leukocyte cell adhesion molecule (ALCAM, CD166), and Syntaxin-4.[35]

Independent of its role in immune modulation, K5 has also been implicated in vascular permeability during lytic infection by targeting the junctional endothelial protein, VE-cadherin, for ubiquitin-mediated degradation, thereby preventing endothelial cell adhesion.[457] Alpha-, beta- and gamma-catenins were also targeted for proteosomal destruction.[406]

Interferon Evasion by Viral Interferon Regulatory Factors

Several KSHV lytic proteins are involved in preventing the activation and function of type I interferons that are produced in response to infection. As described above, interferons are

induced by PAMPs, which are recognized by innate immune sensors such as TLRs and RIG-I like receptors (RLRs), for example, RIG-I and MDA-5. Activation of TLRs and RLRs leads to the activation of cellular IRFs, for example, IRF3 and IRF7 depending on which TLR is stimulated, type I interferon (IFNα and IFNβ), and inflammatory cytokines. IFN-α/β released from the cell can bind to IFNα and IFNβ receptors present on surrounding cells. This signal is transduced to the nucleus thereby stimulating the transcription of multiple IFN-sensitive genes (ISGs), which include known antiviral effectors (e.g., OAS, Mx and PKR) as well as the IRFs themselves.

IFN-α/β binding to IFN receptor leads to the phosphorylation and activation of STAT1 and STAT2. The activated STATs then bind to IRF9 (p48), and relocate to the nucleus to induce transcription from ISG promoters. Both the IFN-α/β and the ISG promoters contain IRF binding sites for many cellular IRFs.

The KSHV genome encodes four different homologs of cellular IRFs from a single locus, which is suggestive of the fact that they arose from an ancestral gene through gene duplication, followed by divergence. vIRF1, -2, -3, and -4 were named based on their order of discovery and not by their homology to a particular cellular IRF. vIRF3 is a latent gene as discussed above.

The remaining vIRFs (vIRF1, -2, and -4) are mostly expressed during the lytic cycle. Although vIRF1 is a lytic gene, it was found to be transcribed in latently infected KS cells as well.[115,162] vIRF1, -2, and -3 do not share the DBD of the cellular IRFs and hence do not bind to IRF binding sites in ISG and type I IFN promoters, although vIRF2 was shown to bind DNA.[271] In contrast to cellular IRFs, these three vIRFs hinder the function of cellular IRFs thereby suppressing IFN production (Fig. 15.15). The three vIRFs also differ in their inhibition of interferon activation mediated by TLR3.[283]

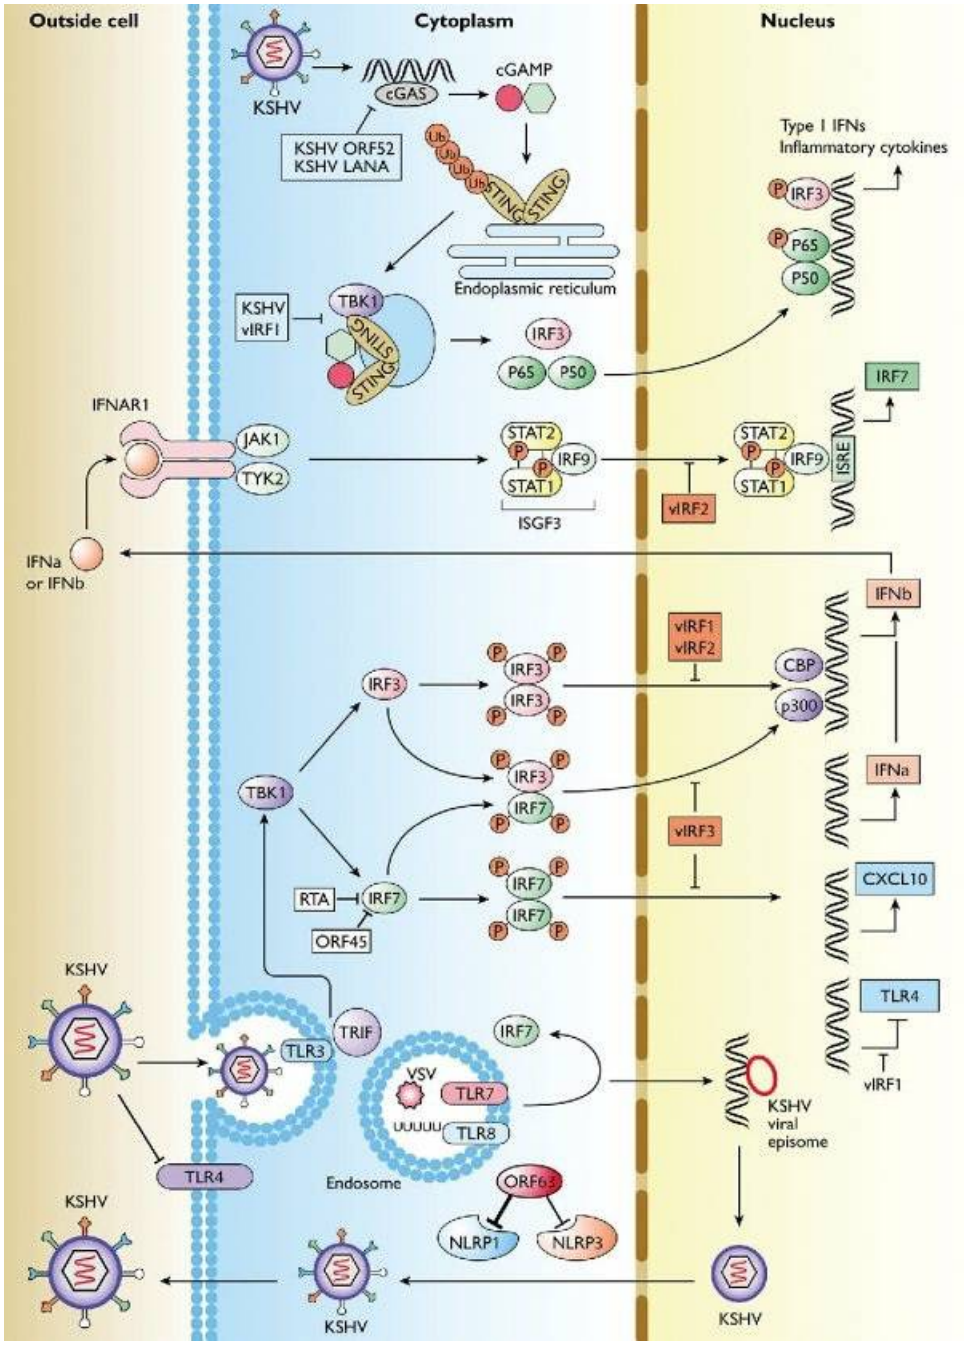

FIGURE 15.15 Innate immune evasion by KSHV vIRFs, ORF50/RTA, ORF45, and ORF63. KSHV entry triggers activation of TLR3 in monocytes and TLR4 in endothelial cells. Furthermore, binding of latently infected cells by TLR7/8 agonists leads to reactivation of KSHV from latency. The vIRFs block interferon activation by host cells. ORF50/RTA targets IRF7 for degradation while ORF45 inhibits IRF7 function. ORF63 inhibits activation of NLRP1 and NLRP3 innate immune sensors.

vIRF1 (encoded by ORF K9) is the most well studied vIRF and can inhibit IFN production in response to Sendai virus infection.[202] vIRF1 dimerizes with cellular IRF1 and IRF3, which

prevents the cellular IRFs from transactivating the IFN promoters although DNA binding does not appear to be affected. Inhibition of IRF function is thought to occur through vIRF1's ability to bind and sequester coactivator CBP/p300 from cellular IRFs and inhibition of its HAT activity.[362,374] vIRF1 also binds HERC5, the major ubiquitin ligase for ISG15 resulting in decreased ISG15 conjugation of proteins.[284] vIRF1 is also able to block STING-mediated TBK1 activation[395] and block mitochondrial antiviral signaling protein (MAVS) mediated apoptosis and type I interferon gene expression.[273] vIRF1's ability to prevent apoptosis and evade immune responses is likely to greatly contribute to KSHV pathogenesis.

Studies have also demonstrated the ability of vIRF2 to impair IFN-dependent transcription. In the context of type I IFN, vIRF2 inhibited ISG56 activation,[192] cellular IRF1- and IRF3-mediated transcriptional activation, IFNβ promoter activity in response to double-stranded RNA and IRF3 transfection,[19] and ISRE transactivation mediated by the IFNγ family members IL28A or IL29.[192] vIRF2 was unable to inhibit IRF7-mediated transactivation of ISG promoters, as well as IFNγ promoter (pGAS) activity in response to IFNγ treatment.[192] However, it was recently reported that vIRF2-dependent regulation of the KSHV life cycle might involve up-regulated expression of interferon-induced genes, for example, IFIT proteins 1, 2, and 3, which antagonize the expression of early KSHV lytic proteins.[317]

Similar to vIRF1 and vIRF2, vIRF3 has been shown to inhibit transactivation of the IFN-α4 and IFN-α6 promoter upon Sendai virus infection as well as in the presence of exogenous IRF3 and IRF7.[389] KSHV vIRF1 and vIRF3 mediate some of their functions through interacting with the USP7 deubiquitinase.[664] vIRF3-expressing B cells show resistance to recognition by KSHV-specific CD4 T cells.[707]

KSHV vIRF4 has been shown to bind to IRF7 and inhibit IFN alpha production[275] and to target cellular IRF4 as well as interact with Myc and RTA to augment KSHV lytic replication.[353,662] vIRF4's ability to target IRF4 also results in enhancement of BCL6 expression.[683]

In addition to their ability to inhibit interferon, the vIRFs have also been shown to prevent apoptosis. vIRF1 was shown to relocalize the pro-apoptotic protein, Bim, a negative regulator of KSHV replication, to the nucleus.[125] This nuclear sequestration of Bim prevents apoptosis during viral replication, thereby leading to increased viral production during the lytic phase.[125] Furthermore, vIRF1 expression in mouse fibroblasts can induce cellular transformation, which is probably due to the fact that vIRF1 can also bind p53 and inhibit apoptosis.[202,452] vIRF1 co-precipitates with p53 and inhibits p53-driven transcription and targets, for example, p21 and Bax.[452] Expression of vIRF1 can also lead to a decrease in total p53 levels, due to vIRF1 directed ubiquitination and degradation of p53.[548] This activity required the p53 E3 ligase, MDM2. Inhibition of p53-mediated apoptosis may be a mechanism through which KSHV is able to establish latency. In addition to vIRF1, vIRF3 and vIRF4 also interfere with p53 signaling. Like vIRF1, vIRF3 was shown to interact with p53 *in vitro* and reduce p53 reporter activity.[516] vIRF3 also decreased apoptosis and activation of caspase 8 mediated by p53[516] and inhibited apoptosis in response to Fas and TRAIL.[652] Finally, vIRF4 interferes with the p53 pathway by interacting with MDM2 to increase MDM2 protein levels[351] through the inhibition of MDM2 autoubiquitination and prevention of MDM2 proteosomal degradation.[351] Interestingly, both vIRF1 and vIRF4 induce MDM2-mediated p53 degradation but through different mechanisms.

For a more detailed review of the function of the four vIRFs please see review article.[282] Finally, vIRF2 was shown to activate the phosphatidylinositol 3-kinase(PI3K)/Akt pathway, inhibiting FOXO3A-mediated caspase-3 cleavage and apoptosis.[311] Furthermore, KSHV vIRF3 was detected in over 40% of various KS lesions and was demonstrated to function as a pro-lymphangiogenic factor by blocking the phosphorylation-dependent cytosolic translocation of HDAC5.[354]

Two other KSHV proteins, which are not homologs of cellular IRFs, can also block IRF action. ORF50 was shown to induce IRF7 degradation as described earlier. Additionally, the IE protein ORF45, can interact with IRF7 and prevent its phosphorylation and nuclear translocation[694] (Fig. 15.15). ORF45 interacts with an inhibitory domain in IRF7,[536] which keeps IRF7 in a closed inhibitory state. Since ORF45 is a tegument protein, in theory it should be able to hinder type I interferon activation pretty soon after viral infection. A KSHV recombinant virus deleted for ORF45 exhibited lower viral replicative capacity compared to wild-type virus.[696] ORF45 has also been shown to interact with p90 ribosomal S6 kinases (RSKs), RSK1 and RSK2, and strongly stimulates their kinase activities leading to ERK activation.[328]

Overall, KSHV encodes a battery of viral proteins dedicated to the ablation of IRF activation, and their function is testimony to the significant role innate immunity plays in the viral life cycle (Fig. 15.15).

Modulation of Inflammatory Pathways

In addition to the viral IRF proteins, KSHV also encodes for virally encoded CC chemokines: vCCL1 (formerly known as v-MIP-I, the product of ORF K6), vCCL-2 (vMIP-II, from ORF K4), and vCCL-3 (v-MIP-III, from ORF K4.1). Although chemokines are generally positive mediators of immune and inflammatory responses, the receptor preferences for the KSHV-encoded chemokines are consistent with their function as inhibitors of inflammation in response to viral infection. The CD4 T-cell subset of Th1 cells shape antiviral cytotoxic immune responses by promoting IL2, TNFα, and IFNγ induction, which can activate macrophages and promote the development of CD8+ CTL responses. Th2 cells on the other hand promote induction of IL4, IL5, IL6, IL10, and IL13, in order to elicit B-cell differentiation and humoral immunity (as well as allergic-type responses). Th2 cells also polarize immunity away from cytotoxic responses regulated by Th1 cells. The chief chemokine receptor on Th1 cells is CCR5, while Th2 cells express CCR3, CCR4, and CCR8 receptors. KSHV vCCL-1 signals through CCR8; vCCL-2 signals through CCR8 and CCR3; and vCCL-3 signals through CCR4.[467,576] In summary, the KSHV chemokines activate chemokine receptors that are distributed on Th2 cells. Moreover, vCCL-2 can interact with other chemokine receptors including CCR1, CCR2, CCR5, CXCR1, CXCR2, and CXCR4. However, binding of vCCL-2 to these receptors does not activate signaling but rather inhibits signal transduction by these receptor proteins in the presence of their chemokine ligands. For example, binding of RANTES and MIP-1α to activate CCR5 is inhibited by low amounts of vCCL-2. Thus, vCCL-2 appears to promote Th2 responses and also inhibit Th1 responses (Fig. 15.16). Consistent with this observation, KS lesions contain more Th2 T cells (CCR3+) than Th1 T cells (CCR5+).[642] Moreover, treatment of LCMV-infected mice with vCCL-2 inhibits CD8 T-cell migration into the lesion and impairs local inflammation.

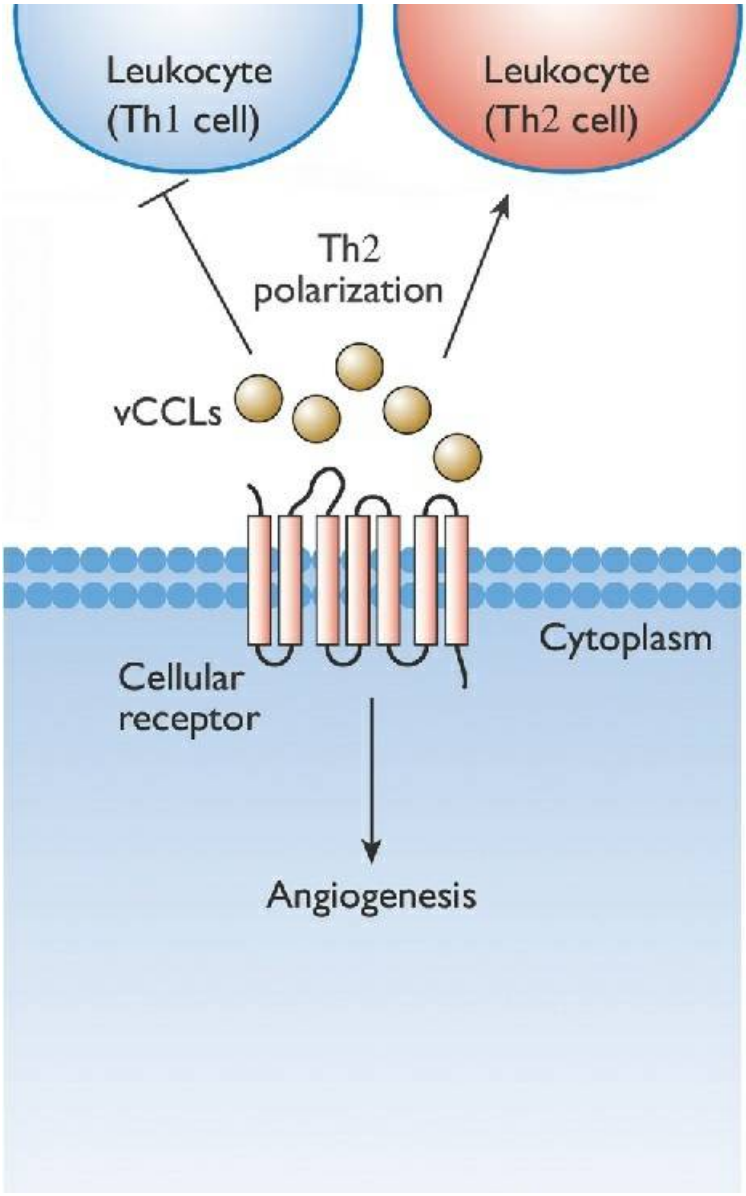

FIGURE 15.16 The KSHV encoded viral chemokines (vCCLs) block Th1 responses and augment Th2 responses. These viral chemokines have also been shown to activate angiogenic pathways.

Apart from their anti-inflammatory properties, the viral chemokines can also promote angiogenic responses and induce VEGF from PEL.[379] Additionally, the vCCLs can promote cell survival in an autocrine and paracrine manner—the vCCLs inhibit the expression of the pro-apoptotic protein, Bim, during KSHV lytic replication.[124]

KSHV K14 encodes a glycoprotein of the Ig superfamily that resembles cellular CD200 (also known as OX2). CD200 is expressed on many cell types (B, T, and endothelial cells) and its receptor (CD200R) is located on cells of the myeloid lineage (basophils, neutrophils and monocyte–macrophages). Cellular CD200 is a negative regulator of inflammation and myeloid cells, and CD200 knockout mice have an increase in monocytes and macrophages, macrophage

and microglial activation, and increased susceptibility to experimentally induced autoimmune disease.[260] Soluble recombinant KSHV K14/vOX2 protein binds to CD200R.[186] There is some discrepancy in the literature regarding the inflammatory nature of K14. One study observed proinflammatory signaling by K14,[129] but other studies found K14/vOX2 suppresses markers of myeloid activation including suppression of TNF-α production by activated macrophages, decreased MCP-1 and IL8 production by a monocytic cell line, reduced oxidative burst in primary neutrophils triggered with a phagocytic stimulus, and a blunted release of histamine from basophils activated by Fc-ε receptor cross-linking.[186,514] Both cellular CD200 and vOX2 were reported to have a T cell–attenuating role resulting in the negative regulation of antigen-specific T-cell responses.[432]

KSHV encodes a viral protein, ORF63, with homology to the nucleotide-binding and oligomerization, leucine-rich repeat (NLR) family of proteins.[221] NLRs mediate antiviral immune responses to many different invading viruses. Some NLRs form a large molecular structure called an inflammasome upon activation. The inflammasome contains oligomerized NLRs, apoptotic-associated speck-like protein (ASC), and procaspase-1. Activation of this complex results in the autocatalytic processing of procaspase-1 to caspase-1. Activated caspase-1 subsequently cleaves the precursors of proinflammatory cytokines, pro-IL-1β and pro-IL-18, to their biologically active forms, IL-1β and IL-18, respectively. ORF63 is a tegument protein and hence is present in the incoming virion. ORF63 could bind and inhibit the association of the NLR family member, NLRP1, with procaspase-1 and prevent the processing of pro-caspase-1 and subsequent processing of pro-IL-1β and pro-IL18 (Fig. 15.15).[221] ORF63 inhibition of NLRP1 was found to be important during reactivation from latency and primary infection.[221]

Moreover, the KSHV ORF64 protein encodes a viral deubiquitinase,[213] that has been shown to inhibit the innate immune sensor, RIG-I.[277]

Signaling Proteins

K15

The coding regions adjacent to the KSHV TRs encode two signaling proteins: K1 (described above) is located at the left end of the genome while at the right end of the genome lies ORF K15, which encodes for another transmembrane signaling protein. Expression of K15 is highly increased during lytic growth, and its expression during latency has been controversial. It was initially named latency-associated membrane protein (LAMP)[211] and is expressed at low levels during latency.[2,547] K15 mRNAs originate from alternatively spliced transcripts that include 8 or less exons, encoding up to 12 TM domains and a cytosolic tail.[126,211] All spliced variants encode the carboxy-terminal tail linked to varying numbers of transmembrane domains. The full-length proteins contain 8 exons (12 TM). All the K15 protein variants are found on intracellular membranes and the plasma membrane. A subset of K15 in the plasma membrane is associated with lipid rafts.[65] The K15 cytoplasmic region can be tyrosine-phosphorylated and appears to inhibit B-cell receptor (BCR) signal transduction.[126] The cytosolic tail contains a SH2 binding motif (YEEVL), and the Y is phosphorylated *in vivo* by the Src family of kinases. The cytoplasmic domain contains an SH3-binding region, and another motif (YASIL) represents an endocytosis signal and a potential site of tyrosine phosphorylation.

The cytoplasmic tail also contains a TRAF binding site (ATQPTDD). K15 binds TRAFs 1, 2, and 3 and constitutively activates NFκB, JNK, and ERK, MAPK signaling pathways, leading to up-regulation of the transcription factor, AP-1.[65,211] Activation of NFκB involves the recruitment of NFκB—inducing kinase (NIK) to K15.[250] In this manner, K15 is capable of inducing the expression of an array of cytokines and chemokines, including IL-8, IL-6, CCL20, CCL2, CXCL3, and IL-1α/β, Dscr1, and Cox-2[66] (Fig. 15.9).

Activation of MAPK signaling might be important for mediating lytic replication since MAPK activation is necessary for full lytic induction and reactivation from latency.[132,481,546,667] K15 also interacts with the protein HAX-1, an antiapoptotic factor, suggesting another mechanism (besides NFκB induction) by which K15 contributes to enhanced cell survival.[547] K15 can interact with Lyn and Hck kinases.[491] Thus, K15 appears to contribute to KSHV pathogenesis through the up-regulation of multiple inflammatory cytokines and the activation of multiple signaling pathways (Fig. 15.9). K15 also recruits PLCγ1, and thereby activates Calcineurin/NFAT1-dependent RCAN1 expression to induce angiogenesis.[25,217] Finally, KSHV K15 has been shown to be expressed in KS tumor biopsies and to be required for viral lytic replication.[2]

vGPCR

In addition to K1 and K15 discussed above, KSHV encodes a third transmembrane signaling molecule encoded by ORF74, a viral G-protein coupled receptor (vGPCR). It is a member of the family of seven transmembrane G-protein coupled chemokine receptors. Expression of this protein is dependent on ORF50 and is restricted to the lytic cycle. The protein displays constitutive signaling activity in the absence of ligand, although its activity can be stimulated further by chemokines, for example, GRO-α, and down-regulated by chemokines, for example, CXCL10/IP10.[20,207] The resulting signaling activates the PI3K/Akt/mTOR and p38 pathways,[435,559,563] as well as upregulates NFκB activity, angiogenesis, and cell proliferation[24,244] (Fig. 15.9). Indeed, vGPCR-deleted recombinant viruses are impaired for viral replication and vGPCR's function in lytic replication is dependent on its ability to signal through G-α(q) and activate MAPK signaling.[532]

Due to this potent signaling activity, vGPCR activates expression of many host genes. Among these are Rac1[437] and VEGF,[24,562] a critical mediator of vascular permeability and angiogenesis. vGPCR can also activate PDGF receptor.[94] KSHV vGPCR can promote tumorigenesis by activating the oncogenes, YAP/TAZ through inhibition of the tumor suppressive Hippo pathway.[382] Further, expression of vGPCR in mice in several different cell lineages generates focal angioproliferative lesions that have some features in common with KS.[234,436,669] What is a notable commonality among two of the models where expression was evaluated at the cellular level is that vGPCR was expressed only in a small proportion of the cells in the lesions, which has led to the belief that in KS lesions, expression by a few lytic cells can induce pathology through paracrine mechanisms. Because vGPCR can be linked to both proliferation and angiogenesis, it may be a key element in KS pathogenesis.[23,562] Additionally, siRNA suppression of vGPCR in the context of the whole viral genome also inhibited angiogenesis and tumorigenicity.[446] Interestingly, transgenic mice that express the constitutively active form of the small GTPase Rac1 develop KS-like lesions.[394] Transcription profiling

showed many consistencies between KS tumors and the Rac1 tumors. The tumorigenesis seen in the Rac1 model was dependent on activation of Akt signaling, ROS-induced proliferation, and HIF-1 alpha. Furthermore, inhibitors of ROS reduced tumorigenesis in this model.[394] The contribution of lytic genes to oncogenesis is further discussed in the section on KSHV pathogenesis.

ORF36/vPK

ORF36 encodes for a viral protein kinase (vPK) that is a serine–threonine kinase.[247] vPK expression is induced by hypoxic environments due to the fact its promoter contains hypoxia-inducible elements[247] and vPK expression has been observed in 59% of KS biopsies.[264]

vPK is present in both the nucleus and cytoplasm,[330] and it can modulate signal transduction pathways. vPK can bind and phosphorylate the histone acetyltransferase TIP60,[365] which is a protein involved in the DNA damage response. Both mitogen-activated kinases 4 (MKK4) and 7 (MKK7) are phosphorylated by vPK resulting in c-Jun N-terminal kinase (JNK) phosphorylation and consequently phosphorylation of c-Jun transcription factor.[242]

vPK can also phosphorylate cyclin-dependent kinase substrates, retinoblastoma, and lamin A/C.[330] In addition, vPK shows some homology to cellular ribosomal protein S6 kinase (S6KB1) and can phosphorylate ribosomal S6 protein.[46] Moreover, vPK transgenic mice show an eightfold increase in the incidence of B-cell non-Hodgkin lymphoma (NHL) compared to age-matched wild-type mice.[16]

Host Shutoff

Many previous attempts to examine the effects of lytic replication on host gene expression in KSHV were hindered by the low frequency of lytic replication in chemically induced PEL lines. However, systems now exist where lytic reactivation is seen in the majority of cultured cells.[448,616] This is typically performed by infecting cultured cells with KSHV at high MOI after which cells are allowed to establish latency; these cells are subsequently superinfected at a high MOI using baculoviral or adenoviral vectors expressing ORF50. This induces the lytic cycle in the vast majority of cells in culture. Under these conditions, the majority of lytically infected cells display some degree of inhibition of host gene expression 10 to 12 hours postinfection. The principal block appears to be at the level of host mRNA accumulation.[210] This phenomenon can be attributed to a single protein encoded by ORF37.

KSHV ORF37 encodes for a DE protein named SOX (*s*hut-*o*ff e*x*onuclease). Homologs of SOX exist in other herpesviruses as well. In HSV, the SOX homolog is not involved in host shutoff (which instead is mediated by ICP27 and VHS). The KSHV SOX protein retains DNA exonuclease activity similar to its HSV counterpart, but this function can be genetically separated from its function in host RNA shutoff.[210] There is a coordinated destruction of cellular mRNAs by SOX and the mammalian exonuclease Xrn1.[142] Cleavage sites of SOX are specific and are defined by a degenerate sequence motif containing a small number of conserved residues rather than a strong consensus sequence.[193] Importantly, a small subset of host mRNAs escape SOX-mediated turnover. The cellular IL-6 message is one of these transcripts. Mapping studies have shown that the 3′ untranslated region of IL-6 mRNA contains elements that allow it to escape

from SOX-induced degradation and that these elements are protected by the binding of a ribonucleoprotein complex.[444] The length of polyadenylated tails is emerging as a distinct marker of mRNA fate and differences from the canonical length lead to either degradation or nuclear retention. KSHV SOX stimulates RNA turnover through polyadenylation-linked mRNA turnover.[345] Inhibition of poly(A) tail formation blocks ORF37/SOX activity and transcripts in SOX-expressing cells exhibit extended poly(A) polymerase II generated poly(A) tails. The poly(A) binding proteins (PABPs) were also shown to be essential for SOX function.[345] Exactly how selectivity for host mRNAs is achieved by SOX, while viral transcripts are spared, remains to be elucidated.

KSHV PATHOGENESIS

In this section we review the cellular and molecular mechanisms that underlie KSHV's relationship with its associated cancers.

Molecular Pathogenesis of KS

Histologically, KS tumors are highly complex and unlike most classical cancers that arise as a clonal outgrowth of a single cell type.[509] This makes KS different from traditional forms of cancer, where the malignant cell is of a clear, distinct type. In KS, the chief proliferating cell is called the "*spindle cell,*" which is named after its spindle-like shape. As mentioned above, the spindle cells are of endothelial lineage, since they express many markers of endothelial origin, including factor XIII, CD31, CD34, CD36, En-4, and PAL-E.[17,97,256,509] However, some spindle cells lack the presence of factor VIII, which is a marker of differentiated vascular endothelium. Spindle cells also display heterogeneity in marker expression.[509] For example, some spindle cells in KS biopsies stain for factor VIII, while other cells stain for smooth muscle α-actin.

Gene expression profiling studies of infected endothelial cells[89,243,261,629] found that latent viral infection reprograms expression of endothelial markers, inducing the vascular endothelium to express lymphatic markers such as PROX1, while the lymphatic endothelium displays a more vascular-like profile. On the basis of microRNA profiling it has been shown that there exist multiple distinct stages of endothelial cell reprogramming by KSHV, most significantly associated with the down-regulation of mir-221.[470] In view of the stage-wise reprogramming, which endothelial cell type represents the actual progenitor of the KS spindle cell is still unclear; it is still possible that multiple types of endothelial cells could give rise to the KS spindle cell following viral infection. The resultant KS spindle cell may be shaped as much by the viral infection as by the microenvironment. Gene expression profiling of KS tumor biopsies have shown multiple subtypes of KS lesions—those that express just the latency transcripts and those that express both latency and lytic transcripts.[264]

KSHV-infected endothelial cells have also been found to up-regulate several signal transduction pathways including the PI3K/Akt/mTOR pathway and JAK2/STAT3 pathway.[442,627] STAT3 activation was mediated by gp130 receptor, a common receptor of the IL-6 cytokine family. Both Akt and STAT3 were necessary for KSHV-induced lymphatic

reprogramming of endothelial cells.[442]

In addition to spindle cells, KS lesions also contain infiltrating T cells, B cells, monocytes, and aberrant, slit-like neovascular spaces. The neovascular spaces are lined with both infected and uninfected endothelial cells.[173] They don't contain pericyte or smooth muscle cells and are very susceptible to leakage and rupture. Because of these features, KS lesions often exhibit hemorrhage, with erythrophagocytosis by inflammatory cells in the interstitial spaces. The KSHV-infected endothelial cells display increased vascular permeability—lytic infection is associated with VE-cadherin degradation[177,406,497] attributed to the actions of K5 and vGPCR, while latent infection is associated with increased Rac1 activation and ROS generation leading to disruption of endothelial junctions due to the phosphorylation of VE-cadherin.[231] Thus, the histologic appearance of KS probably results from at least four different processes—proliferation, inflammation, reprogramming, and angiogenesis. These processes are intertwined but distinguishable. These distinctions are important because KSHV contributes through different genetic mechanisms to each of these disease components.

KS can occur in a variety of sites. It is frequently localized to the skin, and in the sporadic classical form, it may be restricted to the lower extremities. In the skin, the dermis is involved, with sparing of the overlying epidermis.[483] While progression is not quite linear, and patients may present with lesions in all stages, in general terms, cutaneous KS is thought to begin as a *patch* lesion, with histologically demonstrable spindle cells that are not necessarily the predominant cell type; inflammatory cells and neovascular elements are also abundant at this stage. The lesion may progress through a plaque-like stage to the *nodular* stage, with the proportion of spindle cells becoming progressively larger as the lesion progresses. By the nodular stage, spindle cells fill up most of the lesion. The spindle cell progressively dominates during the course of KS and is therefore considered to be the key tumor cell.

In immunocompetent adults, classical KS is frequently indolent. However, in immunocompromised hosts, KS is highly aggressive, with widespread involvement of lymphoreticular structures and multiple organs such as the GI tract, the lung, and skin. Pulmonary KS has a grave prognosis since it is often accompanied by death from respiratory failure. Analysis of KS spindle cell clonality has revealed that KS lesions are either oligo- or polyclonal.[294] Although clonality is observed in some KS lesions,[500] the lesion is generally thought to be oligo- or polyclonal throughout much of its development, including progression to macroscopically visible KS. One striking feature is how frequently the individual lesions in a KS patient appear to have arisen independently. This is different than that observed in most classical cancers and underscores the uniqueness of KS. This scenario is reminiscent of that seen with EBV-driven posttransplantation lymphoproliferative disorders, where lesions can be polyclonal, showing a possible progression to monoclonality, and when there are multiple lesions, they may be of different clonal origin a single patient.[99,316] Cellular pre-miRNA profiling of KSHV-infected endothelial cells and KS tumors revealed that as cells infected with KSHV transition from immortalization to fully tumorigenic, there was a loss of mir-221 expression and a gain of mir-15 expression.[470] Additionally, expression of mir-140 and the KSHV viral miRNAs increased proportionally with the degree of transformation.[470] Additionally, down-regulation of multiple tumor suppressor miRNAs was observed in KS and PEL.[471] Since the tumor suppressor proteins themselves are, for the most part, not mutated in these tumors, regulation of their expression in KS and PEL highlighted a novel, alternative mechanism of transformation.[471]

KS spindle cells exhibit only a few of the hallmarks of transformation. KS cells are very dependent upon growth factors and cytokines when cultured *in vitro*. KS also do not display genetic instability, although this may reflect the nature of viral cancers, which tend to show less genetic instability (e.g., p53 mutations) in general. KS spindle cells are diploid and do not display microsatellite instability, although certain advanced AIDS-KS tumors can display these characteristics. The KS spindle cells are dependent on cytokines and growth factors (perhaps from infiltrating inflammatory cells) in their microenvironment for their proliferation, but they themselves can generate angiogenic and proinflammatory factors to recruit additional blood vessels to the site of the infected lesion. Thus, KS is highly dependent on its microenvironment for growth and survival.

The Role of Hypoxia in KS Biology

One descriptive observation involving KS was that it often (but not always) develops in the lower extremities, such as the feet, where tissue may be less oxygenated. A seminal finding revealed that low oxygen conditions, that is, hypoxia, lead to the reactivation of KSHV replication from latently infected PEL.[149] Hypoxia augmented vIL-6 secretion as did several compounds that increase the levels of HIF-1. Hypoxia also increased expression of the viral kinase, KSHV ORF36, and the thymidine kinase encoded by ORF21.[150] HIF-1 is a master regulator of angiogenesis and is activated posttranscriptionally by hypoxia, leading to increased protein stability of HIF-1alpha and/or HIF-2alpha, which are two subunits that constitute HIF-1. Consistent with this hypothesis, the KSHV genome contains several hypoxia response elements (HREs).[246] The ORF50/RTA and the ORF34 promoters contain HREs, which under hypoxic conditions are activated by HIF-1 alpha and/or HIF-2 alpha.[246] As mentioned above, XBP-1s can reactivate KSHV from latency and it has been reported that hypoxia also induces active XBP-1s.[147]

Additionally, in the context of primary KSHV infection, there is an increase in HIF activity under normoxic conditions.[90] Both HIF-1alpha and HIF-2alpha proteins are elevated in KSHV-infected cells.[90] KSHV also appears to utilize a portion of the hypoxic cellular response—for example, during KSHV infection there is a significant portion of hypoxia-induced changes in cellular gene expression.[621]

Impact of KSHV Infection on Metabolic Pathways

KSHV infection of endothelial cells has been shown to increase aerobic glycolysis (leading to lactate secretion) and decrease oxidative phosphorylation in the cell. This effect is common to tumors and is known as the “Warburg effect.” Inhibitors of glycolysis appear to enhance cell death of KSHV-infected cells.[156] Additionally, KSHV also induces lipogenesis for survival of latent infection in endothelial cells.[157] Latent KSHV infection was shown to result in increased levels of intracellular glutamine and enhanced glutamine uptake through the glutamine transporter, SLC1A5.[530] Thus, multiple pathways including glycolysis, glutaminolysis, and fatty acid synthesis (FAS) are up-regulated by KSHV infection of endothelial cells and inhibitors of these pathways block the production of infectious virus from lytically infected cells, each at a different stage of viral replication.[531] Interestingly, in KSHV-induced cellular transformation of rat primary MSCs, glycolysis is suppressed and KSHV appears to accelerate glutamine

metabolism.[698] These differences might be due to a difference in cell types.

In B cell–derived PEL, both aerobic glycolysis and FAS are significantly up-regulated compared to primary B cells, and PEL were more sensitive to the FAS inhibitor, C75.[45]

Molecular Pathogenesis of PEL and MCD

Gene expression profiling demonstrated that PEL display a distinct profile from all other NHL that is neither related to germinal center (GC) nor to memory B cells.[313] The mRNA profile of PEL was defined as plasmablastic because it showed features of both immunoblasts (similar to EBV-transformed lymphoblastoid cells) and plasma cells (similar to multiple myeloma cells).[313] Another group reported that the stage of B-cell development represented by PEL closely resembles that of malignant plasma cells.[286] The unfolded protein response is partially activated in PEL (XBP-1) and genes overexpressed in PEL include those involved in inflammation, cell adhesion, and invasion.[286] KSHV-infected PEL have also been found to up-regulate the PI3K/Akt/mTOR signaling pathway,[44,554,602] as well as higher levels of B-Raf and angiogenic VEGF-A as compared to other lymphoma subtypes. MEK inhibition reduced VEGF-A expression in PEL.[10] In PEL, Interleukin 1 receptor-associated kinase 1 (IRAK1) appears to be essential for KSHV PEL.[671] NFkB is also active in PEL cells, but knock-out of single genes in this pathway do no result in PEL cell death.[407] In contrast, PEL cells are dependent on IRF4, MDM2, cyclin D2, cellular FLIP, and MCL1. Genome-wide comparative genome hybridization (CGH) found consistent deletions in fragile sites that encode the FHIT and WWOX tumor suppressor genes.[520] In terms of viral gene expression, most of the PEL cells express latent genes, for example, LANA, vCyclin, vFLIP, vIRF3 etc.[181,453] However, between 1% and 5% of PEL cells spontaneously reactivate in culture and display lytic gene expression.

MCD is associated with both latent and lytic infection. In MCD, latent (LANA) and lytic (ORF59, K8, and K10) viral proteins are expressed.[483] One protein that is constitutively expressed in a significant proportion of KSHV-infected cells in MCD is vIL-6, which as described above is expressed during latency and is highly up-regulated during lytic infection. It is thought that expression of lytic proteins contributes extensively to the pathobiology of MCD.

KSHV Gene Expression in KS and PEL

KSHV viral DNA is present in all KS tumors, regardless of type of KS or disease stage. As mentioned above, KSHV specifically targets the spindle cell compartment within the tumor.[173,569] However, when passaged *in vitro*, the spindle cells generally lose the viral genome. It has been reported that monocytes in the lesion can also be infected by KSHV[52,477] as well as some epithelial cells.[185,483,569] *In situ* hybridization for latent mRNA transcripts suggest that most KS spindle cells are latently infected; however, a small subpopulation (<1% to 2%) express markers of lytic infection in some lesions.[163,173,299,569,577] With the exception of vIRF3, all latent genes expressed in PEL are also found as latent genes in KS.[516]

Similar to EBV, it is thought that the latency program drives tumorigenesis. Early (patch) lesions of KS have only a small proportion of spindle-like cells that are LANA positive (<10%), while in more progressed lesions a variable, but higher, proportion of spindle cells are latently infected.[173,569] The *in vitro* properties of the latent proteins (e.g., the inhibition of p53 and Rb by

LANA, the induction of NFκB by vFLIP, the stimulation of CDK6 by vCyclin, and the up-regulation of β-catenin by LANA) are commensurate with transformation, growth advantage, and survival. However, it is important to note that many of these functions were identified in experiments involving overexpression of individual viral proteins. When most transformed cell lines are infected with KSHV, the resulting latent infection does not greatly impact their biology.[36,335] However, when KSHV infects primary (or immortalized) human endothelial cells, the virus replicates for the first few days (usually with significant CPE) and spreads through the monolayer. Over the next 7 to 10 days postinfection, lytic replication subsides and most of the cells are latently infected. The resulting LANA-positive cells exhibit a change in morphology, that is, elongation to a spindle morphology similar to that seen in KS tumors *in vivo*. In most cases, primary human cells are not immortalized by KSHV. However, efficient cellular transformation of primary rat mesenchymal precursor cells has been observed.[439] Similarly, most KSHV-positive primary endothelial cells cannot form tumors in nude mice or grow in soft agar. However, Renne and colleagues did isolate a KSHV-infected immortalized endothelial line (TIVE) in which KSHV-infected cells were tumorigenic and grew out many weeks following infection.[14] These KSHV-infected TIVE cells do give rise to tumors in nude mice.[14] However, this cell line appears to represent the exception to the rule, rather than the norm.

The above results may simply reflect the paucity of culture conditions to successfully propagate KSHV-infected endothelial cells. Indeed, a similar situation is observed in EBV where epithelial cells like nasopharyngeal carcinoma (NPC) cells lose the EBV genome during passage in tissue culture.[165] This is despite the fact that EBV-infected B lymphoma cells do not lose the virus during similar passage as is the analogous situation with KSHV-infected B lymphoma cells. Thus, in contrast to B lymphoproliferative cells, it is generally not possible to establish cell lines from either NPC or KS that retain the EBV and KSHV episomes respectively, during passage in tissue culture. However, *in vivo*, every KS and NPC tumor cell retains the viral genome.

Early studies showed that KSHV infection of primary B cells *in vitro* is inefficient and, in contrast to EBV, does not lead to immortalization. Infection efficiency was enhanced when primary B cells were activated and expressed DC-SIGN.[507] When KSHV DNA was transfected into BJAB B cells, the virus was maintained as an episome and could establish latency with a low level (1% to 5%) of underlying spontaneous lytic replication.[113] The latent viral gene profile was similar to that observed in PEL and the virus could be reactivated to produce infectious progeny virions.[113] *In vivo*, it appears that KSHV can infect B cells and *in vitro* infection of primary tonsillar B cells has shown that activated T cells help to promote and stabilize latency[447] and that these infected B cells predominantly express lambda light chain.[249] Analysis of specific B-cell lineages from human tonsils infected with KSHV revealed that infection of immunoglobulin κ (Igκ) naïve B cells induces expression of Igλ, with eventual loss of Igκ.[601]

Recently, a number of papers have examined the coinfection of EBV and KSHV in B cells. It was reported that persistent KSHV infection increases EBV-associated lymphomagenesis in humanized mice through enhancement of EBV lytic gene expression.[423] Another report showed that EBV enhances genome maintenance of KSHV in B cells[48] and supports optimal coinfection of B cells with KSHV.[183]

The Unprecedented Role for Viral Lytic Proteins in KSHV

Oncogenesis

The latency program has traditionally been associated with tumorigenesis (as is the case with EBV). Hence, it was surprising that independent evidence from clinical studies suggested that both lytic replication and latency play an important role in KS development. In the case of patients with advanced AIDS, the administration of ganciclovir (GCV)—a drug that blocks lytic, but not latent KSHV infection—prevented the onset of new KS tumors.[412] This is a striking result because these patients were infected with HIV and KSHV for many years; the fact that the administration of GCV blocks tumor appearance suggests that viral reactivation may be necessary to support KS development. Further, patients with KS typically display circulating KSHV DNA in the peripheral blood.[79] Two other antiviral drugs, however, failed to affect already established KS lesions.[326,378] One could speculate that dependence of KSHV lytic genes exists during the initial stages of lesion formation. Subsequently fully tumorigenic spindle cell clones may emerge, in which host cell mutations lead to independence of KSHV lytic proteins.

How might lytic replication contribute to KS tumor development?

The lytic and latent phases of the viral life cycle go hand in hand. Without lytic proteins, the virus cannot replicate, survive in the human population, or exert paracrine effects on neighboring uninfected cells in the tumor microenvironment. Without latent proteins, the virus cannot persist in the infected host and establish latency for the lifetime of the infected host. Thus, these two phases of the viral life cycle are interdependent on one another, and the cumulative pathogenesis seen with KSHV infection is a contribution of both lytic and latent genes. Albeit there is no firm answer to the question of how lytic genes contribute to KS tumor development, several (nonexclusive) possibilities can be considered:

1. Latent KSHV infection is not clearly immortalizing *in vitro* using current culture conditions, which distinguishes it from EBV. If spindle cells do not proliferate indefinitely, then for a tumor mass to grow, KSHV-positive cells that die must be replaced by newly infected cells. The source of such cells could be generated from *de novo* infection of endothelial cells with virus produced from lytically replicating cells.
2. When recently infected cells bearing latent KSHV genomes undergo sustained proliferation *in vitro*, they lose their viral genome.[226] This is supported by the consistent observation that when infected KS spindle cells are explanted from clinical specimens and placed in culture under conditions that favor their proliferation and expansion, they rapidly lose their viral episomes but retain their transformed nature.[184] Thus, lytic replication may be continuously needed for KS development to infect and restore latent infection to spindle cells that have lost their viral genomes. Some experimental evidence indicates that selective pressures exist *in vivo* to retain the KSHV genome, and these are different from those of explanted KSHV-infected cells in culture.[14,446]
3. The third way that lytic KSHV replication may contribute to KS pathogenesis is through activation of three processes required for KS development: proliferation, inflammation, and angiogenesis. Since fully lytically infected cells die, they are not able to contribute to the proliferative component of the disease. However, in the context of abortive lytic replication, the lytically infected cells can produce paracrine factors that support the inflammatory and angiogenic nature of the lesion. As described before, KSHV encodes multiple secreted signaling proteins expressed during the lytic cycle—examples include the three viral CC chemokines and vGPCR. The viral chemokines exhibit chemotactic

properties for both Th2 cells[576] and endothelial cells.[245] Polarization of local T cells away from Th1 responses might inhibit antitumor cytotoxic responses, while the effect of viral chemokines on endothelial chemotaxis suggests that KS lesions are likely to recruit more endothelial cells for latent or lytic infection. Indeed, the application of the viral chemokines to chick chorioallantoic membranes stimulates angiogenesis.[576] Moreover, vGPCR is a potent signaling protein as discussed above and is capable of activating pro-survival, pro-angiogenic, and pro-proliferative cellular pathways.

4. Finally, it is also possible that some lytic proteins are expressed outside of the traditional lytic cycle—if not during the canonical latent phase, then in response to an extracellular signal or microenvironment cue, which allows the lytic gene to be expressed in the absence of other lytic genes. An example of this is that hypoxic conditions have been shown to turn on expression of viral genes like ORF36.[247]

Conversely, one conundrum is the ability of a subset of latent proteins to up-regulate inflammatory cytokines. Several latent proteins are linked to the induction of inflammatory responses including vFLIP, K15, and kaposin B, as described above. Cytokines play important roles in KS and MCD pathogenesis, and it is likely that these viral proteins induce cytokine production in KS and MCD. Although understandable from a pathogenesis standpoint, from an evolutionary point of view it appears contradictory that KSHV would embed such proinflammatory biology in the heart of its latency program. In contrast, many viruses encode proteins that prevent inflammatory responses or evade those they cannot ablate. This conundrum remains unresolved. It is possible that cytokines are important to maintain latency in naturally infected cells *in vivo*, or for sustaining the viability of latent cells. Alternatively, an inflammatory microenvironment may help to recruit KSHV-permissive cells to sites of viral infection, thereby facilitating viral spread from cells undergoing lytic reactivation. The fact that some of the latent viral proteins also possess antiapoptotic activity suggests that these viral proteins acting in concert may negate the negative effects of proinflammatory cytokines, while the positive effects of these cytokines, for example, recruitment of target cells, are retained. In addition, there is increasing experimental evidence suggesting that expression of lytic genes (at least vGPCR) in small subsets of cells can augment the proliferation or tumorigenicity of cells expressing latent genes (such as vFLIP and vCyclin).[436,438]

The identity of the origin of the KSHV-infected tumor cells remains unresolved. One report suggested that bone marrow precursors serve as a reservoir for KSHV.[484] Primary MSCs in human bone marrow were shown to be susceptible to KSHV in tissue culture.[484] A recent report provides evidence that KS might actually originate from MSCs through KSHV-induced mesenchymal-to-endothelial transition.[367]

Human CD34+ hematopoietic progenitor cells (HPCs) were also subjected to KSHV infection and differentiated *in vitro*.[659] Infection of CD34+ HPCs with a recombinant GFP-containing KSHV followed by reconstitution with KSHV-infected CD34+ HPCs showed that the virus could be detected in human CD14+ and CD19+ cells recovered from NOD/SCID mouse bone marrow and spleen following infection.[659] These results suggest that KSHV can establish persistence in CD34+ HPCs and this may serve as a KSHV reservoir to allow the virus to be disseminated to B cells and monocytes after differentiation.[659]

EXPERIMENTAL SYSTEMS FOR STUDYING KSHV

Animal Models

KSHV does not establish persistent infection in mice; hence humanized mouse models have been used. Early studies showed that C.B-17 SCID mice implanted with human fetal thymus and liver grafts (SCID-hu Thy/Liv mice) were susceptible to KSHV infection, with an early phase of lytic replication and subsequent sustained latency.[164] Viral gene expression in CD19+ B lymphocytes was observed, and infection was inhibited by ganciclovir. However, no disease was evident in the infected animals.[164] Another humanized model of NOD/SCID mice with functional human hematopoietic tissue grafts (NOD/SCID-hu mice) was also injected with KSHV. A portion of these animals generated human KSHV-specific antibodies. Antiviral treatment of the NOD/SCID-hu mice with ganciclovir led to prolonged but reversible suppression of KSHV DNA and RNA levels, suggesting that KSHV can establish latent infection *in vivo*.[485] Human CD34+ cells have been infected *in vitro* and followed in immunodeficient mice, also without any disease.[659] A humanized BLT (bone marrow, liver, and thymus) mouse (hu-BLT) model generated from NOD/SCID/IL2rγ mice showed that KSHV can establish infection in human B cells and macrophages.[638]

Viruses related to KSHV from other species, for example, murine herpesvirus 68 (MHV68), rhesus monkey rhadinovirus (RRV), and HVS, are used as experimental models of KSHV pathogenesis (reviewed in Ref.[166]). However, *in vivo*, KSHV infection is restricted to the human population and no natural infection of any other species has been identified. KSHV is not successfully transmitted to small animal experimental hosts. Implantation of PEL cells into immunodeficient mice leads to tumor engraftment, but not to spread of virus or infection in murine tissues. As described above, SCID/hu mice transplanted with human lymphoid tissues display infected human B cells within the implant, but there is no spread to the surrounding mouse tissue, and no disease state developed in these animals.[164]

KSHV can be successfully transmitted to New World primates, specifically common marmosets (*Callithrix jacchus*).[110] Infected common marmosets displayed antibody reactivity to KSHV, and LANA protein and KSHV genomic DNA could be detected in PBMCs from these animals indicating that KSHV could establish persistent infection in these animals.[110] One KSHV-infected animal developed a KS-like skin lesion consisting of spindle cells and infiltrating leukocytes.[110]

Xenograft models have been very useful for the study of pathogenesis, and to test a variety of potential therapies. Xenograft models of PEL have been reported by several laboratories,[166] and PEL cell lines expressing firefly luciferase have allowed *in vivo* tracking of tumor growth (BC3-NFκB-luc). Xenograft models of KS have also been reported, but these have used cell lines, such as SLK, KS Y-1, and KS-IMM, obtained from KS patients but lacking KSHV. Other cell implantation models include injection of human endothelial cells that have been infected with KSHV *in vitro*,[14] and mouse bone marrow cells that have been transduced with a KSHV

BAC.[446] These models have provided interesting biological insights and are particularly important because they assess the effect in the context of the entire virus. A related system, which has been used to evaluate the interaction of cells expressing a lytic gene (vGPCR) and cells expressing latent genes (vFLIP and vCYC), is the implantation in mice of endothelial cells transduced to express viral genes.[436] These important studies have confirmed that KSHV can produce vascular tumors, that vGPCR is a critical viral gene for this process, and that there is a selective pressure *in vivo* for viral maintenance.

Cell Culture Models of Infection

In order to determine parameters of KSHV tropism and transmission, many different cell culture systems have been developed as experimental models to examine these events. The first successful cultivation of cells containing KSHV utilized PEL from AIDS patients with advanced disease.[96,511] These cells grew as ascites tumors in the KS patients and were readily established in cell culture. A panel of these lines has now been established, from both EBV-positive and EBV-negative cases of PEL. These cell lines have complex, hyper-diploid karyotypes with multiple structural abnormalities, a few of which are recurrent (trisomy 7, trisomy 12, and aberrations in the proximal long arm of chromosome 1 (1q)).[520,653] However, in general, they do not contain structural alterations in common genes involved in lymphomagenesis (such as MYC, p52, RAS).[451] PEL cells predominantly harbor latent KSHV episomes[511] with only a handful of latent viral genes being expressed, and virus is not produced. However, in most experimental systems, 1% to 5% of PEL cells display lytic replication with the viral genome being expressed in a temporally regulated fashion, resulting in viral DNA replication and yielding infectious virions as described above. The viral titers are quite low, but can be greatly increased by the addition of chemical inducers (e.g., phorbol esters) or the histone deacetylase inhibitors (e.g., sodium butyrate and valproic acid).[430,512] Chemical inducers reactivate 15% to 30% of latent PEL, which begin to exhibit lytic gene expression. Virions isolated from PEL have been utilized for structural studies of the virus particle and for studies of infection studies *in vitro* and animal infectivity studies *in vivo*. These cell lines have also been utilized for serologic assays.

While cell lines established from patients with advanced KS do exist (SLK, KS Y-1, and KS-IMM), these lack the KSHV genome, and are therefore not useful for virological studies. Thus, immortalized endothelial cell lines have been generated that contain the KSHV genome. While these in general do not result in stable viral infection, a few cell lines have been generated that do appear to maintain the virus and grow indefinitely. The first such system used dermal microvascular endothelial cells immortalized with HPV E6 and E7, prior to infection with KSHV.[443] Another important cell culture system was generated by infecting telomerized endothelial cells (TIVE), to generate long-term cultures (TIVE-LTC).[14] A different cell line—latently-infected SLK cells that are tightly latent—has been shown to be efficiently induced by doxycycline. These cells seem to produce increased quantities of infectious KSHV virions.[448]

Most KSHV-infected cells *in vitro* result in viral latency and not lytic replication. These include common cell lines, for example, HeLa and HEK293.[36,618] Human cell lines of fibroblastic, endothelial and epithelial lineages, monocytes, and rodent cell lines (3T3 and BHK) can all support latent infection *in vitro*.[36,265a,335,443] Thus, the entry machinery for KSHV is likely distributed across different cell types and infection in culture is highly amenable and often does not parallel the pattern of infection seen *in vivo*. Established cell lines (e.g., HEK293,

TIME, Vero, HFF) that are readily infected can also be induced to reactivate by the same chemical stimuli mentioned above for PEL (e.g., TPA or sodium butyrate). A workhorse cell line in the field is the inducible iSLK.219 cell, which allows for doxycycline-induced KSHV reactivation from latency.[448] A B-cell version of this was also developed.[300]

Oral Infection Model

KSHV has been shown to infect epithelial cells, including those from the oral cavity.[176,290,540,617] Indeed, KSHV has been detected in the saliva of KSHV seropositive individuals[50,318,486] and is also known to be transmitted orally to children from KSHV-positive breast-feeding mothers.[64,154,419] Tissue culture–based infection of oral keratinocyte raft cultures with a recombinant KSHV virus resulted in latent infection in the basal layer, but when these keratinocytes differentiated, lytic replication was induced and virions were produced at the epithelial surface.[290] Interestingly, early keratinocyte differentiation did not result in lytic replication in cells attached to a substratum and only occurred in the suprabasal cell layer.[540] Consistent with this model of adherence-dependent latency, keratinocytes that were differentiated in a suspension activated lytic KSHV.[540] It appears that the engagement of integrins on the KSHV-infected cell surface plays a key role in maintaining latency and preventing reactivation. *In vivo*, it is likely that virus present in oral epithelial cells is subsequently transmitted to tonsillar B cells (such as those mentioned above) where the virus can establish lifelong latency.

KSHV can infect both T and B cells from primary tonsillar explant cultures.[249,447,449] T cells, however, do not support lytic replication (they display abortive replication), while B cells spontaneously produce substantial amounts of infectious virus. When mixed cultures of B cells and activated T cells were exposed to KSHV, virus production was not seen unless the T cells were removed from the cultures or the culture was spiked with immune suppressants. Thus it appears that oropharyngeal activated T cells recognize ligands on KSHV-infected B cells suppressing lytic replication and thereby promoting latency.[249,447,449] Furthermore, when human tonsillar cells were infected with KSHV and analyzed using multispectral imaging flow cytometry (MIFC), LANA expression was mostly seen in cells that expressed the lambda light chain of the B-cell receptor.[249] The KSHV-infected B cells displayed increased expression of Ki67 and IgM and IL-6 receptor. They proliferated and also displayed blast morphology. All these characteristics are similar to those seen with MCD, which are IgM lambda-expressing plasmablasts.[249] The preference for lambda light chains is not due to preferential infection of B cells expressing this type of Ig, because KSHV can infect both kappa and lambda light chain–expressing tonsillar B cells. However, kappa-expressing cells begin coexpressing lambda light chains soon after infection (being double positive), and eventually many become only lambda light chain positive.[601] This is accompanied by regulation of Rag proteins, which account for induction of V(D)J recombination and receptor revision. Thus, it is likely that oral transmission of KSHV leads to latent infection of a subset of tonsillar B cells that become IgM lambda positive and can expand and resemble plasmablasts.

Taken altogether, these observations suggest several possibilities through which KSHV could establish infection in endothelial cells and B cells *in vivo*. A putative model is shown in Figure 15.17.

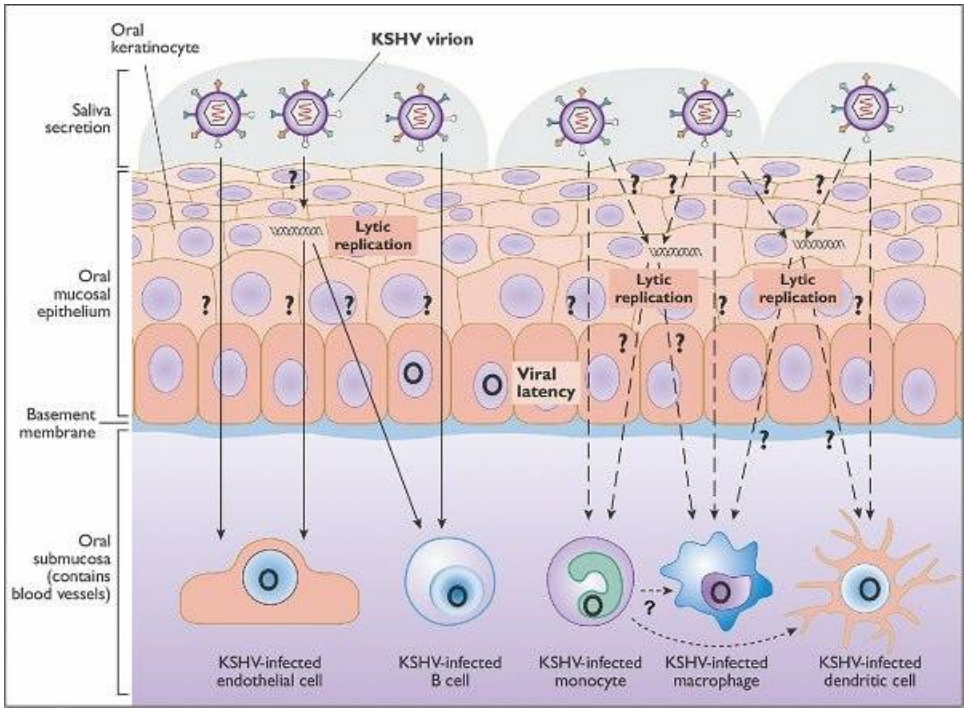

FIGURE 15.17 Hypothetical model of KSHV infection in the oral cavity. This model is based on various tissue culture studies and correlative measures of viral loads in different compartments *in vivo*. A number of scenarios are depicted to indicate how KSHV establishes latency in B cells and endothelial cells following primary infection.

1. It is possible that the virus first infects the oral epithelium from which it is shed into the saliva and can then subsequently infect either endothelial cells or B cells in the oral submucosa.[176,447,540]
2. It is equally possible that the virus can directly infect B cells (and plausibly endothelial cells) in the oral submucosa through a break in the mucosal epithelium as described previously for KSHV infection of tonsillar B cells.[447]
3. Since KSHV-infected monocytes and macrophages have been detected *in vivo*,[52,477,556] it is also conceivable that KSHV can directly infect these cells in the oral submucosa or indirectly through the oral keratinocytes as described above.
4. Although KSHV has not been detected in dendritic cells *in vivo*, it can infect these cells *in vitro*,[255,506] which raises the possibility that these cells might also be directly or indirectly infected by KSHV in the oral submucosa. Alternatively. KSHV-infected monocytes may be able to differentiate into dendritic cells.

It is important to note that the above described model is based on different tissue culture studies and correlative measures of viral loads in various compartments *in vivo*. However, it provides some insight into how KSHV can establish latency in B cells and endothelial cells *in vivo*.

EPIDEMIOLOGY

Age

KSHV infection can occur at any age, beginning in early childhood. KS was reported to afflict children in endemic regions indicating that viral transmission can occur during childhood.[558] Studies evaluating the age in which viral transmission occurs have been possible in sub-equatorial Africa, where prevalence of KSHV is highest. Transmission is unlikely to occur during delivery, since a study in an endemic area found no evidence of KSHV in cord blood.[84] However, seroconversion can begin soon thereafter; studies have largely shown that infection occurs at an early age, arguing for nonsexual transmission. The presence of antibodies to KSHV increases gradually with age (reviewed in Ref.[97]), with as many as 15% of children under 2 years of age having been exposed to KSHV in endemic areas (Fig. 15.18). One study in rural Uganda showed that 90% of children are seropositive for KSHV by the age of 15.[464] Closely following puberty, seroprevalence of KSHV continues to rise through early to mid-adulthood, which is a pattern suggestive of inefficient heterosexual transmission[22,179] with close to half of the population being seropositive by the age of 50.[74] There is a strong familial association, with a higher likelihood of a child being positive if the mother or a sibling is positive for the virus. A large study (>2,500 participants) was conducted to address whether possible sociodemographic, behavioral, and biological factors were associated with transmission in rural Uganda. This study confirmed that in highly endemic regions, infection is mostly acquired from intrafamilial contacts in childhood, and that it continues into adulthood most likely through nonsexual routes.[75] The finding of childhood transmission routes has more recently been confirmed by assessing seroconversion in Zambia. Increased risk of seroconversion was found as a consequence of sharing of utensils between a child with a primary caregiver, having more KSHV-infected household members and five or more children in the household.[143]

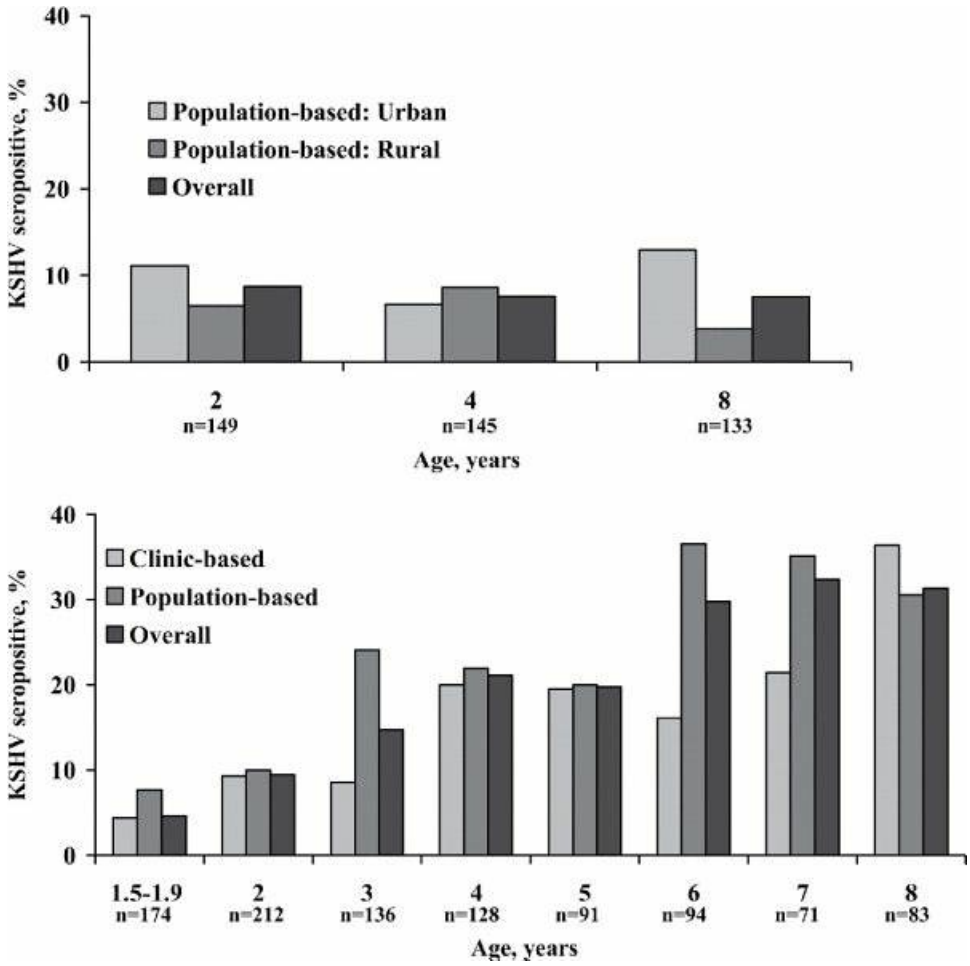

FIGURE 15.18 KSHV seroprevalence among children in South Africa (top) and Uganda (bottom), by age. *n* values underneath bars refer to the overall number of children in each age group. (From Butler LM, Dorsey G, Hladik W, et al. Kaposi sarcoma-associated herpesvirus (KSHV) seroprevalence in population-based samples of African children: evidence for at least 2 patterns of KSHV transmission. *J Infect Dis* 2009;200(3):430–438. Reproduced by permission of Infectious Diseases Society of America.)

Routes of Transmission

KSHV has been found in maternal saliva and in breast milk in endemic areas, arguing for an oral/salivary route of transmission in African children.[64,154,403,419] The presence of KSHV in saliva is not correlated with KSHV viremia, but it increases with age and is more common in males, as found in a study from Uganda.[455]

Analysis of a cohort of Italian patients with classic KS and their first-degree relatives showed that infection in these was significantly higher than in healthy controls, and these included spouses, siblings, and offspring. These relatives were found to contain viral DNA in their saliva, indicating that close contact contributes to the spread of KSHV, and that this spread can occur via nonsexual routes, although sexual transmission in the spouses could not be excluded.[405]

In contrast to endemic areas (Africa and the Mediterranean Basin), in Western Europe and the United States, which are zones of low prevalence (seropositivity 1% to 7%), infection is generally acquired sexually: prepubertal children are uninfected, while infection rates rise in adulthood, coinciding with sexual activity. Sexual transmission occurs efficiently among men who have sex with men (MSM) where seroprevalence can range from 25% to 60%[111,201,303,553,560]; in this group, there is a clear linkage to infection and the number of sexual partners.[411] Seroprevalence rates tend to be lower among women than men,[304] though rates of infection among female attendees of STD clinics and commercial sex workers are elevated,[82,303] suggesting that heterosexual transmission to females occurs. The finding that virus is consistently detected in saliva,[486,617] and only sometimes in genital secretions,[486] favors an important role for salivary virus-mediated sexual transmission.

The possibility of blood-borne transmission through blood transfusion has been witnessed, and there is evidence that it may occur, albeit rarely.[258] One prospective observational cohort study of transfusion recipients was conducted in Uganda, where the seroprevalence among blood donors was very high, leukocyte reduction was not used, and blood storage time was usually short. In this study, an estimated 12 of the 425 patients who received KSHV-seropositive blood were infected by transfusion. Other studies have confirmed that in some settings transfusion may lead to acquisition of KSHV, and a few case reports have documented transfusion-associated KS.[3,478,636] In contrast, a study in the United States that evaluated a historical cohort of participants in the Transfusion-Transmitted Viruses Study showed that there was no statistically significant difference in KSHV seroconversion in the transfusion and nontransfusion groups.[83] The question of whether organ transplants should be screened has also been raised. While the incidence of KS is highly increased in organ transplant recipients, this is mostly due to reactivation as a consequence of the immunosuppressive therapy. However, molecular studies have documented that the KSHV originated from the donor in some instances.[167,190,392,620] A study found that among 454 organ recipients (281 renal, 116 liver, and 57 heart) close to 30% of recipients seroconverted among those where the donor was seropositive for KSHV. Only liver transplant recipients developed KSHV viremia (close to 4% of recipients). In this study, two liver and one kidney transplant recipients developed KS.[344]Thus, some investigators have advocated for screening for organ transplantation, and for blood transfusion in endemic areas, but there are no formal guidelines.

Morbidity and Mortality

The major disease caused by KSHV is KS, and the incidence of this disease globally varies. In the early AIDS epidemic, KS incidence skyrocketed, and was reported to be 20,000 times more frequent in HIV-infected patients with AIDS than in the general population. The use of combination antiretroviral therapy (cART) starting in the mid 1990s dramatically decreased the incidence of AIDS-related KS.[518] The overall incidence of KS in Western countries decreased from around 15 per 1,000 person-years to 5 per 1,000 person years between 1992 and 1999.[281] The current rates of KS were reported recently in a large study with over 200,000 patients that included 42 cohorts from 57 countries. Incidence rates per 100,000 person-years were 237 in North America, 244 in Latin America, 180 in Europe, 52 in Asia Pacific, and 280 in South Africa.[5] KS risk was approximately 2 times higher in heterosexual men than in women and 6 times higher in MSM than in women.[5] Globally, it appears that while incidence of AIDS-related

KS has dramatically decreased, the rates have mostly reached a plateau, without reaching pre-HIV levels,[325,418,672] and there is anecdotal evidence and case reports that KS is presenting in people living with HIV who are treated with combined antiretroviral therapy (cART) and with controlled HIV loads and CD4 counts.[309,611] There is also evidence that risk groups of individuals presenting with classic KS may be changing, as documented by a retrospective cohort study of classic KS in Paris between 2006 and 2015 that reported that less than 40% of patients were of Mediterranean origin and 28% were MSM.[159]

In sub-Saharan Africa, the incidence of KS increased close to 20-fold when the AIDS epidemic began. The effect of cART on the incidence of AIDS-related KS in sub-Saharan Africa is difficult to quantitate since not much data are available.[98,541] However, we know that most of the global burden of KS is currently happening in Sub-Saharan Africa. According to Cancer Today,[276] the annual incidence of KS is currently estimated to be 41,799, with 32,446 of these deaths occurring in Africa, while the annual mortality is estimated to be of 19,902 cases, where 17,659 are in Africa.

Origin and Spread of Epidemics

KS has been grouped into four major epidemiological forms[195]: Classic KS affecting elderly men of Mediterranean or eastern European Jewish ancestry; endemic KS, existing in parts of Central and Eastern Africa, described long before the HIV pandemic and often affecting children with disseminated lymphadenopathy[43,472,558]; iatrogenic KS, developing in immunosuppressed individuals such as after an organ transplant or for autoimmune disorders[551]; and epidemic or AIDS-KS, a major AIDS-defining malignancy. In the western world, AIDS-KS predominantly affects HIV-infected gay men. However, in Africa, since the spread of HIV, epidemic KS has become more common in both genders, with a lowering of the male to female ratio.[623] The incidence of childhood KS has risen more than 40-fold in the era of AIDS in endemic regions.[702]

Lymphadenopathies linked to KSHV infection, namely PEL and MCD, are much more common in HIV-infected individuals. While MCD is increasingly recognized in Africa,[214] KSHV-associated lymphomas appear to be extraordinarily rare in regions that are endemic for KSHV, even in individuals with HIV infection.[180]

Prevalence and Seroepidemiology

Strong epidemiological studies suggest that KSHV infection is absolutely required for the development of Kaposi’s sarcoma. Studies that utilized the measurement of antiviral antibodies demonstrated that these antibodies are made during primary infection, but since primary infection gives way to latent infection in the host, seropositivity is a marker for not only past exposure but also the presence of ongoing viral latent infection.

Like the disease incidence, the prevalence varies globally. As individuals with KS have higher anti-KSHV antibody titers than do individuals without KS, the overall seroprevalence may be underestimated. However, despite this caveat and some regional exceptions, there is a strong concordance between KSHV seroprevalence rates and incidence of KS. Different tests have been used to determine seroprevalence, and these are variably reliable, with some assays overestimating, and others underestimating, the true prevalence. Thus, some studies are difficult to interpret. Since KSHV encodes multiple latent and lytic antigenic proteins,[103] assays have

variably targeted these antigens. The earlier studies used immunofluorescence using latently infected PEL cells, or PEL cells treated with TPA to induce lytic replication.[201,303,358,553] Newer generation methods rely on enzyme-linked immunosorbent assays (ELISAs) using recombinant proteins or peptides, most frequently LANA (ORF73), which is the major latently expressed antigen, or the lytic antigens K8.1 and ORF65. Usually testing for both LANA and at least one lytic antigen is encouraged, because infected subjects may have detectable antibodies to one or the other,[47,431] and develop seroreactivity to these antigens at different times.

In an assessment of which proteins encoded by KSHV induce an antibody response, 72 KSHV ORFs were used to make recombinant proteins and tested in people with KSHV-associated diseases. In addition to LANA and K8.1, ORF38, ORF61, ORF59, and K5 were found to elicit significant responses.[331] Given that many studies from different areas used variable methodology to assess the seroprevalence, one analysis using a single method was conducted to determine the presence of antibodies among a cohort of over 6,000 people in sub-Saharan Africa testing for antibodies to LANA and K8.1. This study showed age, higher rates of coinfection occurring in rural areas, geographical variation (highest seroprevalence in West Nile, Uganda, of 70%, and lowest in Nigeria, of 23%), and gender (higher in men than in women) impacted seroprevalence.[490] This study also nicely confirmed that variations in KSHV seropositivity parallel the cumulative incidence of KS. Regional variation was also shown in a study evaluating seroprevalence in China, where higher rates were found in the Uygur, Mongolian, and Kazar ethnic groups, in which most of the cases of KS occur, as compared to the Han people.[636]

Nearly all KS patients are seropositive for KSHV with current testing techniques. Prospective studies suggest that KSHV infection predates AIDS-KS development and is a strong predictor of KS risk. Fifty percent of men infected with both HIV and KSHV, who received no effective treatment for either agent, develop KS within 10 years.[411] The association of KSHV infection with KS is also evident from the fact that KSHV viral genomic DNA and viral antigens are present in all cases of HIV-positive or HIV-negative KS.[272,440] These data indicate that KSHV is the etiological agent of KS and that KSHV is the *sine qua non* of KS—patients that do not have KSHV infection will not develop KS. Treatment of AIDS patients at high risk for KS with ganciclovir reduces KS incidence and further bolsters this conclusion.[412]

When comparing three time periods in a rural Uganda cohort (1990–1991, 1999–2000, and 2007–2008) for prevalence, titer, and temporal trends, a modest reduction was found in prevalence in the most recent period, which was more pronounced in children.[464] If this trend holds true, there may be hope for eventual decrease in this population, where the vast majority are infected with this virus. This report also found higher seroprevalence rates in males than females. Notably, boys tend to shed more KSHV in saliva than girls as determined by a study in Uganda.[463]

Geographical Distribution and Genetic Diversity

KSHV infection is found at variable rates all worldwide, with rates lowest in Western Europe and America and highest in Africa.[97,153,410,537,648] In Europe, however, KSHV is more prevalent in the Mediterranean region, for example, Italy and Spain.[197,647] KSHV isolates from different regions in the world show differences that help explain KSHV evolution and its relationship with its human host. As described in Figure 15.3, large blocks of KSHV sequence are highly conserved and do not exhibit much variation from different isolates. However, some genomic

regions in the virus display remarkable sequence variability, which makes them useful as markers for strain diversity and markers to track epidemiological spread. These include regions surrounding the internal sequence repeats and the coding regions directly adjacent to the left- and right-hand TRs namely ORFs K1 and K15, respectively. The biochemical functions of these transmembrane proteins have been discussed earlier, and here we discuss their sequence variability in the context of KSHV evolution.

ORF K1 is a transmembrane protein whose N-terminal cysteine-rich ectodomain is highly variable; amino acid differences in K1 between geographically disparate isolates range from 30% to 60% of the total residues in the K1 ectodomain[704,705] (Fig. 15.19). Importantly, the cysteine residues, N-linked glycosylation sites, and signaling motifs in the cytoplasmic tail are not changed, which reflects the important nature of these amino acids for K1 function. A vast degree of sequence variation occurs in the hypervariable regions of K1, named V1 and V2, in which amino acids surge to 60%. It is assumed that host immune pressure drives this variability, but another hypothesis is that this diversity might have been driven by the need to recognize highly polymorphic cell surface proteins.[706] K1 sequence variation allows for the separation of KSHV isolates into four major subtypes (A, B, C, and D) (Fig. 15.19). These subgroup identifications are also supported by sequence variations in other genomic loci.[705,706] However, it is important to note that the viral strains are stable in a given individual since different samplings recovered from a single patient taken at various time points often yield identical sequences. The A and C subgroups are viral isolates from KSHV-infected subjects in Europe, the United States, the Middle East, and Asia, while subgroup B strains are viral isolates from sub-Saharan Africa; type D strains are found primarily in Australia, South Asia, and the Pacific islands. These data indicate that KSHV is an ancient human infectious agent that entered the human population at or around the time that modern humans arose in Africa in the early Pleistocene Age.[251] The diversification of the main branches (A/C, B, and D) is thought to occur from isolation and founder effects associated with proposed migrations of humans out of Africa—the first (ca 100,000 years ago) disseminating subtype B through sub-Saharan Africa, the second (ca 60,000 years ago) spread subtype D to South Asia, and onto Australia and the Pacific islands, and the third (ca. 35,000 years ago) carried subgroups A and C to Europe and northern Asia, and onto the Americas.[706] Alternative interpretations of these findings exist as well, but seem less likely.[422] The clustering of subtypes with ethnic and geographic population also implies that the virus is primarily transmitted in a familial pattern (e.g., vertically from parent to child and horizontally among siblings), with wider horizontal transmission being less efficient. Of course, in the context of the AIDS epidemic, viral spread occurred by a predominantly sexual route.

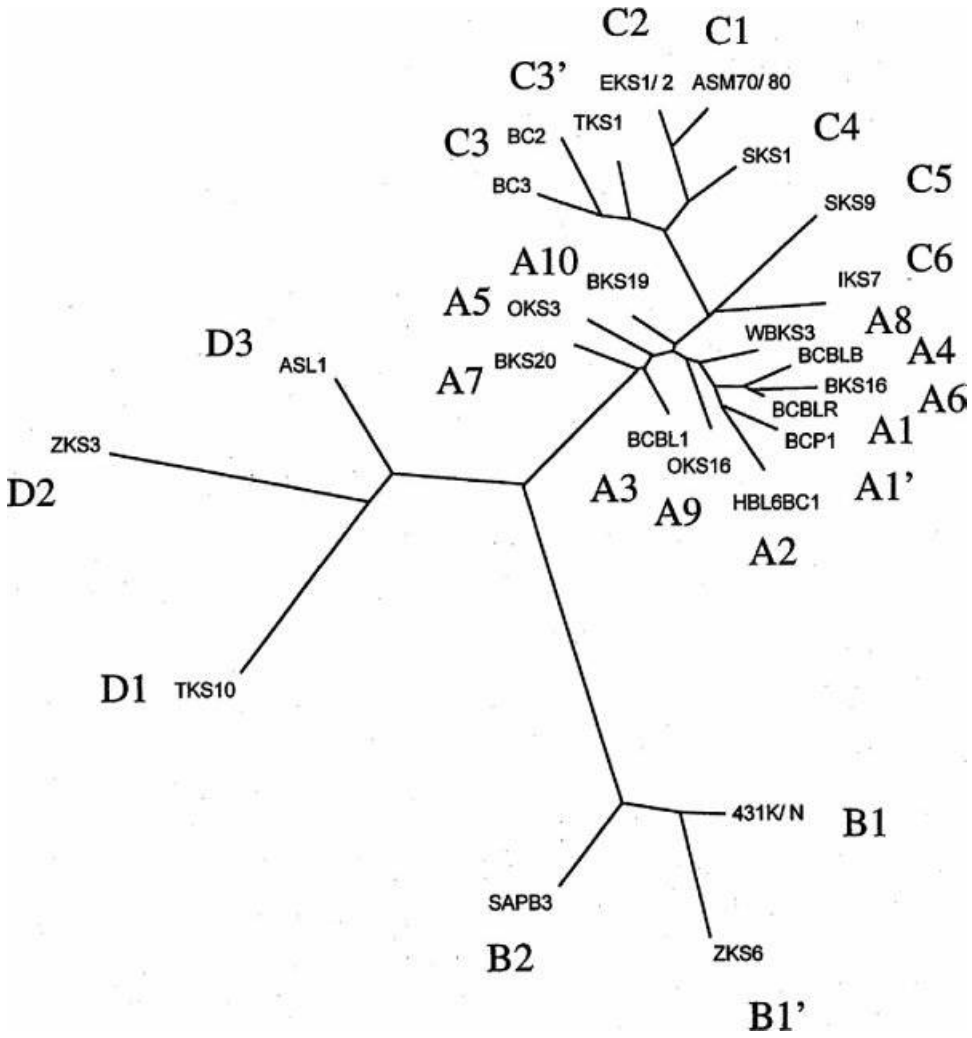

FIGURE 15.19 Clades of KSHV based on ORF K1 sequence differences. A and C clades cluster together and are typically found in Europe and the United States. B clade isolates are from sub-Saharan Africa, and D clades are from Australia and the Pacific islands. The subgroups within each individual clade are denoted by numbers following the clade letter, for example, C1 to C6. Many of the isolates shown here are from commonly used PEL cell lines, including BCBL-1, BC-1, BC-3, and BCP-1. (Reprinted from Zong J, Ciufo DM, Viscidi R, et al. Genotypic analysis at multiple loci across Kaposi's sarcoma herpesvirus (KSHV) DNA molecules: clustering patterns, novel variants and chimerism. *J Clin Virol* 2002;23(3):119–148. Copyright © 2002 Elsevier, with permission.)

There is additional sequence diversity at the right-most end of the viral coding region—in the K15 coding sequence. Here, the A and C subgroups (and only rare B isolates) display two allelic variants, termed P (for prototype) and M (for minority). The K15 alleles show large sequence differences that sometimes can extend into the adjacent ORF 75 gene (and sometimes up to 20 kb from the right-hand TRs).[496,706] A functional ORF K15 gene is preserved in both P and M alleles. The P and M K15 isolates only share 33% amino acid identity. This extensive sequence

divergence is consistent with the notion that the allelic variants were generated from recombination events with an unknown progenitor herpesviral genome during the course of evolution. The fact that both M and P alleles exist among KSHV subgroups A and C suggests that this recombination event likely occurred after the first two waves of emigration from Africa, but occurred soon after this, which allowed for dissemination of these alleles to both the Middle East and northern Europe.[705] Additional alleles (N and Q) at the right-hand end of the genome have been identified.[706]

The impact of the different strains in pathogenesis has been analyzed in different defined geographical areas, mostly based on K1 sequencing. One study in Brazil showed a significant predominance of A genotypes in KS lesions from HIV-positive patients, whereas C genotypes were found mostly in the HIV-negative setting.[504] In China, subtype A was significantly more frequent in mucosal KS lesions than subtype C.[685] One study in Italy showed that patients with rapid progression of KS and higher blood viral loads contained type A KSHV, while C type was mainly present in slow progressing patients.[404]

Cofactors

Although KSHV infection is necessary for KS to develop, it is not sufficient and cofactors have been identified. Globally, the presence of antibodies to KSHV is much more common than KS, indicating that on average only about one in 10,000 infected people gets the disease. The most important cofactor is clearly HIV infection. It is not yet completely clear if immunodeficiency itself is the main determinant of KS, or whether HIV has a more direct role. Individuals with iatrogenic immunosuppression, particularly renal transplant patients, also have an increased risk for KS, but not as great as that seen with HIV infection. This may reflect differences in KSHV infection rates, rather than HIV-specific causes, or differences in immune dysfunction, but a direct role for HIV as a cofactor has not been excluded. KS is clearly more common in males than females, which is more dramatic in classic KS. The reasons for this gender disparity are not known.

Potential contributions from host genetic factors have been reported, including genetic polymorphisms of inflammatory and immune-response genes. Classic KS risk is associated with diplotypes of interleukin 8 receptor β (IL8RB), IL13[68] and certain human leukocyte antigen (HLA) haplotypes.[141,169] Transplant KS risk is associated with an IL6 promoter polymorphism,[205] and genotypes of FcgammaRIIIA may influence the development of KS in HIV-infected men.[355] Thus far, these association studies have only shown a relatively small overall increased risk and have not included very large patient cohorts.

Environmental exposures have also been evaluated and found to have an effect on KSHV seroprevalence, or incidence of KS. These include regional variations associated with certain volcanic soils, arthropod bites, and living in rural areas.[490,504,685,701] In Sub-Equatorial Africa, malaria in particular has been shown to increase KSHV seropositivity[454,456] and shedding in saliva.[455] Helminth infection, in particular *S. mansoni* and hookworms, have also been found to be associated with higher KSHV seropositivity.[456,625]

These data suggest that common host genetic variants, in addition to coinfections, environmental factors, gender, timing, and possibly routes of infection, all contribute to the oncogenic outcome of KSHV infection.

CLINICAL DISEASE

Kaposi's Sarcoma

Clinical Features

Moritz Kaposi first described five patients with a hemorrhagic sarcoma of the skin and mucous membranes, but also involving internal organs as appreciated during postmortem examination.[298] While he described an aggressive tumor, this form was eventually recognized to be a rare, frequently indolent disease confined to the skin, and mostly occurring in older men of Mediterranean and Eastern European origin and referred to as sporadic or classic KS. An endemic form of KS was recognized and described by the early sixties, occurring in sub-Saharan Africa.[398] While African KS was histologically indistinguishable from the sporadic form, it tended to be more aggressive, and a lymphadenopathic form was documented to occur in children.[558] Subsequently, patients receiving immunosuppressive agents, such as solid organ transplant recipients, were also found to develop KS, which has been designated iatrogenic KS.[248] With the advent of AIDS, KS was found to occur with greatly increased frequency, therefore called epidemic KS. In the context of HIV infection, KS was reported to occur mostly in men who have sex with men (MSM), and have a much more aggressive clinical behavior, with frequent dissemination to internal organs.[188] Increasingly, an additional epidemiologic form of KS has been recognized, which is in HIV-negative MSM.[160,189,340,508]

Kaposi's sarcoma can have a variable clinical presentation, ranging from limited to fulminant disease, where in general it tends to be more indolent in sporadic KS and more aggressive in Africans and in individuals with AIDS.[97] The main clinical features in the different epidemiological forms are listed in Table 15. 2. Cutaneous lesions are most common in the lower extremities, face and genitalia, but can appear anywhere[123] (Fig. 15.20). In the context of HIV infection, the appearance of cutaneous KS lesions in visible areas may be indicative of AIDS and carry a heavy psychosocial burden because of existing stigma. Cutaneous KS lesions are typically multifocal and have the appearance of papules, patches, plaques, or nodules, and there can be fungating lesions and tumors. Among these, the patch lesions are considered early-stage lesions and other forms are considered more advanced. However, while these definitions are useful as dermatologic descriptors, in practice these distinctions frequently do not reflect disease progression; several forms can appear simultaneously. There can be patch-type lesions constituting large areas, or nodules with limited disease. Lymphedema may be extensive and debilitating. KS can also involve noncutaneous sites. Particularly common is involvement of the oral cavity, which can be the initial site of presentation. KS can also affect practically all internal organs, most frequently the gastrointestinal tract, lungs, and lymph nodes. In children, lymph node involvement signifies a poor prognosis subset, while in adults, focal lymph node involvement is quite common and does not signify the same poor prognosis as other visceral disease.[450]

TABLE 15.2 Comparison of the epidemiological forms of Kaposi's sarcoma

Form of Kaposi's Sarcoma (KS)	Clinical Presentation	Risk Factors	Progression
Acquired immune deficiency syndrome (AIDS) related (also known as epidemic)	Multiple cutaneous lesions on the limbs, trunk, and face. Mucosal lesions are common (identified in 20% of cases) and visceral involvement is seen in 15% of cases. Patients can also present with tumor-associated edema.	The risk of KS rises with declining CD4 cell counts and falls with the use of combination antiretroviral therapy (cART).	May follow an indolent course but visceral involvement is not uncommon and may be aggressive. It may regress with effective cART.
Iatrogenic	Often presents as cutaneous KS lesions but both mucosal and, rarely, visceral disease can occur.	Occurs following solid organ allograft; the risk of occurrence correlates with the level of immunosuppression. Hence, the risk of occurrence is higher in multi-organ transplants and with greater human leukocyte antigen (HLA) mismatching.	Usually localized but may involve organs. It may regress with the reduction of immunosuppression or with modification of the immunosuppressive regimen.
Endemic	Children often present with multiple lymph nodes with lymphedema and a very aggressive natural history of the disease, including visceral dissemination. Adults present with lower limb lesions that resemble classic KS.	Occurs most commonly in sub-Saharan Africa in HIV-seronegative individuals	In children, progression is often aggressive with widespread lymphadenopathy and visceral involvement. In adults, progression is indolent or locally invasive but occasionally has visceral involvement.
Classic (also known as sporadic KS)	Typically confined to lower limbs with few lesions. Visceral and mucosal disease is rare and usually occurs in the gastrointestinal tract.	Occurs in middle-aged and elderly individuals and is more common in men than in women. Ethnic groups from regions of high Kaposi's sarcoma herpesvirus prevalence (Middle East, Eastern Europe, Mediterranean) are at increased risk.	Usually indolent; rarely aggressive and disseminated
HIV-negative MSM (men who have sex with men)	May occur at any skin sites, usually with few lesions. Visceral and mucosal disease is rare.	HIV-negative MSM who are young or middle aged and are not immunocompromised.	Usually indolent, although disseminated disease has been described

A clinical classification scheme was proposed for AIDS-related KS by the AIDS Clinical Trials Group (ACTG) Oncology Committee.[323,324] This staging system incorporates extent of tumor, where T0 (good risk) is when KS is confined to skin and/or lymph nodes and/or minimal oral disease (i.e., nonnodular KS confined to the palate), and T1 (poor risk) is when there is any of the following: tumor-associated edema or ulceration, extensive oral KS, gastrointestinal KS, or KS in other nonnodal viscera. Other criteria in this classification are severity of immunodeficiency (I0 and I1 with a cutoff of <200 CD4 cells per cubic millimeter) and presence of systemic symptoms. This classification was validated prospectively in the pre-cART era[324]; this study found that the combination of poor immune response and tumor stage most accurately predicted survival. Subsequently, a prospective evaluation of the ACTG staging system conducted in the cART era showed that the combination of poor tumor stage and systemic illness identified patients with unfavorable prognosis[460] (Table 15.3. For classic KS, the classification focuses on tumor only and is based on a case series of 300 patients (Table 15.4). There are no staging systems specifically for iatrogenic or endemic KS.[63]

TABLE 15.3 The modified AIDS Clinical Trials Group staging of AIDS-related KS

TIS Staging of KS	Good Risk (T0)	Poor Risk (T1)
(T) Tumor	Confined to skin and/or lymph nodes, or minimal oral disease	Tumor-associated edema or ulceration, extensive oral Kaposi's sarcoma (KS), gastrointestinal KS or KS in other nonnodal viscera
(I) Immune status	CD4 cell count >150/mm^3	CD4 cell count <150/mm^3
(S) Systemic illness	Karnofsky performance status >70	Karnofsky performance status <70 or other HIV-related illness

From Cesarman E, Damania B, Krown SE, et al. Kaposi sarcoma. *Nat Rev Dis Primers* 2019;5(1):9.

TABLE 15.4 Staging of classic Kaposi's sarcoma

Stage	Description	Features
Stage 1	Maculonodular	Small macules and nodules primarily confined to the lower extremities
Stage 2	Infiltrative	Plaques mainly involving lower extremities, sometimes associated with a few nodules
Stage 3	Florid	Multiple angiomatous plaques and nodules involving the lower extremities that are often ulcerated
Stage 4	Disseminated	Multiple angiomatous nodules and plaques extending beyond the lower extremities

From Cesarman E, Damania B, Krown SE, et al. Kaposi sarcoma. *Nat Rev Dis Primers* 2019;5(1):9.

Early lesions can be mistaken clinically for purpura, hematomas, hemangiomas, and dermatofibromas, so a biopsy and histological confirmation is necessary, especially when lesions that are not entirely typical of KS occur. It is important to rule out mimics, such as bacillary angiomatosis and angiosarcoma when KS is associated with systemic symptoms. Other diseases that can be confused with KS clinically include lymphangioma, hemangioendothelioma, hemangiopericytoma, and pyogenic granuloma.

Laboratory Diagnosis

Diagnostic confirmation of KS is done through histopathology, as there are currently no blood tests for this disease, mostly because viremia is highly variable, and seropositivity does not necessarily indicate a diagnosis of KS. The histologic features of KS are essentially very heterogeneous and indistinguishable.[97] In skin, it affects the dermis, and similar to the clinical appearance of cutaneous KS, there is a range in the cellularity and microscopic appearance of the lesions. Lesions are characterized by the presence of jagged, thin-walled, and poorly formed dilated vascular spaces with large endothelial cells that may protrude into the lumen (Fig. 15.21). Between these vascular spaces is a spindle cell proliferation that can range from sparse to significant, sometimes forming sheets and extending irregularly in various directions. These spindle cells are considered to be the KS tumor cells. The elongated nuclei vary in size, and some are atypical, thus resembling a fibrosarcoma. However, the presence of narrow irregular, angulated slits containing erythrocytes among the spindle-shaped cells is a distinguishing feature of KS. These can be intertwined with normal vascular channels as well as lymphatic channels, some of which may show considerable cystic dilatation. There is a variable but consistently present inflammatory mononuclear cell infiltrate, composed of lymphocytes, plasma cells, and macrophages. Red blood cells and hemosiderin pigment are frequently present, often extravasated between the spindle cells. Small granules of intracytoplasmic or extracellular hyalin material may be identified. Granules of hemosiderin can also be seen within the spindle-shaped cells as a result of phagocytosis.[72,131] Confirmation of a diagnosis of KS is most commonly done by immunohistochemistry in formalin-fixed paraffin-embedded tissues using commercially available monoclonal antibodies to the KSHV latent nuclear antigen, LANA (ORF73). Since this protein is essential for viral episome maintenance, it is expressed by all the KSHV-infected cells. Using immunohistochemistry for LANA, KSHV is detected in a variable proportion of the spindle cells and endothelial cells lining the vascular spaces (Fig. 15.21). KSHV can also be detected by PCR in KS biopsies. Given that most cases of KS occur in Sub-Equatorial Africa, where there is a scarcity of pathology resources, new methods for easier and more affordable molecular testing of KSHV for the diagnosis of KS in poor-resource settings have been developed and are currently being evaluated.[561]

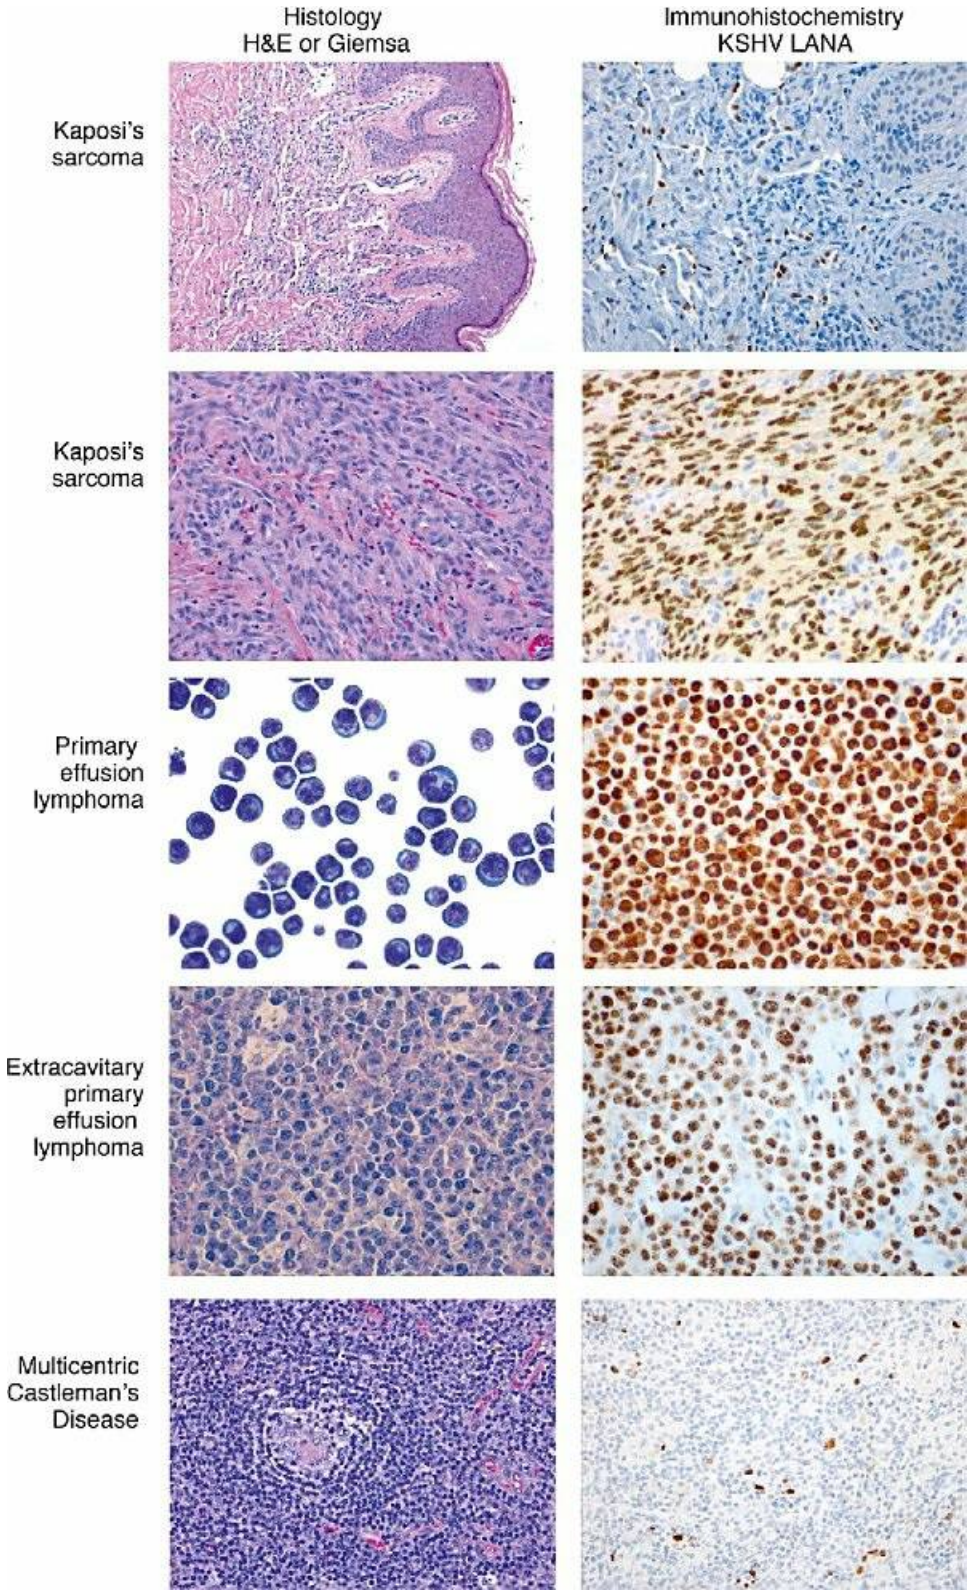

FIGURE 15.21 Histologic features of Kaposi's sarcoma, primary effusion lymphoma and multicentric Castleman disease. Skin biopsies of two different patients with KS are shown, illustrating the spindle cell proliferation and presence of

irregular vascular spaces. **Left columns** are hematoxilin and eosin (H&E) staining of formalin fixed, paraffin-embedded tissues and the **right column** shows immunohistochemical (IHC) staining for LANA, demonstrating broad variability in the number of infected cells. The **third row** shows a cytospin preparation stained with Giemsa of a primary effusion lymphoma on the left, and IHC for LANA in the right, performed on a PEL cell block. The **fourth row** shows H&E staining of a biopsy from a patient with a non-Hodgkin lymphoma that was positive for KSHV LANA (right), therefore subclassified as extracavitary PEL. The lower row exemplifies a case of MCD, with scattered LANA-positive cells. (Original magnification, left column rows 1–2: 20× and 40×, rows 3–4: 60×, row 5: 20×; right column rows 1–2 and 5: 40× and rows 3–4 60×.)

Clinical Course

The clinical course of disease can be highly variable. In general, initial presentation is usually a mild to moderate disease without symptomatic visceral symptoms, lymphatic obstruction or function-altering edema, difficulty swallowing or chewing, or any other functionally disabling manifestation, and has good clinical outcomes. It can be stable, have marked exacerbations, or even regress, especially in posttransplant patients in whom immunosuppressive therapy can be adjusted and HIV-infected individuals who begin antiretroviral therapy. The latter is likely due to the improvement of the immunological response to KSHV and possibly due to decreased circulating HIV-associated pro-angiogenic and inflammatory cytokines.[196] Interestingly, in some patients, KS may progress dramatically, and even be fatal, upon treatment with antiretrovirals, due to an immune reconstitution inflammatory syndrome (IRIS).[133] Currently, diagnostic criteria for KS-IRIS include evidence of progressive KS within 12 weeks of initiating cART in parallel with the suppression of HIV-RNA levels by ≥0.5 to 1 log10 and/or an increase in CD4 T-cell counts by at least 50 cells/μL compared to pre-cART levels. Early systemic chemotherapy can be effective in suppressing IRIS-associated flares,[265,357] but it has also been demonstrated that patients with IRIS not receiving chemotherapy can have good clinical outcomes if they survive the initial period of KS-IRIS.[622] KS-IRIS incidence and mortality were reported to be higher in Sub-Saharan Africa than in the United Kingdom, and this difference was attributed to more advanced KS and lower chemotherapy availability.[359] But it is also likely that careful management of systemic disease and coinfections in patients with IRIS improves the clinical outcome of these patients.

Treatment

cART has reduced the incidence of AIDS-KS in developed countries and can induce AIDS-KS regression in some individuals. Up to 80% of patients with T0 stage KS who were not previously treated with cART will require no other treatment for KS besides continued cART over 10 years.[58] HIV protease inhibitors have been shown to display direct antitumor activity,[434] but non–protease-inhibitor-containing antiretroviral combinations also induce KS regression.[56] However, KS remains a clinical problem,[465] and patients can present with HIV-KS in spite of having good HIV control and high CD4 counts.

Clinical staging is important for the decision on how to treat AIDS-KS.[97] cART should be

given to patients with T0 early stage disease (if not already receiving this treatment for HIV), to which KS will often respond (i.e., lesions will shrink by 50% or more in size and/or number) within 6 to 12 months. T1 advanced-stage or progressive AIDS-related KS is best treated with liposomal anthracyclines, such as Doxil, in combination with cART. Another useful chemotherapeutic agent is paclitaxel. This is particularly important for cases with anthracycline-resistant disease and in health care settings where liposomal anthracyclines are not available, or the cost is prohibitive. One head-to-head comparison of pegylated liposomal doxorubicin and paclitaxel in the treatment of advanced AIDS-related KS showed no significant differences in response rate,[130] but paclitaxel has more toxicities. While clinical trials are still at an early stage and are small and limited, assessment of pathogenesis-directed therapies is ongoing. One notable example is the use of the mTOR inhibitor, rapamycin, given that KSHV activates this pathway. Complete regression of cutaneous KS was reported in patients with transplant-associated KS when the immunosuppressive therapy was switched to rapamycin.[80,568] Good response rates have been confirmed by other investigators in the majority of patients with transplant KS (cutaneous and visceral) when rapamycin was used as the immunosuppressive regimen.[235,343,703] Rapamycin has also shown some clinical responses in AIDS-KS,[327] but data regarding treatment with rapamycin in patients with KS in other risk groups are very limited.[230] It is difficult to know with certainty if the effects are due to changes in immune response to KSHV as a result of changing the immunosuppressive therapy, or to direct effects on the KSHV-infected lesional cells, or both. Recently, it was demonstrated that the use of MLN0128, another mTOR inhibitor, circumvents rapamycin and chemoresistant PEL.[87]

Additional pathogenesis-related treatments have shown promise in small clinical trials: imatinib, which inhibits tyrosine kinase–mediated transmembrane receptor signaling to prevent KS cell proliferation and angiogenesis[319]; bevacizumab, a monoclonal antibody inhibiting VEGF, which is an angiogenic growth factor that is highly expressed in KS lesions[605]; interleukin-12, a cytokine that enhances immune responses, mediates antiangiogenic effects, and down-regulates vGPCR activity[673]; immunomodulatory imide drugs (IMiDs), including thalidomide, lenalidomide, and pomalidomide, all of which possess anti-inflammatory, antiangiogenic and immunomodulatory properties[495]; and proteasome inhibitors, such as bortezomib,[510] which may promote the KSHV lytic cycle and/or inhibit NFκB signaling.

Primary Effusion Lymphoma

Soon after the discovery of KSHV in KS, viral sequences were also identified in a unique type of lymphoma,[95] referred to as PEL. Given the initial descriptive name of body cavity–based lymphoma (BCBL), many of the PEL cell lines are designated BC or BCBL. The first reported cases of malignant lymphoma occurring as body cavity effusions were described as AIDS-associated lymphohematopoietic neoplasms containing EBV and displaying an indeterminate immunophenotype.[315] In this first report of three cases, two were lymphomatous effusions, and a B-cell lineage was demonstrated by using DNA-based clonality assays. Subsequent studies recognized that these lymphomatous effusions occurred relatively frequently in HIV-infected individuals.[219,626] However, they were thought of as unusual AIDS-related lymphomas, and it only became clear that they represent a quite distinct clinicopathological entity with the recognition of the presence of KSHV within them.[451] As described above, the presence of KSHV in this subset of lymphomas allowed the development of cell lines that have been used as a tool

for its propagation, for serologic assays and for viral purification. PELs contain many KSHV genomes, ranging from 40 to 80 copies per cell, a feature that has facilitated analysis of this virus.

PELs possess quite distinctive clinicopathologic features. Most importantly, they commonly present as lymphomatous effusions in body cavities, which are usually the pleural, peritoneal, or pericardial cavities, but can also occur in unusual sites, such as an artificial cavity related to the capsule of a breast implant or cerebrospinal fluid.[433,526] Although they are more common in HIV-positive males, HIV-negative men and women can also develop a PEL.[451,526] Because some KSHV-negative lymphomas, such as BL, can involve body cavities as lymphomatous effusions, and KSHV-positive lymphomas can present as solid-tissue masses, diagnostic criteria for PEL have been proposed.[451,505] These criteria include immunoblastic–anaplastic large-cell morphology (Fig. 15.21), null-cell phenotype (including the lack of B cell–associated antigen and immunoglobulin expression in most cases), and B-cell genotype. The expression of CD138/Syndecan-1[194] and hypermutation of the immunoglobulin genes[414] indicated that PELs are at a preterminal stage of B-cell differentiation. This assumption was confirmed by gene expression profiling of PEL,[286,313,479] as these studies found that PEL resembled plasma cells and had a profile between multiple myeloma and EBV-associated immunoblastic lymphoma.

Lymphomas containing KSHV can also arise with the first presentation as a solid tissue mass, nodal or extranodal, similar to other AIDS-related non-Hodgkin lymphomas. While some of these patients subsequently develop a lymphomatous effusion, others apparently do not. These cases may be diagnosed as diffuse large cell, immunoblastic, or anaplastic large cell lymphomas, in which the presence of KSHV in practically all the tumor cells has been demonstrated (Fig. 15.21).[101] Most of these are immunoblastic in appearance, have a high mitotic rate and variable amounts of apoptotic debris. Since these lymphomas have some of the defining features of PEL, including a similar morphology, they lack expression of B-cell antigens and immunoglobulin, and they are frequently coinfected with EBV, they have been classified as a variant of PEL, called either extracavitary PEL or solid PEL.

The almost invariable presence of KSHV in PELs suggests that it is necessary for the development of this disease. But like in the case of KS, infection by KSHV is necessary but clearly not sufficient, as PELs are very rare tumors, even in populations with high KSHV seroprevalence. The true incidence of PEL is not known, but based on retrospective analyses of specimens seen in a pathology department, it is estimated to constitute approximately 4% of AIDS-related lymphomas and 0.4% of all AIDS unrelated diffuse large cell NHLs. Therefore, it is evident that KSHV infection represents only one of several events involved in the development of PEL. Another cofactor appears to be EBV, because many PELs contain both viral genomes. Analysis of the pattern of EBV gene expression in PELs revealed that only EBNA1 was expressed, corresponding to Latency I,[263,586] and expression of at least one EBV microRNA (BART2) has been shown.[469,663] In spite of the limited EBV gene expression in PEL, it has been shown that EBV plays a role in dually infected PEL since dominant-negative variants of EBNA-1 inhibit colony formation of PEL cells.[397]

The cellular genome of PEL has not been well characterized, likely due to the rarity of these disease. These tumors have complex cytogenetics but lack structural alterations in common lymphoma-associated oncogenes (MYC, BCL2, RAS, TP53, etc.), with the possible exception of mutations in the regulatory region of BCL-6 (the relevance of which is unclear because PELs do

not express BCL6).[86,451] Two fragile site tumor suppressor genes FHIT and WWOX were found deleted in the majority of PEL cell lines.[520] Recurrent cytogenetic alterations are present, namely trisomy 7, trisomy 12, and aberrations in the proximal long arm of chromosome 1 (1q).[653] Mutational signatures revealed by DNA sequencing have shown an APOBEC signature in PEL, consistent with a cellular defense against viral infection.[624] These observations suggest that KSHV is the critical element for the development of PEL, which is supported by the essential role of several latent viral genes in this disease.

Survival with conventional chemotherapy was initially reported to be very poor, with a median survival of approximately 6 months.[451,552] Nevertheless, there are case reports of good outcomes with antiviral therapy, bortezomib, or rituximab[54,208,259,373,476,550] or pleurodesis with bleomycin.[675] A recent retrospective analysis of 20 patients seen at the NIH provides the best current appraisal of the viral, immunological, and clinical features of PEL.[393] These patients were diagnosed between 2000 and 2013 and treated with EPOCH. The main observations include more hypoalbuminemia, thrombocytopenia, and elevated IL-10 levels than patients with AIDS-related diffuse large B-cell lymphoma (DLBCL). The median overall survival was 22 months, with a plateau in survival after 2 years and a three-year cancer-specific survival of 47%. EBV+ cases had better survival and patients with elevated IL-6 had inferior survival. The outcomes in this study are better than in previous reports, but still quite poor. Clinical trials using pomalidomide or lenalidomide and EPOCH-R are ongoing and may lead to improved survival.

Multicentric Castleman Disease

Castleman disease is an atypical lymphoproliferative disorder that encompasses various clinicopathologic entities. There have been both pathological and clinical classifications, which overlap partially. Two distinct histopathologic subtypes were described prior to the identification of KSHV: the more common hyaline vascular type and the plasma cell type.[307] Clinically, Castleman disease can be localized, or the patient may have multiple enlarged lymph nodes, therefore called “multicentric” Castleman disease (MCD). Approximately 90% of patients with MCD have the plasma cell type morphology. Systemic constitutional symptoms in MCD include fevers, malaise, wasting, hypoalbuminemia, cytopenias, and hyponatremia.[641] There is a strong risk for these patients to develop malignancies, most commonly KS and NHL, and soon after the discovery of KSHV, association of this virus with MCD was described.[567] Approximately half of MCD cases from immunocompetent individuals have detectable KSHV, while in individuals with HIV, almost all patients with MCD have KSHV in involved lymph nodes. Currently MCD is divided into idiopathic and KSHV-associated categories, which are considered to be different disease entities with overlapping histologic features.

The presence of both KS and MCD in a single lymph node is not uncommon in HIV-positive patients. Notably, MCD, also called multicentric angiofollicular hyperplasia in early publications, is characterized histologically by a vascular proliferation, which is reminiscent of KS. One study showed that KSHV-positive endothelial cells can also be found in MCD lymph nodes, in both HIV-positive and HIV-negative patients.[67] The KSHV-infected B cells can be numerous, coalesce, and form microlymphomas or frank lymphomas. KSHV-infected plasmablasts are B cells that are monotypic but polyclonal, almost invariably expressing IgM-lambda.[170] These infected cells are different from PEL cells in terms of B-cell differentiation, in that they lack somatic hypermutation of the Ig genes and they express cytoplasmic Ig but lack

expression of CD138 and variably express CD27.[102,170] Therefore, it appears that even if both PEL and MCD originate from KSHV-infected pre–terminally differentiated B cells, infected cells in MCD arise from extrafollicular B cells that did not undergo a germinal center reaction, whereas PELs may originate from cells that have traversed the germinal center. An explanation for the Ig lambda restriction is that KSHV induces up-regulation of Rag proteins leading to Ig recombination in a process called B-cell receptor revision.[601] Since kappa light chains rearrange first, receptor revision leads to subsequent recombination leading to V(D)J recombination and expression of lambda light chains.

Lymphomas arising in KSHV-associated MCD have been described mainly as occurring in HIV-positive patients,[174] and were originally called plasmablastic lymphomas and subsequently lymphoma arising in KSHV-associated MCD.[585] More recently, this has been replaced by "HHV8-positive diffuse large B-cell lymphoma, not otherwise specified" in the current WHO classification.[585] These lymphomas are usually associated with MCD, but not always. They are usually EBV negative, do not contain mutations in the immunoglobulin genes, and are thought to arise from naïve IgM lambda-expressing B cells rather than terminally differentiated B cells. A different rare entity has also been reported, called germinotropic lymphoproliferative disorder, in which germinal center B cells are coinfected with EBV and KSHV.[171] It appears that KSHV-associated lymphoid proliferations encompass a set of entities ranging from MCD, to microlymphomas, to monoclonal B-cell expansion with a range of clinical and pathological features, which may be overlapping among these different entities.[610]

Systemic symptoms in MCD are believed to be a result of production of excess cytokines, and in particular interleukin-6 (IL-6), and probably both the cellular and viral versions of this cytokine contribute to pathogenesis. vIL-6 has been demonstrated to be expressed in MCD in scattered plasmablasts surrounding the lymphoid follicles.[81,482,570] Lytic antigens are also expressed more frequently in KSHV-infected cells in MCD than in other disorders associated with this virus, indicating that lytic viral replication may be a feature of MCD.[299] It is possible that MCD falls in the spectrum of KSHV-associated lymphadenopathies, as KSHV-infected cells can be found in lymph node biopsies in patients with HIV-associated lymphadenopathy that lack all the defining pathologic characteristics of MCD.[100]

Median survival of HIV-associated MCD in the pre-cART era was approximately of 14 months.[475] A variety of approaches have been used for the treatment of patients with MCD, including cytotoxic chemotherapy, with variable success.[55] Evidence of lytic viral expression has led to testing of ganciclovir or other antiviral therapy, with mixed results.[92,135] The best responses have been obtained with the advent of two different antibody therapies. A humanized anti–human interleukin-6 (IL-6) receptor monoclonal antibody (tocilizumab) has been reported to result in clinical responses in two studies of patients in Japan, but the patients did not have AIDS, and only two patients were positive for KSHV.[468,566] Larger studies have used the humanized monoclonal anti-CD20 antibody, rituximab, which has resulted in successful treatment with responses in approximately 70% of patients.[42,57,135,206] The mechanism of action is not very clear, since KSHV-infected cells in MCD frequently lack expression of CD20.[102] The use of rituximab monotherapy for good performance status patients without organ involvement and rituximab with chemotherapy for more aggressive disease has been recommended[55] although rituximab was reported to exacerbate or unmask KS.[57] A report demonstrated that targeting lytic proteins, ORF21 and ORF36 with valganciclovir and zidovudine, respectively, showed very

promising results.[604]

KSHV Inflammatory Cytokine Syndrome

An inflammatory syndrome with symptoms very similar to those of MCD has been described in patients with HIV and KS, but in the absence of generalized lymphadenopathy and without a pathologic diagnosis of MCD.[603] This entity was called KSHV inflammatory cytokine syndrome (KICS). These patients frequently have elevated levels of IL-6 and IL-10,[88,589] and may have other KSHV-associated tumors, such as KS or PEL. Outcome is poor, with a median survival of 13 months.[494] It is unclear how best to treat this disease.

PREVENTION AND CONTROL

Prevention of KSHV infection is challenging, especially in endemic areas where the prevalence rate is high, and transmission occurs mainly through saliva within families. Immunization would be ideal, but to this date, no candidate vaccines have been developed. As with EBV, it is difficult to use live, attenuated viruses because of the establishment of persistent infection and the potential danger of malignancy development.[660] So far, the clearly successful approach in individuals with HIV has been the use of antiretroviral therapy, which has led to a marked decrease in the incidence of KS. This decrease in the incidence of KS is believed to be due to improvement in immune function, but a direct role on KS or KSHV has also been proposed.[198] Several reports have shown regression of AIDS KS following treatment with protease inhibitor–based therapy, suggesting that this approach may be better for patients with AIDS and a high risk of KS than the use of nucleoside or nonnucleoside reverse transcriptase inhibitors.[342,413,655] However, one relatively small prospective study found that both regimens with and without protease inhibitors can decrease KSHV viremia and result in clinical improvement of KS, which occurred more commonly in patients that had undetectable or very low HIV loads.[209] Since a direct effect of HIV infection in KS pathogenesis has been proposed (e.g., due to paracrine angiogenic effects of Tat), it could be argued that control of HIV infection itself may be partly responsible for the beneficial effects of antiretroviral therapy.[33] Nevertheless, there is evidence that protease inhibitors have a direct role on KSHV. In particular, nelfinavir has been found to inhibit KSHV replication using a recombinant virus assay at concentrations that are achieved in plasma with standard oral dosing.[199] Nelfinavir has also been found to reduce viral shedding, potentially limiting transmission.[200]

Prevention of KS may also be possible in high-risk individuals using inhibitors of lytic replication, such as valganciclovir, which has been found to reduce KSHV shedding.[93] One study where ganciclovir was used for the treatment of CMV retinitis in patients with HIV showed that the incidence of KS was markedly reduced by 75%.[412] While oral valganciclovir did not show beneficial effects on HIV-negative patients with established KS, it appears that compounds that inhibit KSHV lytic replication may have a role in preventing the spread of KSHV and the development of KS. However, ganciclovir-associated toxicities make this approach impractical as a preventive strategy.

A preventive approach would be ideal to reduce the global burden of KS, and studies are under way to tackle this issue. An eventual HIV vaccine could greatly diminish the global incidence of KS, and development of a KSHV vaccine can potentially eliminate it altogether. In contrast to most malignancies, the geographic location of the majority of KS patients in low-resource countries makes these studies challenging. Nevertheless, our increased understanding of the pathobiology of KS and our increased armamentarium of targeted agents and immunomodulators makes preventing and curing KSHV-associated diseases an achievable goal.

ACKNOWLEDGMENTS

CHAPTER 16

Poxviridae: The Viruses and Their Replication

Bernard Moss • Geoffrey L. Smith

Introduction
Classification
Virion structure
- Morphology
- Chemical composition
- Genome
- Polypeptide components

Cell entry
- General considerations
- MV entry
- EV entry and virus spread
- Cell–cell fusion

Gene expression
- Programmed expression of POXV genes
- Regulation of early-stage transcription
- Early-stage promoters and termination signals
- Enzymes and factors for early-stage transcription
- Regulation of intermediate-stage transcription
- Intermediate-stage promoters
- Enzymes and factors for intermediate-stage transcription
- Regulation of late-stage transcription
- Late-stage promoters and RNA processing signal
- Enzymes and factors for late-stage transcription
- Regulation of translation

DNA replication
- General features
- DNA replication models
- Enzymes involved in DNA precursor metabolism
- Viral proteins involved in DNA replication
- Concatemer resolution
- Homologous recombination

Virion assembly
- Overview
- Formation of crescent and IV membranes
- Association of the genome, core proteins, and transcription complex with IVs
- Removal of the D13 scaffold and proteolytic processing of virion proteins

Intramolecular disulfide bond pathway
Occlusion of MVs
Formation of EV
Overview
Wrapping
Intracellular movement and exocytosis
Actin tail formation
Virus–host interactions
Tropism and host range
Effects on the cytoskeleton
Effects on host macromolecular synthesis
Interactions with the ubiquitin-proteasome system
Stimulatory effects on cell pathways
Viral defense molecules
Overview
Extracellular defense proteins
Intracellular defense proteins
Adaptive immune response to poxviruses
Antivirals
Expression vectors
Acknowledgments

INTRODUCTION

The *Poxviridae* comprise a fascinating family of complex DNA viruses that replicate entirely in the cytoplasm of vertebrate or invertebrate cells. Two members of the family, variola virus (VARV), and molluscum contagiosum virus (MOCV) are obligate human pathogens, and others such as monkeypox virus (MPXV) are transmitted from animal hosts to humans and cause severe disease. VARV was the cause of smallpox, a once common and highly lethal disease that altered human history. Smallpox was eradicated in 1977 through a dedicated effort spearheaded by the World Health Organization, nearly two centuries after the introduction of highly effective prophylactic inoculations with cowpox virus (CPXV) and vaccinia virus (VACV). In addition to public health value, vaccination contributed to present concepts of infectious disease and immunity. From a historical perspective, VACV was the first animal virus seen microscopically, grown in tissue culture, accurately titered, physically purified, and chemically analyzed. Moreover, the general view of virus particles as packets of nucleic acid was revised following the discovery of RNA synthetic activity in purified poxvirus (POXV) virions. This finding sparked investigations that led to the discovery of transcriptase and reverse transcriptase activities in RNA viruses and to the elucidation of structural features of viral and eukaryotic mRNA, including the 5′ cap and 3′ poly(A) tail. Recombinant DNA technology eliminated obstacles to working with large viruses, and considerable progress has been made in elucidating the virus replication cycle. Discoveries of virus-encoded proteins that affect cell growth and modulate immune defense mechanisms continue to provide new insights into virus/host

relationships. In addition, the development of POXVs as live recombinant expression vectors provides a powerful tool for immunologists and biochemists as well as an alternative approach to the development of vaccines and therapeutics against a variety of infectious agents and cancer.

CLASSIFICATION

Distinguishing properties of the family *Poxviridae* include a cytoplasmic site of replication and a large complex enveloped virion, which contains enzymes that synthesize mRNA and a genome composed of a linear double-stranded DNA molecule of 128 to 380 kilobase pairs (kbp) with a hairpin loop at each end. POXVs are divided into the subfamilies *Chordopoxvirinae* and *Entomopoxvirinae*, based on vertebrate and insect host range (Table 16.1). DNA sequencing and bioinformatic analysis confirm the genetic relationship between the POXV subfamilies and further suggest that POXVs are distantly related to *Asfarviridae*, *Ascoviridae*, *Iridoviridae*, and *Phycodnaviridae* and the giant viruses *Mimiviridae*, *Marseilleviridae*, *Pandoraviridae*, and *Pithoviridae*.[366] These nucleocytoplasmic large DNA viruses (NCLDV) are believed to form a monophyletic group based mainly on the presence of about 40 genes that can be traced back to their last common ancestor.

TABLE 16.1 Family *Poxviridae*

Subfamily	Genus	Species[a]	DNA Genome
Chordopoxvirinae	*Avipoxvirus*	*Canarypox, Fowlpox*[b] (FWPV), *Juncopox, Mynahpox, Pigeonpox, Psittacinepox, Quailpox, Sparrowpox, Starlingpox, Turkeypox*	270 kbp, G + C ~35%
	Capripoxvirus	*Goatpox, Lumpy skin disease, Sheeppox*[b]	150 kbp, G + C 25%
	Centapoxvirus	*Yokapox*[b]	176 kbp, G + C 26%
	Cervidopoxvirus	*Mule deerpox*[b]	170 kbp, G + C 27%
	Crocodylipoxvirus	*Nile crocodilepox*[b]	190 kbp, G + C 62%
	Leporipoxvirus	*Hare fibroma, Myxoma,*[b] *Rabbit fibroma, Squirrel fibroma*	160 kbp, G + C 40%
	Macropoxvirus	*Eastern kangaroopox,*[b] *Western kangaroopox*	173 kbp, G + C 58%
	Molluscipoxvirus	*Molluscum contagiosum*[b]	190 kbp, G + C ~60%
	Mustelpoxvirus	*Sea otterpox*[b]	128 kbp, G + C 31%
	Orthopoxvirus	*Camelpox* (CMLV), *Cowpox* (CPXV), *Ectromelia* (ECTV), *Monkeypox* (MPXV), *Raccoonpox, Skunkpox, Taterapox* (TATV), *Vaccinia*[b] (VACV), *Variola* (VARV), *Volepox*	190 kbp, G + C 36%
	Oryzopoxvirus	*Cotia*[b]	185 kbp, G + C 24%
	Parapoxvirus	*Bovine papular stomatitis, Orf,*[b] *Parapoxvirus of red deer, Pseudocowpox*	140 kbp, G + C 64%
	Pteropoxvirus	*Pteropox*[b]	134 kbp, G + C 34%
	Salmonpoxvirus	*Salmon gillpox*[b]	242 kbp, GC 38%
	Sciuripoxvirus	*Squirrelpox*[b]	148 kbp G + C 67%
	Suipoxvirus	*Swinepox*[b]	146 kbp, G + C 28%
	Vespertilionpoxvirus	*Eptesipox*[b]	177 kbp, G + C 24%
	Yatapoxvirus	*Tanapox, Yaba monkey tumor*[b]	135 kbp, G + C 30%
Entomopoxvirinae	*Alphaentomopoxvirus*	*Anomala cuprea, Aphodius tasmaniae, Demodema boranensis, Dermolepida albohirtum, Figulus subleavis, Geotrupes sylvaticus, Melolontha melolontha*[b]	246 kbp, G + C 20%
	Betaentomopoxvirus	*Acrobasis zelleri, Adoxophyes honmai, Amsacta moorei,*[b] *Arphia conspersa, Choristoneura biennis, C. conflicta, C. diversuma, C. fumiferana, C. rosacea, Chorizagrotis auxiliars, Heliothis armiger, Locusta migratoria, Mythimna separata, Oedaleus senegalensis, Operophtera brumata, Schistocerca gregaria*	228–307 kbp, G + C 20%
	Deltaentomopoxvirus	*Melanoplus sanguinipes*	236 kbp, G + C 18%
	Gammaentomopoxvirus	*Aedes aegypti, Camptochironomus tentans, Chironomus attenuatus, C. luridus,*[b] *C. plumosus, Goeldichironomus haloprasimus*	~250–380 kbp

[a]Four-letter abbreviations of species used in text appear in parentheses.

[b]Prototypal member.

The subfamily *Chordopoxvirinae* consists of 18 genera (Table 16.1). Members of the same genus are genetically and antigenically related and have a similar morphology and host range. Salmon gill poxvirus is the deepest representative of the *Chordopoxvirinae*.[263] The orthopoxviruses (OPXVs) have been studied most intensively. The species names frequently refer to the host from which the virus was first isolated rather than the reservoir species, for example, rodents are reservoirs for CPXV and MPXV. VACV, the prototype OPXV, has been propagated as the smallpox vaccine and its natural host remains unknown, although vaccine-derived strains are currently circulating in cattle in Brazil and occasionally infect humans.[179] DNA sequencing reveals that genes common to camelpox virus (CMLV), CPXV, ectromelia virus (ECTV), MPXV, taterapox (TATV), VACV, and VARV share greater than 90% nucleotide identity, whereas OPXVs indigenous to the USA (e.g., raccoonpox, skunkpox, and volepox virus) exhibit greater genetic divergence. CPXV contains all genes present in other OPXVs, suggesting that it resembles the ancestral member of this genus, whereas other species have genes that are deleted or disrupted. Recent analyses suggest that more than one species of OPXV have been grouped under the CPXV species.[239] The entomopoxviruses are divided into four genera based in part on the insect host of isolation (Table 16.1).

VIRION STRUCTURE

Morphology

The basic infectious form of a POXV is the mature virion (MV), which has a barrel shape and is composed of an outer membrane, a dumbbell-shaped core, and lateral bodies within the concavities.[168] For VACV, dimensions of approximately 360 × 270 × 250 nm were derived by cryoelectron tomography[158] (Fig. 16.1). The thickness (5 to 6 nm) and density of the outer layer is consistent with one lipid membrane bilayer, the outside of which appears corrugated because of irregular protrusions extending 3 to 5 nm. The core wall seems to be composed of two layers with an overall thickness of 18 to 19 nm. The inner layer appears continuous, except for a small number of channels. The outer layer has a palisade structure made of T-shaped spikes (8 nm in length and 5 nm wide) that are anchored in a putative inner membrane. Freeze fracture and deep etch electron microscopy confirm both the outer structure of the virion as consisting of a single membrane bilayer with surface corrugations and the palisade structure of the core wall but evidence for an inner membrane was not found.[292] The ultrastructure of the core appears to consist of two phases: the denser layer just under the core wall has a fiber-like morphology suggesting nucleoprotein. Cylindrical elements that may take an S-shape representing nucleoprotein have been visualized within POXV cores.[333,548]

Chemical Composition

The mass of a VACV MV is 9.5 fg.[279] The principal components of the MV are protein, lipid, and DNA, accounting for 90%, 5%, and 3.2%, respectively, of the dry weight.[817] In contrast, about one-third of fowlpox virus (FWPV) virions is lipid.[417] The lipid components of VACV MVs are predominantly cholesterol and phospholipids,[145] whereas FWPV virions also contain squalene and cholesterol esters.[417] Carbohydrate is present in the VACV extracellular virion (EV) as a constituent of glycoproteins. Spermine and spermidine[384] and trace amounts of RNA[594] have been found in VACV MVs.

Genome

POXVs have linear double-stranded DNA genomes that vary from 140 kbp in parapoxviruses to over 300 kbp in some avipoxviruses. The ends of the genome consist of identical but oppositely oriented sequences referred to as inverted terminal repetitions (ITRs). The ITRs include an A+T-rich, incompletely base-paired, hairpin loop that connects the two DNA strands[53]; a highly conserved region of less than 100 bp that contains sequences required for the resolution of replicating concatemeric forms of DNA[190,458]; sets of short, tandemly repeated sequences; and up to several open reading frames (ORFs). The ends of the VACV genome are depicted in Figure 16.2. The ITRs are variable in length due to deletions, repetitions, and transpositions.

Complete genome sequences have been reported for at least one member of each chordopoxvirus and three entomopoxvirus genera. Nearly 100 genes are conserved in all chordopoxviruses and about half of these can be recognized in entomopoxviruses.[742] Based on the above, several generalizations can be made: genes are largely nonoverlapping, tend to occur in blocks pointing toward the nearer end of the genome, are usually located in the central region if highly conserved and concerned with essential replication functions, and are usually located in

the end regions if variable and concerned with host interactions. An ORF map of the VACV genome is shown in Figure 16.3. The arrangement of the central genes is remarkably similar in all chordopoxviruses. A convention for naming VACV ORFs, originating prior to sequencing the entire genome and used for the complete sequence of the Copenhagen (CPN) strain of VACV, consists of using the HindIII restriction endonuclease DNA fragment letter, followed by the ORF number (from left to right except for HindIII C) within the fragment, and L or R, depending on the direction of transcription. Protein names correspond to ORF names, except that L or R is dropped. In addition, ORFs have been numbered successively from one end of the genome to the other in most subsequent complete POXV genome sequences; nevertheless, the old letter designations have been retained as common names for homologs to provide continuity in the literature. The ORF number of the Western Reserve (WR) strain of VACV, which has been used for the majority of biochemical and genetic studies, is included in tables.

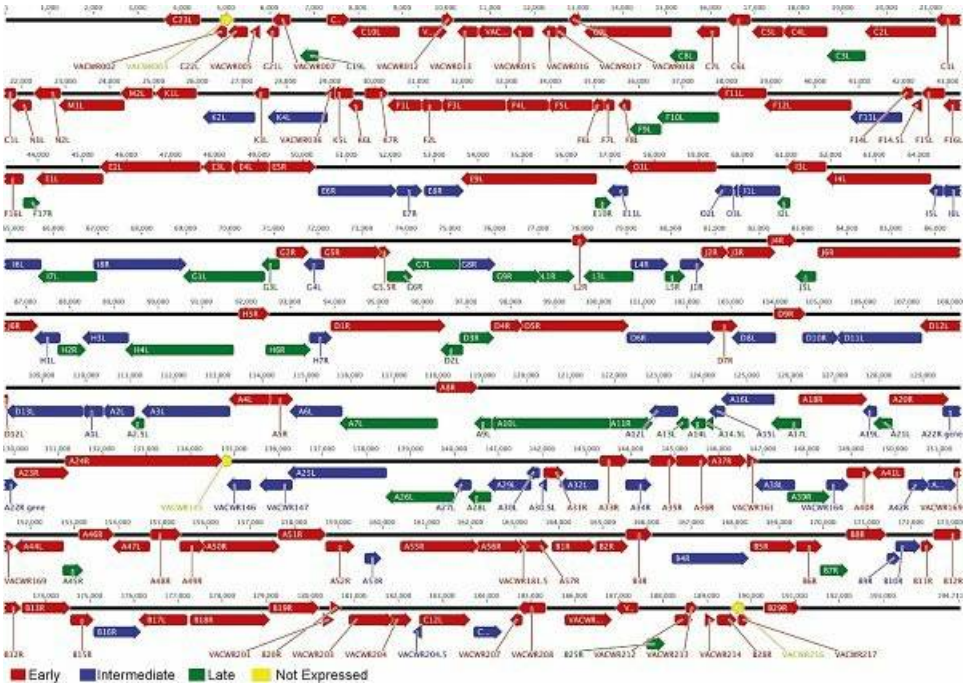

FIGURE 16.3 Transcriptional map of the VACV genome. VACV WR ORFs are shown as *colored arrows* indicating the direction of transcription. When applicable, the common (Copenhagen) HindIII fragment letter/number name was used to identify ORFs; otherwise, the VACV WR number was provided. The numbers from 1 to 194,711 indicate the nucleotide positions on the VACV genome. Each ORF has been assigned the stage at which its earliest expression can be detected; additional promoter elements that potentially contribute to later stages of gene expression are not indicated. (Adapted from Yang Z, Reynolds SE, Martens CA, et al. Expression profiling of the intermediate and late stages of poxvirus replication. *J Virol* 2011;85(19):9899–9908. Ref.[810])

Polypeptide Components

Consistent with their size and complex structure, POXV virions contain a multitude of polypeptides.[150] Approximately 80 virus-encoded polypeptides have been identified by mass spectrometry[507,580] and approximately 30 have been localized near the exterior of purified MVs by surface-specific labeling, sensitivity to proteases, extraction with nonionic detergents, or reactivity with virus-neutralizing antibodies. Several methods have been used to investigate membrane protein interactions including chemical cross-linking.[462] The surface proteins can be divided structurally into those with transmembrane domains and those without and functionally into those required for attachment, entry, disulfide bond formation, morphogenesis, and virulence (Table 16.2). None of the MV membrane proteins have signal peptides or are glycosylated, suggesting novel trafficking mechanisms.

Virus cores isolated by sedimentation following treatment of MVs with a nonionic detergent and reducing agent contain approximately 50 polypeptides. Of these, approximately 30 are enzymes of which at least half directly participate in early mRNA biosynthesis (Table 16.3); the nonenzymatic proteins may be primarily involved in morphogenesis and structure (Table 16.4). F17, L4, A3, and A10 are particularly abundant. L4 and the transcription system have been localized to the nucleocapsid; A3, A4, and A10 to the core wall; and F17, G4, and H1 to the lateral bodies.[490,619] Cross-linking reveals numerous interactions between core proteins.[462]

[c]Conservation in all POXV (P) or chordopoxviruses (C).

Evidence for a distinct extracellular form of VACV first came from vaccine-related studies. Antibodies to inactivated MVs did not protect rodents against an OPXV infection as well as antibodies to live virus or inactivated EVs.[90] Subsequent studies showed that the EV has an additional outer membrane, which is a target of protective antibodies, and consequently a lower buoyant density.[590] The additional membrane contains several unique glycosylated proteins (A33, A34, A56, B5, K2) and one nonglycosylated (F13) (Table 16.5). Of the six EV membrane proteins, only A34 and F13 are conserved in all chordopoxviruses. Although EVs are usually considered to be MVs with an additional membrane, that is not precisely true. There is evidence that MVs contain at least two surface proteins A26 and A25 that are absent from EVs.[736]

TABLE 16.5 VACV WV and EV membrane proteins

CELL ENTRY

General Considerations

Studies of POXV entry are usually carried out with VACV, which can enter most tissue culture cells suggesting either the absence of a specific receptor or receptors that are ubiquitous. A special feature of POXVs is the existence of two infectious forms: MVs (also called intracellular mature virion, IMV), which have a single outer membrane containing the proteins necessary for fusion, and EVs, which have an additional membrane that is disrupted prior to entry. Although the MV is the more abundant form, the EV is specialized for spread from cell-to-cell and within an infected host. VACV encodes at least four attachment proteins and eleven that comprise the entry fusion complex (EFC) (Table 16.2). Additional descriptions and references may be found in recent reviews.[476,618]

MV Entry

Enveloped viruses typically enter cells by fusion with the plasma or endocytic membrane. VACV MVs use both entry mechanisms (Fig. 16.4A and B), perhaps contributing to their ability to enter most cells. OPXVs that have not undergone extensive *in vitro* passaging preferentially employ the endosomal pathway.[68] Endosomal acidification promotes entry of the virus core into the cytoplasm following actin-dependent macropinocytosis or fluid-phase uptake of the large virus particles,[313,453,725] although there is some disagreement regarding later steps in the endosomal trafficking pathway.[306,588] Preferential use of the endosomal pathway depends in part on the A26 protein, which binds components of the EFC and acts as a suppressor of neutral pH

fusion.[131] Low pH activation of MVs[724] can be explained by conformational changes of A26.[130]

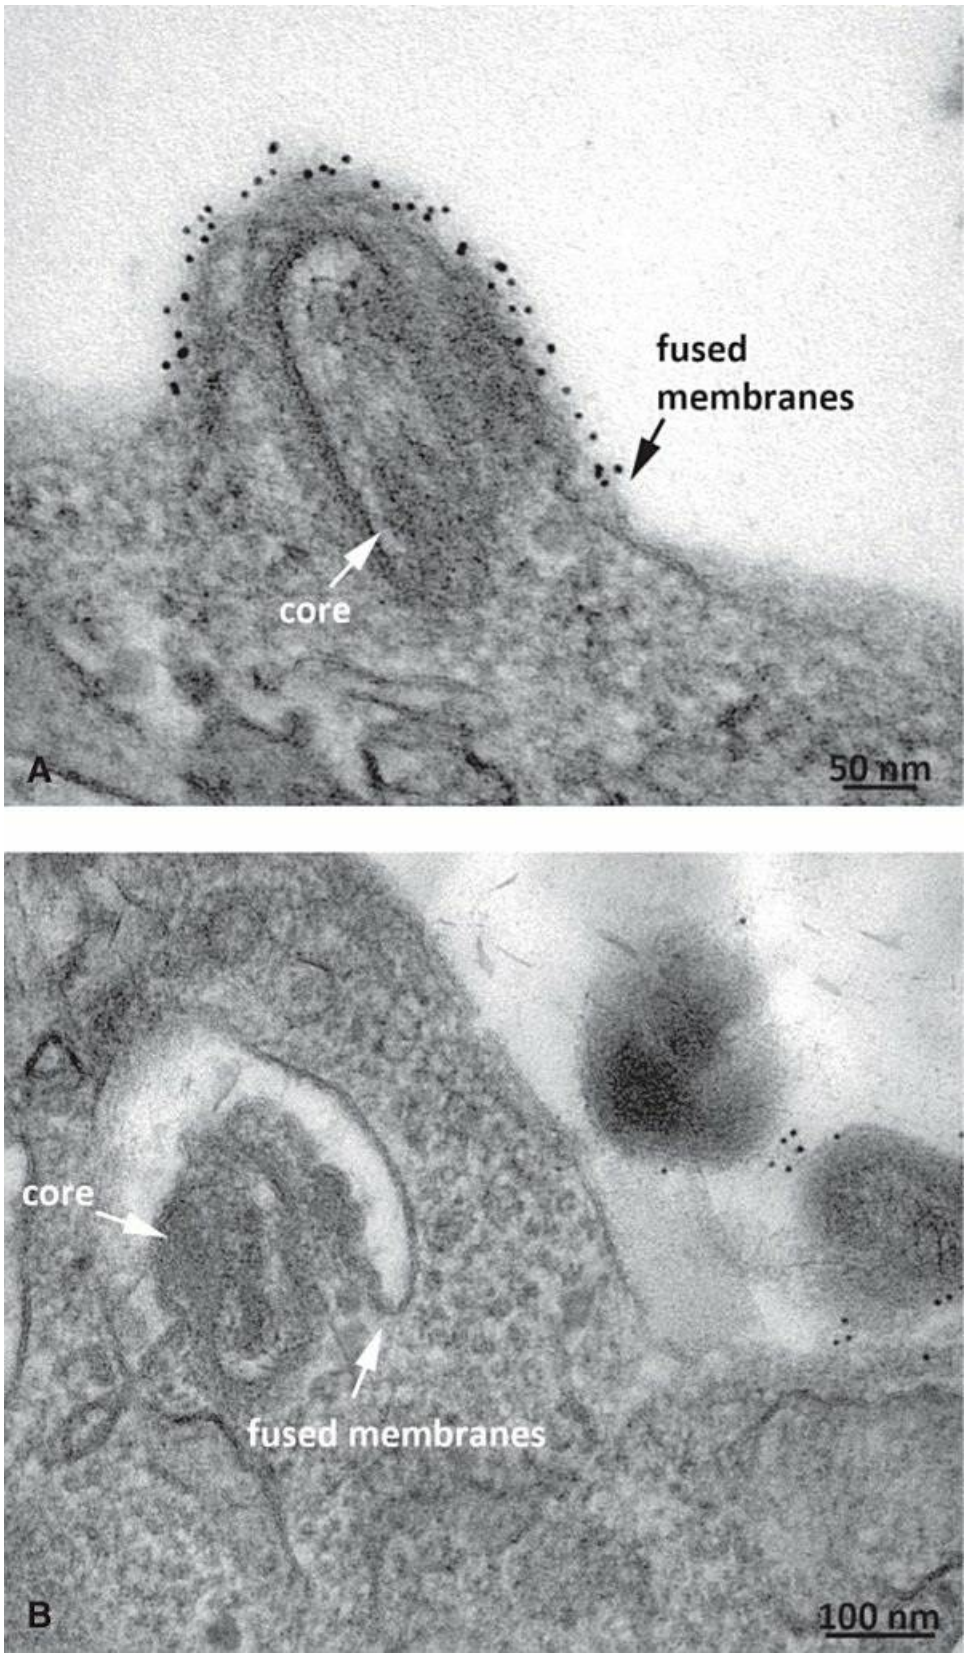

FIGURE 16.4 VACV MVs fusing with plasma and endosomal membranes. VACV

MVs were deposited on the cell surface by spinoculation and incubated at 37°C for 30 minutes. Unpermeabilized cells were incubated with antibody to the D8 membrane protein and labeled with Protein A conjugated to gold spheres. The gold particles are present on the viral membrane that has fused with the plasma membrane **(A)** but not on the viral membrane that has fused with the endosomal membrane **(B)**. (Images provided by A. Weisberg.)

The four VACV attachment proteins are D8, which binds chondroitin sulfate[307]; A27 and H3, which bind heparan sulfate[143,395]; and A26, which binds laminin.[140] The attachment proteins provide some redundancy as individually they are not essential. Only D8 and H3 have transmembrane domains. A26 and A27 interact with each other, and the A17 transmembrane protein anchors the latter.[302,761] The crystal structure of a truncated trimeric form of A27[132] and the tetrameric ectodomain of D8 with a crevice predicted to be the chondroitin-binding site[435] have been solved.

The eleven protein components of the entry–fusion complex (EFC) listed in Table 16.2 are dedicated to entry and conserved in all POXVs.[478,639] The EFC proteins, A16, G9, and J5, are related in sequence as are L1 and F9 suggesting they derive from common genes early in POXV evolution. The EFC proteins vary in size from 4 to 43 kDa, are nonglycosylated, and resemble neither type 1 nor type 2 fusion proteins of other viruses. Except for G3 and O3, the EFC proteins contain conserved intramolecular disulfide bonds that are formed by a cytoplasmic redox system, which is also encoded by all POXVs and will be described below. The EFC proteins are not required for attachment of virions to cells, although the purified L1 ectodomain can bind to the cell surface and reduce MV entry.[237] Entry of VACV is a two-step process comprising lipid mixing (hemifusion) followed by pore formation. Most of the EFC proteins are needed for the first step and all for the second.[382] The anatomy of the complex has not yet been determined, although some interacting partners have been identified and the related atomic structures of L1[699] and F9[203] have been determined (Table 16.2). L1 contains a hydrophobic cavity capable of shielding a myristate moiety suggesting a myristate switch model.[238] The VACV A17 and A27 proteins have also been implicated in membrane fusion,[362] possibly by localizing the entry proteins at the tips of the virion.[268]

Interaction of the MV with the cell surface triggers a signaling cascade that results in membrane rearrangements and the formation of actin-containing protrusions that envelope the virus and are important for fusion of viral and cellular membranes.[382,453] The lipid composition of the cell membrane is important as depletion of cholesterol inhibits virus penetration.[144] Specific fusion activation receptors have not been confidently determined, although the epidermal growth factor receptor[427] and chemokine receptors[379] have been suggested. Infectivity can be increased by incubating MVs with phosphatidylserine,[324] and an apoptotic mimicry model with a role for a specific phosphatidylserine receptor has been suggested based on reconstitution of delipidated virus.[453] However, phospholipids not known to signal apoptotic uptake can also reconstitute infectivity, indicating that the putative receptor has broad specificity or that the phospholipids have a different role in enhancement of infectivity.[380]

Superinfection exclusion mechanisms prevent fusion of MVs with infected cells that have the A56-K2 heterodimer on the plasma membrane at late times after infection; the mechanism

involves interaction of A56-K2 with the A16 and G9 subunits of the EFC.[758] Another mode of superinfection exclusion prevents membrane fusion and entry at earlier times after infection.[381]

EV Entry and Virus Spread

Efficient cell-to-cell spread of VACV is mediated largely by EVs (sometimes called cell-associated EVs or CEVs) that adhere to the cell surface at the ends of long, mobile, finger-like projections that are formed by actin polymerization as illustrated in Figure 16.5.[81,694] Spread to uninfected cells may be enhanced by a repulsion mechanism that hinders superinfection of cells that express the A33 and A36 proteins on the plasma membrane and generate new actin protrusions.[206] Deletion of the A33R, A34R, or A36R ORF (Table 16.5) prevents actin tail formation and reduces the efficiency of virus spread.[600,604,791] However, mutations of the A33, A34, or A36 proteins, which cause enhanced release of free EVs, can overcome a deficiency in actin tail formation restoring spread.[81,351]

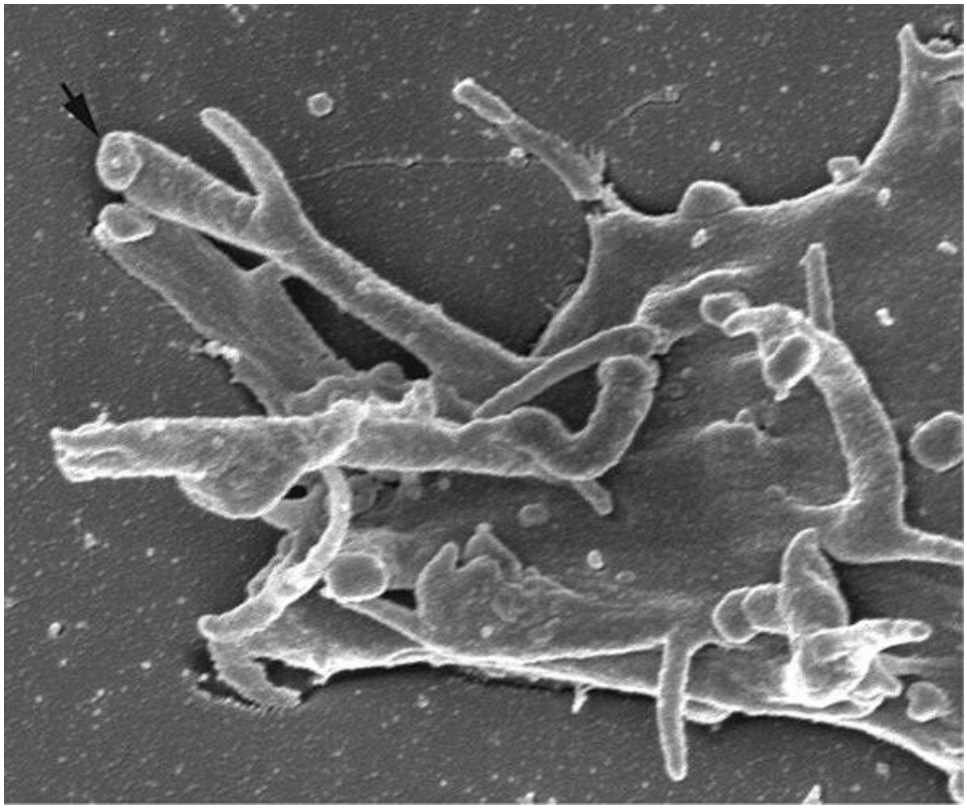

FIGURE 16.5 Scanning electron microscopy of cell infected with VACV. BS-C-1 cells were infected with VACV for 20 hours and then fixed and coated with palladium gold. The *arrow* points to an EV at the tip of a virus-induced actin-containing microvillus. (Image kindly provided by A. Weisberg.)

For technical reasons, most entry studies of EVs have been carried out with free particles, even though the outer membrane is fragile and not always intact. EVs may enter by

endocytosis[322,617] or by fusion at the plasma membrane beneath a disrupted EV membrane.[387] Disruption at the plasma membrane is dependent on polyanionic molecules or low pH and requires the membrane glycoproteins A34 and B5.[387,589]

Cell–Cell Fusion

Two types of cell–cell fusion have been described: fusion from within and fusion from without. The former occurs late in infection, is dependent on progeny virions on the cell surface, and is triggered by lowering the pH or mutations in the A56 hemagglutinin or K2 glycoprotein.[631,733] Fusion from without is induced by infecting cells at a high multiplicity and then lowering the pH, which causes changes in the A26 protein also discussed above. Both types of cell–cell fusion require the EFC and mimic the entry pathway.[758] Unmutated A56-K2 prevents fusion by interacting with the A16-G9 components of the EFC.

GENE EXPRESSION

Programmed Expression of POXV Genes

Studies primarily with VACV have led to an understanding of the POXV gene expression program (Fig. 16.6), which occurs exclusively in the cytoplasm: (a) A complete early transcription system is present within the core of virus particles, providing for the synthesis of viral early mRNAs soon after infection; (b) the early mRNAs encode enzymes and factors needed for synthesis of viral DNA and for transcription of the intermediate class of genes; (c) the intermediate gene transcripts encode enzymes and factors for late gene expression; (d) the products of the late genes include the early transcription factors, which are packaged with the viral RNA polymerase (vRNAP) and other enzymes in progeny virions. Most reports refer to postreplicative gene products as late without distinguishing between intermediate and late classes, although progress in resolving them has been made[810] as shown in the transcription map (Fig. 16.3).

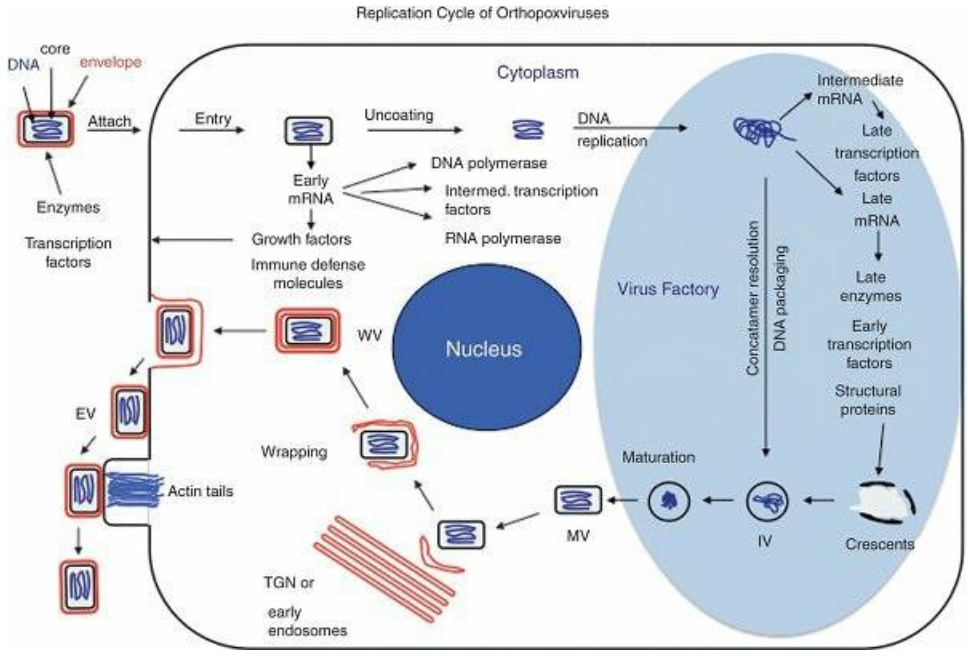

FIGURE 16.6 Replication cycle of VACV. Virions, containing a double-stranded DNA genome, enzymes, and transcription factors, attach to cells and fuse with the cell membrane, releasing cores into the cytoplasm. The cores synthesize early mRNAs that are translated into a variety of proteins, including growth factors, immune defense molecules, enzymes, and factors for DNA replication and intermediate transcription. Uncoating occurs and the DNA is replicated to form concatemeric molecules. Intermediate genes in the progeny DNA are transcribed, and the mRNAs are translated to form late transcription factors. Late genes are transcribed and the mRNAs are translated to form virion structural proteins, enzymes, and early transcription factors. Assembly begins with the formation of discrete membrane structures. Concatemeric DNA intermediates are resolved into unit genomes and packaged in immature virions. Maturation proceeds to the formation of infectious intracellular mature virions (MVs). The virions are wrapped by modified trans-Golgi and endosomal cisternae, and the wrapped virions (WVs) are transported to the periphery of the cell via microtubules. Fusion of the wrapped virions with the plasma membrane results in release of extracellular enveloped virions (EVs).

Regulation of Early-Stage Transcription

Infectious POXV particles contain a transcription system that synthesizes mRNAs that are capped, methylated, and polyadenylated.[344,773] A large number of virus-encoded enzymes and factors that are directly involved in the synthesis or modification of mRNA have been isolated. These include a multisubunit DNA-dependent vRNAP, vRNAP-associated protein of 94-kDa (RAP94), early transcription factor (VETF), capping and methylating enzymes, poly(A) polymerase, nucleotide phosphohydrolase I (NPH I), and topoisomerase (Table 16.3). Additional virion-associated enzymes may participate in transcription within the virus core or remain after carrying out roles in virion assembly, protein processing, or DNA packaging.

Following entry into the cytoplasm, virus cores are transported on microtubules to a

juxtanuclear region[125,422] and mRNA synthesis is detected within 20 minutes[44] (Fig. 16.7). RNA/DNA hybridization studies revealed that about half of the VACV genome is transcribed prior to DNA replication,[86,525] and genome tiling and deep RNA sequencing have corroborated this.[38,808] The 118 early ORFs that have been identified tend to cluster near the two ends of the genome (Fig. 16.3). Early genes can be divided into two groups based on kinetic cluster analysis of transcripts and temporal proteomic analysis,[38,679] but both groups are transcribed in the presence of protein synthesis inhibitors and are classified as immediate early.[808] The cessation of early gene expression coincides with disruption of the virus core, a process known as uncoating that will be discussed later. If uncoating is prevented by protein synthesis inhibitors, early mRNA synthesis is increased and prolonged,[44,795] suggesting that under normal conditions, core disassembly leads to inactivation of the early transcription apparatus.

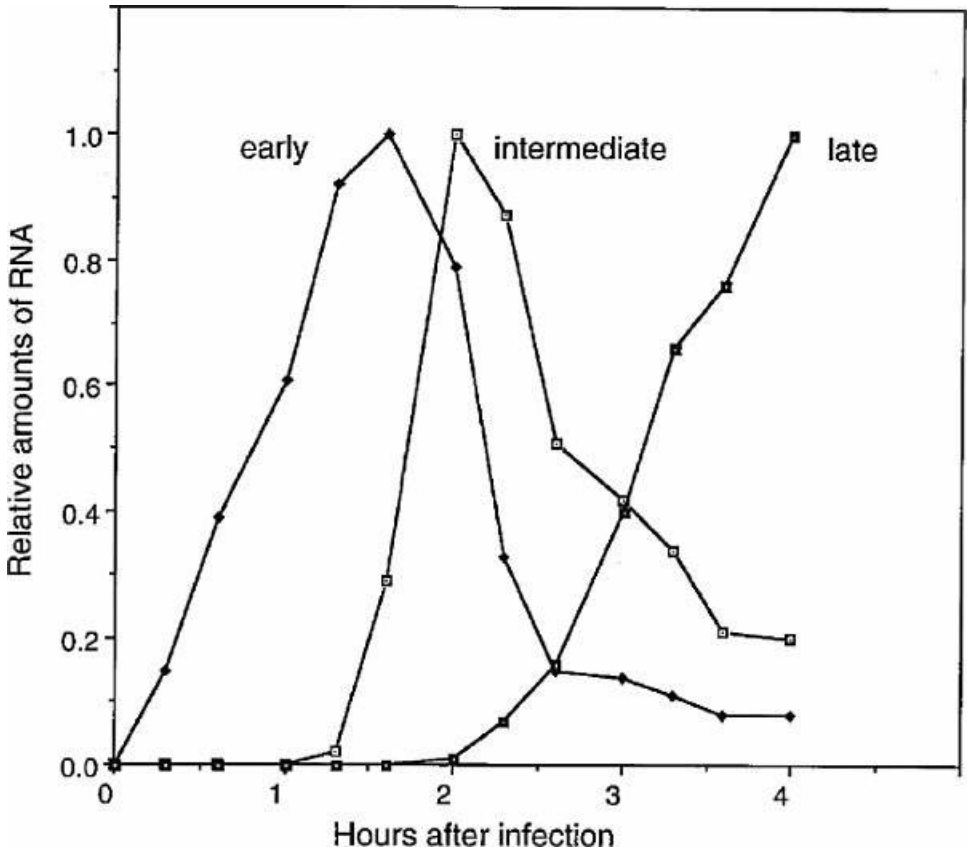

FIGURE 16.7 Steady-state levels of representative early, intermediate, and late-stage mRNAs in VACV-infected cells. Total RNA was isolated from infected HeLa cells at various times after infection and hybridized to antisense RNA probes specific for the 5′-ends of mRNAs encoded by the C11R (early), G8R (intermediate), or F17R (late) ORFs.[44] After ribonuclease digestion, the protected probe fragments were analyzed by polyacrylamide gel electrophoresis and the radioactivity quantified. The numbers were normalized to the peak value in each case.

The rapid decline of steady-state early mRNA levels (Fig. 16.7) is due to an enhanced rate of

mRNA degradation in addition to cessation of transcription. Removal of the cap by the D9 and D10 decapping enzymes[530-533] is followed by activity of the cellular 5′exonuclease Xrn1.[110,411] Rapid mRNA turnover may be advantageous in eliminating cellular mRNA and decreasing viral early mRNA to enhance translation of intermediate and late transcripts. Another important role of the decapping enzymes is to prevent the accumulation of double-stranded RNA (dsRNA).[411]

Early-Stage Promoters and Termination Signals

Transcription of early genes is determined by an A/T-rich sequence upstream of the RNA start site. Saturation mutagenesis of a VACV early promoter defined a critical core region, from −13 to −25 relative to the RNA start site.[173] The consensus core sequence derived from an analysis of the region upstream of all annotated early start sites[807] is consistent with the mutagenesis studies (Fig. 16.8). Transcription initiation occurs with a purine, predominantly 12 to 17 nucleotides downstream of the core region. Many more transcription starts than annotated ORFs have been revealed by deep sequencing, but their significance is not yet understood. Promoter motifs are conserved between POXV genera, explaining genetic reactivation, which consists of rescue of a heat-inactivated POXV by coinfection with a second UV-inactivated POXV of a different genus.[233,283] An explanation is that heat-killed POXVs provide intact templates and the UV-inactivated POXVs provide the transcription apparatus and early gene products.

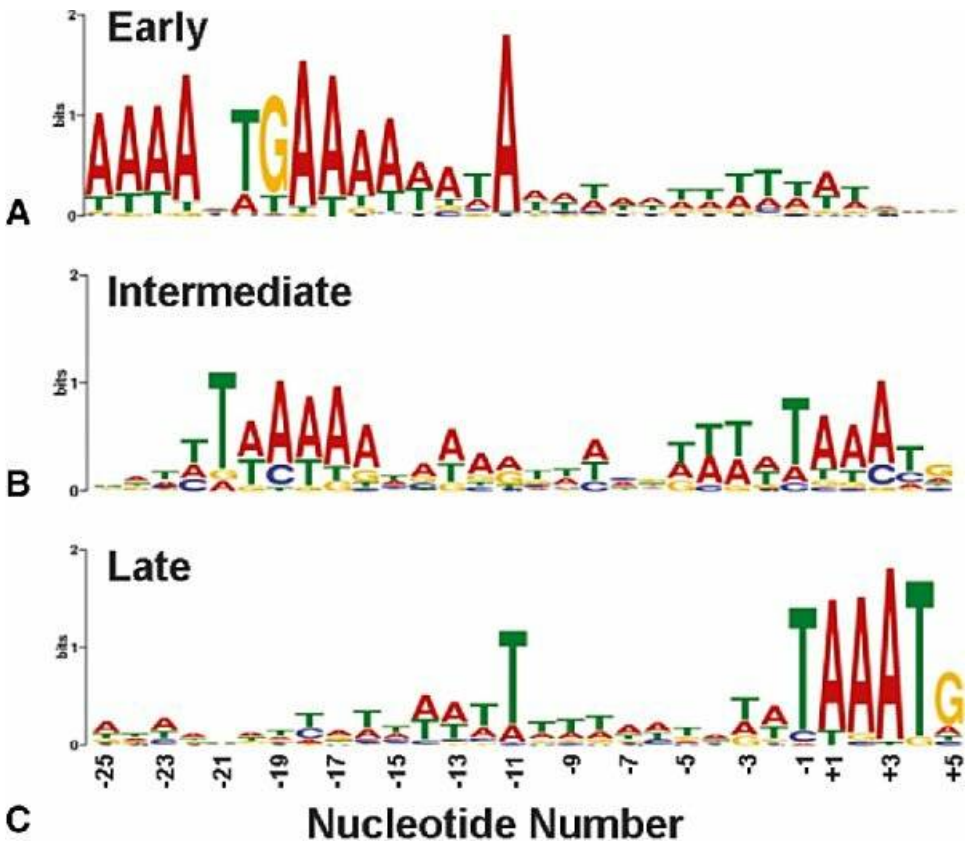

FIGURE 16.8 Motif logos of VACV promoters. Motifs represent early genes **(A)**, intermediate genes **(B)**, and late genes **(C)**. +1 represents the RNA start site. (Adapted

from Yang Z, Bruno DP, Martens CA, et al. Genome-wide analysis of the 5′ and 3′ ends of vaccinia virus early mRNAs delineates regulatory sequences of annotated and anomalous transcripts. *J Virol* 2011;85(12):5897–5909; Yang Z, Reynolds SE, Martens CA, et al. Expression profiling of the intermediate and late stages of poxvirus replication. *J Virol* 2011;85(19):9899–9908. Refs.[807,810])

The transcription of VACV early genes usually stops 20 to 50 bp downstream of the sequence TTTTTNT (T5NT)[815] and the transcripts are then polyadenylated. Mechanistically, termination is mediated by U5NU in RNA.[658] The T5NT sequences are present near the ends of most but not all viral early genes. When absent, the mRNA tail may extend through the next gene downstream. *In vivo* studies suggested that the efficiency of termination following a single T5NT is about 80%,[213] although in some cases, it may be less due to RNA secondary structure.[415] T5NT sequences have been noted near the ends of putative early genes of other POXV genera suggesting a similar role in termination. A VACV genome-wide analysis of the 3′ ends of early mRNAs revealed that about two-thirds have a T5NT sequence implying an additional termination mechanism for the remainder.[807] A pyrimidine-rich sequence in the coding strand up to position −25 relative to the polyadenylation site was found regardless of the presence of T5NT, suggesting that it may also facilitate termination.

Enzymes and Factors for Early-Stage Transcription

The vRNAP has eight subunits ranging from 7- to 147-kDa[52] with 20% or less amino acid identities to host RNA polymerase II subunits.[271,359] RPO30 is an exception with approximately 23% identity to eukaryotic transcription elongation factor SII (TFIIS), which has 3′ exonuclease activity that relieves stalled polymerase. The VACV elongation complex also has a 3′ RNase activity that permits resumption of transcription by stalled polymerase likely mediated by RPO30.[281] The structure of the VACV vRNAP was recently solved by cryo-electron microscopy (EM)[271] and ribbon diagrams of the elongating core enzyme showing the positions of the template DNA and RNA are seen in Figure 16.9A.

The core vRNAP is insufficient to transcribe VACV genome templates, and additional factors present in a larger enzyme complex are needed.[104] The structure of the holoenzyme determined by cryo-EM (Fig. 16.9B) reveals 7 polypeptides in addition to the 8 subunits of vRNAP.[271] The RAP94 polypeptide encoded by the H4L gene serves as a bridge between vRNAP and transcription and processing factors.[271,824] Biochemical studies demonstrated that RAP94 is specifically required for transcription of early promoter templates[6,196] and partially resembles RNA polymerase II transcription factor TFIIB.[271] Synthesis of RAP94 occurs late, at the time of virion assembly, consistent with its role in early transcription. In contrast, the genes encoding the core vRNAP subunits are expressed both pre- and post-DNA replication because they are also needed for intermediate and late transcription.

VETF, a heterodimer of 82- and 70-kDa subunits, is a specific early transcription factor.[105,258] Like RAP94, VETF is synthesized only late during infection. The protein binds to the core region of early promoters and to DNA downstream of the RNA start site, thereby altering the conformation of the DNA.[102,127,814] A DNA-dependent ATPase activity associated with the small subunit of VETF has a role post-promoter binding.[282,392] VETF associates with

vRNAP through direct interaction with RAP94[271,809] (Fig. 16.9B).

Early viral transcripts made *in vivo* or *in vitro* are capped[85,773] and polyadenylated[344] like eukaryotic mRNAs. RNAs synthesized by virus cores contain a cap I structure that consists of a terminal 7-methylguanosine connected via a triphosphate bridge to a 2′-*O*-methylribonucleoside. The N^7-methylguanosine component of the cap is required for mRNA stability and translation of VACV mRNA,[495] whereas ribose methylation prevents inhibition of translation by the interferon (IFN)-inducible IFIT proteins.[166] The VACV capping enzyme was the first such enzyme to be purified and characterized.[429,430,753] The steps in cap formation are (a) removal of the terminal phosphate of the triphosphate end of the nascent RNA to form a pp(5′)N-terminus, (b) transfer of a GMP residue from GTP to form G(5′)ppp(5′)N-, (c) transfer of a methyl group from *S*-adenosylmethionine to produce m^7G(5′)ppp(5′)N-, and (d) transfer of a second methyl group to form m^7G(5′)ppp(5′)Nm. The first three reactions are catalyzed by the virus-encoded 127-kDa capping enzyme heterodimer.[428] The capping enzyme large subunit forms a covalent lysyl-GMP intermediate.[657] The RNA triphosphatase, guanylyltransferase, and N^7-methyltransferase activities all reside in the large subunit; the small subunit binds to the methyltransferase domain and stimulates the activity of the latter allosterically.[375] Both subunits are expressed early in infection.[473,510] The capping enzyme is associated with the VACV vRNAP through interaction with RAP94 (Fig. 16.9B) and capping occurs during transcription when the nascent RNA chains are approximately 30 nucleotides long.[280]

Ribose methylation of the penultimate nucleoside is mediated by a separate viral nucleoside 2′-MTase.[51] This MTase is a 39-kDa protein that exists as a monomeric species and also as the VP39 subunit of poly(A) polymerase.[621] High-resolution X-ray crystal structures of the MTase complexed to its methyl donor and mRNA cap have been obtained.[299] Viral mRNAs synthesized *in vivo* have additional base and ribose methylations that are catalyzed by cellular enzymes.[85]

The enzyme that catalyzes poly(A) tail formation is a heterodimer of virus-encoded 55- and 39-kDa subunits called VP55 and VP39, respectively.[256,489] VP55 binds to uridylate sequences near the end of the RNA chain and catalyzes the processive addition of approximately 30 adenylate residues before changing to slow and nonprocessive addition.[260,813] VP39 binds poly(A) and stimulates VP55 to add additional adenylates.[259] The processivity and MTase activities of VP39 are independent since mutated forms that lack MTase retain adenylyltransferase stimulatory activity.[622,648] Genetic and biochemical studies indicate an additional role of VP39 as an RNA elongation factor for intermediate and late RNA synthesis.[386,798] The finding that the capping enzyme/termination factor and the ribose MTase/poly(A) polymerase processivity factor function at the 5′ and 3′ ends of the mRNA is intriguing. The association of such apparently disparate functions in the same enzymes may provide a specific advantage or represent an economical use of proteins.

Both capping enzyme and NPH I are needed to release nascent mRNA containing a U5NU sequence from the transcription complex in an ATP-dependent reaction.[142,296] The physical interaction of NPH I with RAP94 (Fig. 16.9B) explains the specificity of this termination system for early transcripts.[271,550] NPH I also serves as a polymerase elongation factor to facilitate read-through of intrinsic pause sites.[195]

The minimal components for synthesis of correctly initiated, terminated, capped, and polyadenylated mRNAs were defined by *in vitro* reconstitution assays. However, several

additional proteins are needed within the virus core. These include the DNA topoisomerase,[162] NPH II,[274] the H1 serine/tyrosine phosphatase,[406] the L4 DNA-RNA binding protein,[780] and the L3[581] and E8[346] proteins. E11, a previously described core protein known to be required for infectivity,[766] interacts with RAP94 and associates with the vRNAP complex.[271] The *in vitro* activity of the topoisomerase, which relaxes supercoiled DNA, has been studied extensively.[576]

Regulation of Intermediate-Stage Transcription

Amino acid labeling and transcription studies indicate the existence of an intermediate class of genes that are expressed after DNA replication but before expression of stringent late genes[44,757] (Fig. 16.7). The number of VACV genes belonging to the intermediate class is estimated to be about 53.[810] Three of the intermediate genes (A1L, A2L, and G8R) encode late-stage transcription factors,[352] and others include DNA binding/packaging and core-associated proteins.

Because the intermediate transcription factors are early proteins, the DNA replication requirement for intermediate gene expression may result from inaccessibility of the genome within the infecting particles. This hypothesis is consistent with transfection experiments showing that transfected genomic DNA or recombinant plasmids can serve as a template for intermediate and late transcription in the absence of DNA replication.[352]

Intermediate-Stage Promoters

Mutagenesis of intermediate promoters indicates two important regions: a 14-bp core element separated by 10 or 11 bp from a 4-bp TAAA initiator element.[45,360] The intermediate promoter core element like that of early promoters is A/T rich. A consensus (Fig. 16.8) has been derived from an analysis of the sequences preceding 53 intermediate ORFs.[810] Intermediate-stage RNAs are initiated within the AAA triplet, but additional A residues are incorporated by vRNAP slippage.

Enzymes and Factors for Intermediate-Stage Transcription

Intermediate promoter templates can be transcribed by extracts prepared from cells infected with VACV in the presence of an inhibitor of DNA replication indicating that all necessary proteins are synthesized early in infection.[757] Further studies indicate a role for both viral and cellular proteins. The viral proteins include the vRNAP lacking RAP94; free RPO30 called VITF-1[597]; capping enzyme, which acts by a mechanism that does not involve cap formation[285,756]; and a heterodimer composed of polypeptides encoded by the A8R and A23R genes referred to as VITF-3[607] (Table 16.6). Neither VITF-1 nor VITF-3 has been shown to have ATPase activity or exhibit sequence-specific DNA binding. An additional requirement is for *in vitro* transcription can be fulfilled by two cellular proteins, Ras-GTPase–activating protein SH3 domain-binding protein (G3BP) and cytoplasmic activation/proliferation-associated protein (p137), which form a complex.[349] However, as yet, there are no *in vivo* studies confirming their specific role in transcription. On the other hand, *in vivo* experiments employing RNAi and dominant negative inhibitors suggest that the cellular TATA-binding protein has a positive role in VACV intermediate and late gene expression and that YY1 has a negative role by binding to promoter and initiator elements, respectively.[360,361] However, *in vitro* experiments confirming a direct

action have not been reported. In addition, neither was found by mass spectrometry of proteins cross-linked to viral DNA.[634] A reliance on cellular proteins is surprising since POXVs transcription occurs in the cytoplasm, and they encode their own vRNAP and other transcription factors.

Further studies provided evidence for virus-encoded positive and negative regulators of intermediate and/or late transcription elongation. The VACV A18 DNA helicase acts as a negative transcription elongation and a transcript release factor.[376,802] A18R mutations increase read-through of neighboring genes and increase levels of dsRNA. The G2 protein acts as a positive elongation factor as inactivating mutations result in intermediate and late mRNAs that are truncated.[77] Moreover, mutation of G2R can compensate for A18R mutations.[151] Physical interactions between G2, A18, and H5 (a late transcription factor) were demonstrated by a variety of methods.[78,440] J3, which is the cap 2′-O-MTase and the VP39 subunit of the poly(A) polymerase, also is an mRNA elongation factor.[386,798]

Regulation of Late-Stage Transcription

Transcription of late genes quickly follows that of intermediate genes and persists till the end of

the virus life cycle (Fig. 16.7). Short half-lives of late mRNAs[513,628] emphasize the need for continued high-level transcription. A recent study distinguished intermediate and late genes and identified 38 that belong to the latter class, which encode proteins involved in morphogenesis, the virion membrane, and early transcription.[810] In addition, many intermediate genes also exhibit varying amounts of late expression. Although distributed throughout the genome, late-stage genes cluster in the central region (Fig. 16.3).

Late-Stage Promoters and RNA Processing Signal

Late-stage promoters consist of a core sequence of about 20 bp with some consecutive T residues, separated by a region of approximately 6 bp from a highly conserved TAAAT element within which transcription initiates.[174] A synthetic promoter with exclusively T-residues forming the core sequence was stronger than natural late promoters tested and any mutations of TAAAT severely decreased transcription. A consensus promoter (Fig. 16.8) derived from the sequence upstream of 38 late genes is consistent with the mutational analysis.[810] A G or A usually follows the late promoter TAAAT sequence: in the former case, the TAAATG transcription initiation sequence and the ATG translation initiation codon overlap. The seeming absence of an untranslated RNA leader and in some cases a poor Kozak consensus translation initiation sequence were puzzling until it was found that late mRNAs have a 5′ capped, heterogeneous-length, poly(A) leader sequence formed by RNA polymerase slippage.[535,626] Poly(A) leaders are also present on intermediate mRNAs and mRNAs of a few early genes that have a TAAAT initiation site,[807] suggesting that slippage on an AAA sequence is an intrinsic property of the vRNAP. The 5′ poly(A) may provide a translational benefit.[199]

Most postreplicative transcripts are long, heterogeneous and lack defined 3′-ends.[152,421] Terminal heterogeneity, combined with transcription from both DNA strands, causes overlapping of transcripts explaining their ability to self-anneal or anneal with early transcripts to form dsRNA.[87,147,752] The early termination signal is not recognized even though T5NT is frequently present within the coding region of postreplicative genes. A few exceptions to the general 3′ heterogeneity of late mRNAs occur.[33] The CPXV late mRNA encoding the A-type inclusion protein has a defined 3′-end. The DNA sequence at this position encodes an RNA cis-acting signal for RNA 3′-end formation that can function independently of either the nature of the promoter or the RNA polymerase responsible for generating the primary RNA.[304] Cleavage also generates the 3′ end of F17R transcripts[160] and endoribonuclease activity directly or indirectly associated with the product of the H5R gene can cleave this RNA,[161] which is then polyadenylated. Therefore, POXVs employ at least two mechanisms of RNA 3′-end formation. The first, operative at early times in viral replication, terminates transcription downstream of an RNA signal, whereas the second, operative at late times, involves RNA site-specific cleavage.

Enzymes and Factors for Late-Stage Transcription

The vRNAP catalyzes late mRNA synthesis in conjunction with specific factors. Late transcription factors (Table 16.4) were identified by the systematic transfection of cloned viral DNA fragments: ORFs A1L, A2L, and G8R were necessary and sufficient for transactivation of a transfected late promoter reporter gene in VACV-infected cells that were blocked in DNA replication.[352] An intermediate promoter regulates each of these late transcription factor genes,

which is consistent with a cascade model of regulation. *In vitro* studies confirmed that the products of the G8R, A1L, and A2L genes are VACV late transcription factors,[316,534,796] and they have been named VLTF-1, VLTF-2, and VLTF-3, respectively. Temperature-sensitive and null mutations of A1L or G8R block late gene expression.[123,827] Yeast two-hybrid studies indicate interactions between G8 and itself and with A1.[440] *In vitro* studies indicated that the product of the early H5R gene, named VLTF-4, stimulated late transcription several-fold,[369] and interactions between H5 and other late transcription factors has been described.[192] H5 also appears to have a role in transcript elongation.[78] *In vitro* transcription assays suggest a role for a host factor originally called VLTF-X and shown to consist of the heterogeneous nuclear ribonucleoproteins A2/B1 and RBM3.[797]

Proteins cross-linked to newly replicated VACV DNA were identified by mass spectrometry.[634] In addition to DNA replication proteins, to be discussed below, the following proteins involved in intermediate and late RNA synthesis and processing were found supporting their roles *in vivo*: the four largest vRNAP subunits (RPO147, RPO132, RPO35, and RPO30), two intermediate transcription factors (A23 and A8), two capping enzyme subunits (D1 and D12), the 2′-O MTase (J3), the elongation factor (G2), the late transcription factors (G8, A1, and A2), and H5.

Regulation of Translation

Although POXV gene expression is mainly regulated at the transcriptional and mRNA degradation levels, perturbations of signaling pathways also has translational effects[447] and will be discussed further in the section on viral defense molecules. While early and postreplicative mRNAs like those of eukaryotes have cap I or II 5′ ends,[85] the 5′ poly(A) leader may reduce the requirements for certain translation initiation factors.[199,650] The VACV B1 kinase phosphorylates residues in the small ribosomal subunit protein RACK1 to facilitate translation of mRNAs with poly(A) leaders.[334] Postreplicative mRNAs are translated in or adjacent to virus factories,[347,816] although local translation has been shown to occur at the sites of A-type inclusions.[348] Viral protein synthesis depends on an adequate source of amino acids. A recent study shows that in the absence of glutamine, asparagine becomes limiting.[523]

DNA REPLICATION

General Features

POXV DNA replication takes place in the cytoplasm and occurs even when cells have been enucleated.[544,560] Uncoating, which depends on *de novo* protein synthesis, is required to release the DNA from the virus core to serve as a template.[337] The D5 helicase/primase is required for this process,[357] and two viral ankyrin-repeat proteins may also have roles.[402,410] Proteasome inhibitors prevent uncoating as well as DNA replication by mechanisms that are not yet understood.[454,611]

Discrete cytoplasmic foci of replication, termed factories, are discerned by light and electron

microscopic autoradiography.[118,284] During the first few hours of infection, the factories are delimited by ER membranes.[719] DNA replication begins 1 to 2 hours after VACV infection, and by 3 to 4 hours, the nucleoside analog EdU is incorporated almost exclusively into cytoplasmic DNA factories (Fig. 16.10). Each factory can be initiated by a single virion, although factories merge together with time.[347,398] About 10,000 genomes are synthesized per cell of which half are ultimately packaged into virions.[338]

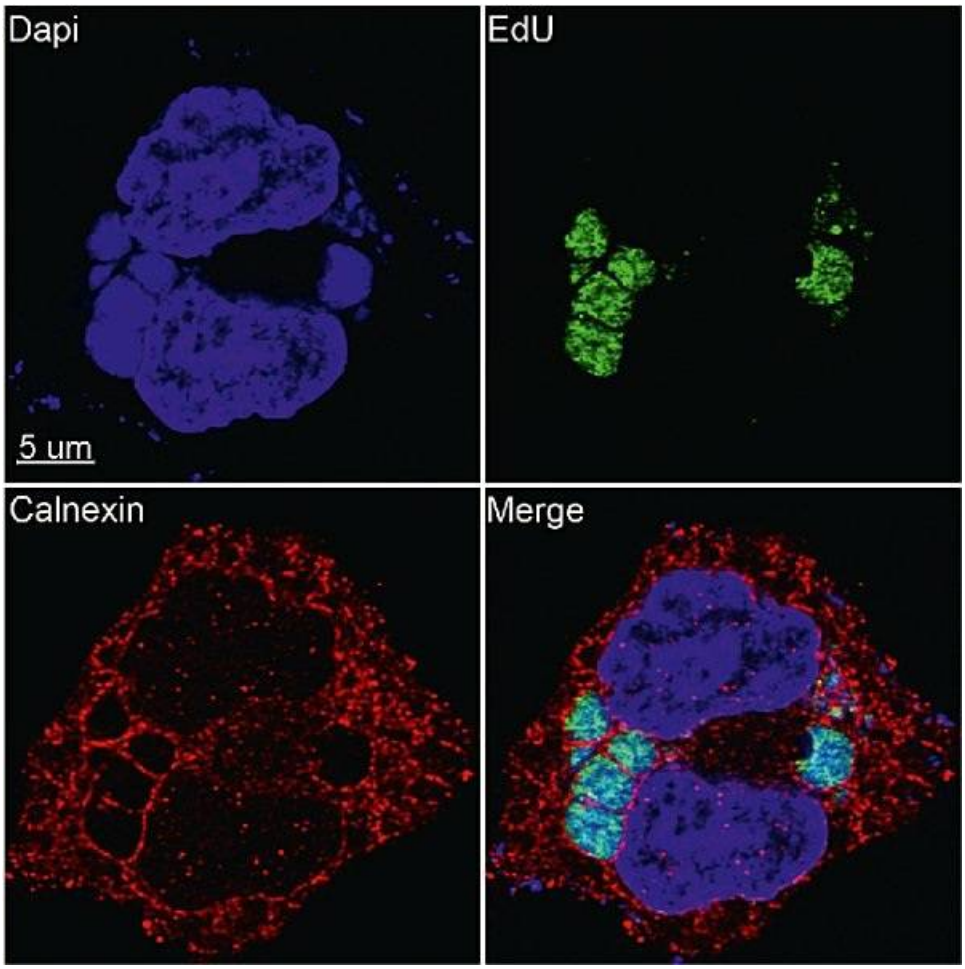

FIGURE 16.10 Localization of nascent viral DNA. A549 cells were incubated for 10 minutes with EdU at 3.5 hours after VACV infection and then fixed, permeabilized, and reacted with Alexa Fluor 488 azide to reveal newly synthesized DNA. The cells were then incubated with rabbit polyclonal antibody to calnexin (Santa Cruz) followed by secondary antibody conjugated to Alexa Fluor 594 and DAPI to visualize ER and total DNA, respectively. (Reprinted from Senkevich TG, Katsafanas GC, Weisberg A, et al. Identification of vaccinia virus replisome and transcriptome proteins by isolation of proteins on nascent DNA coupled with mass spectrometry. *J Virol* 2017;91(19):e01015–17. Ref.[634])

Efforts to locate a specific POXV origin of replication using a plasmid assay in transfected

cells were unsuccessful; surprisingly, any circular DNA replicates in cells infected with Shope fibroma virus (SFV)[191] or VACV.[460] Further studies demonstrated that origin-independent plasmid replication occurs in virus factory areas and requires each protein needed for genome replication confirming the specificity of this activity.[182] Using a transfection assay in which the template is a linear DNA molecule containing VACV hairpin ends, a specific enhancing effect of the terminal 200 bp of the viral genome was found.[211] Deep sequencing of short single-stranded DNA fragments enriched for RNA-primed nascent strands from VACV-infected cells identified a bidirectional origin within the hairpin loop at one end of the VACV genome and within the concatemeric junction of replication intermediates, although the possibility of additional origins was not excluded.[645]

DNA Replication Models

The unique terminal structure of the POXV genome,[53] evidence that nicking and initiation occurs near the ends of the molecule,[552] the presence of telomeric junction fragments,[54,492] and high molecular weight DNA[189,459] suggested the model depicted in Figure 16.11: a nick at one or both ends of the genome provides a free 3′-end for priming replication. The replicated DNA strand then folds back on itself, and the replication complex copies the remainder of the genome. Concatemer junctions form after replication through the hairpin; very large branched concatemers can arise by initiating new rounds of replication before resolution occurs. After the onset of late-stage transcription, unit–length genomes are resolved and the incompletely base-paired terminal loops, with inverted and complementary sequences, are regenerated. Despite the attractiveness of this model, neither the site of nicking nor an essential nicking enzyme needed to initiate DNA replication has been identified.[215]

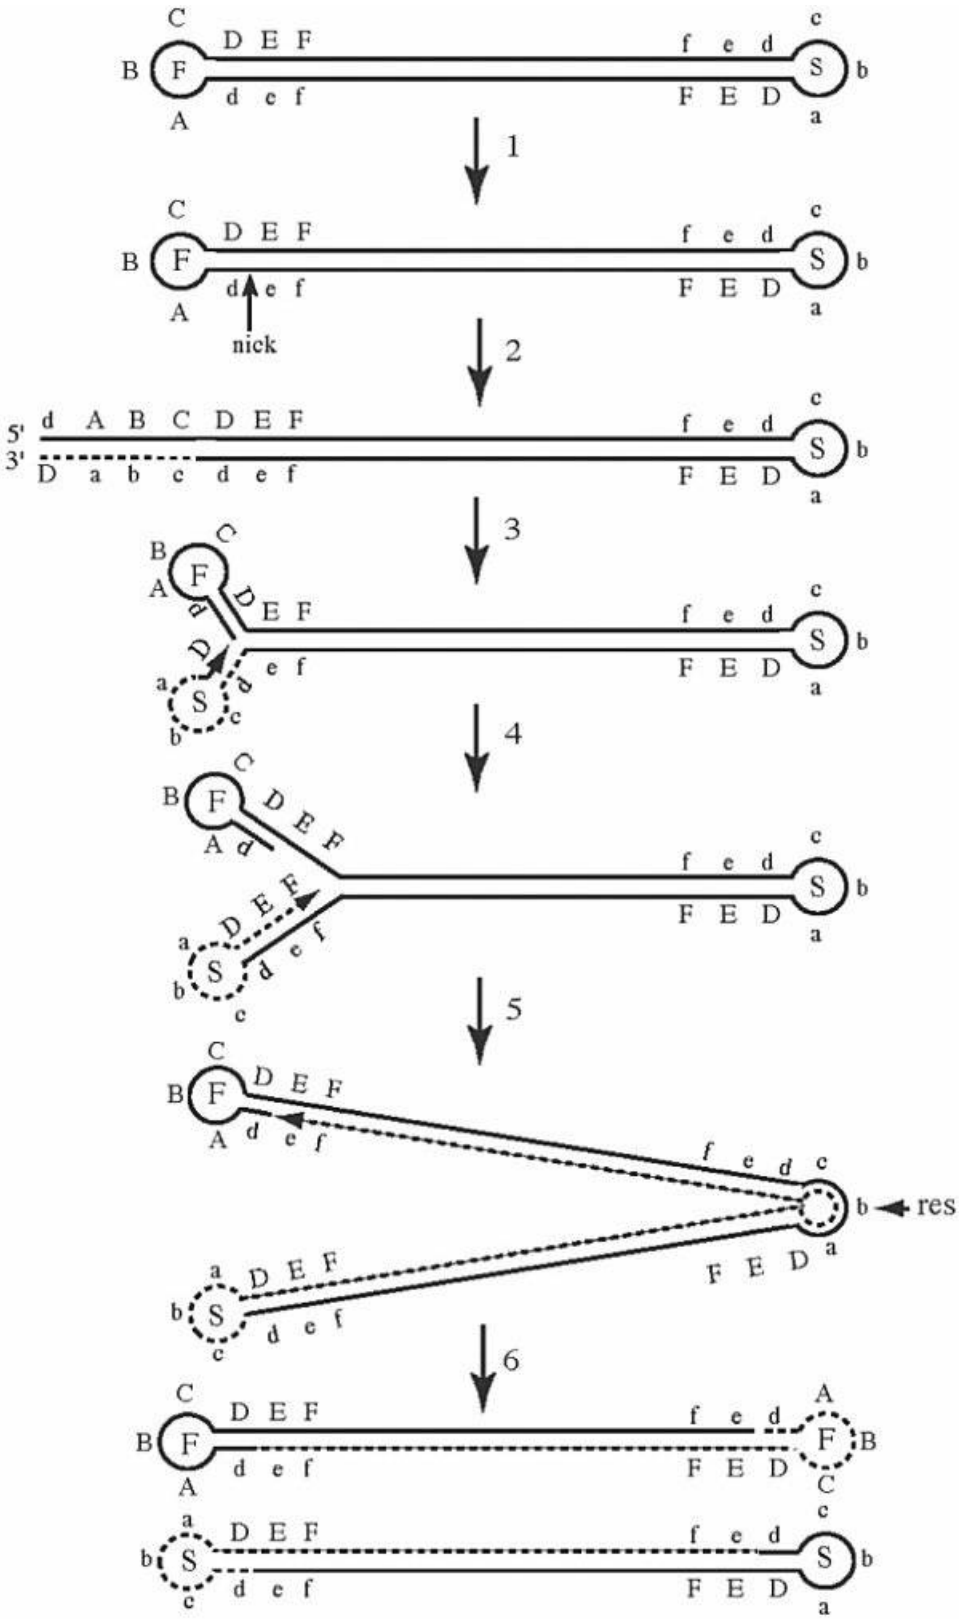

FIGURE 16.11 Self-priming model of poxvirus DNA replication. F and S within the hairpin loops refer to the fast and slow electrophoretic mobilities of DNA

fragments containing inverted and complementary hairpin sequences as shown in Figure 16.2. *Dashed lines* indicate newly synthesized DNA with *arrowheads* at the 3′ OH ends. Complementary sequences are depicted by upper and lower case letters. The resolution site (res) within the concatemer junction is indicated. (Adapted with permission of John Wiley & Sons from Moss B, Winters E, Jones EV. Replication of vaccinia virus. In: Cozzarelli N, ed. *Mechanisms of DNA Replication and Recombination*. New York: A.R. Liss; 1983:449–461; permission conveyed through Copyright Clearance Center, Inc. Ref.[485])

A more conventional model posits RNA priming and semidiscontinuous DNA synthesis at replication forks. Early reports of VACV DNA covalently linked to RNA and the chasing of short DNA into larger molecules suggested lagging strand synthesis.[222,553] Initially, this model was not favored because the viral DNA ligase was found to be nonessential,[148,354] and there was no evidence for a primase. The subsequent discovery of a viral primase and the finding that a cellular DNA ligase substitutes for the absent viral enzyme revived interest in this model.[180,527] Evidence for a bidirectional origin of genome replication near the end of the genome supports leading and lagging strand synthesis at replication forks[645] as illustrated in Figure 16.12. The two models are not mutually exclusive as it is possible that POXVs use multiple mechanisms to achieve replication of their large genomes.

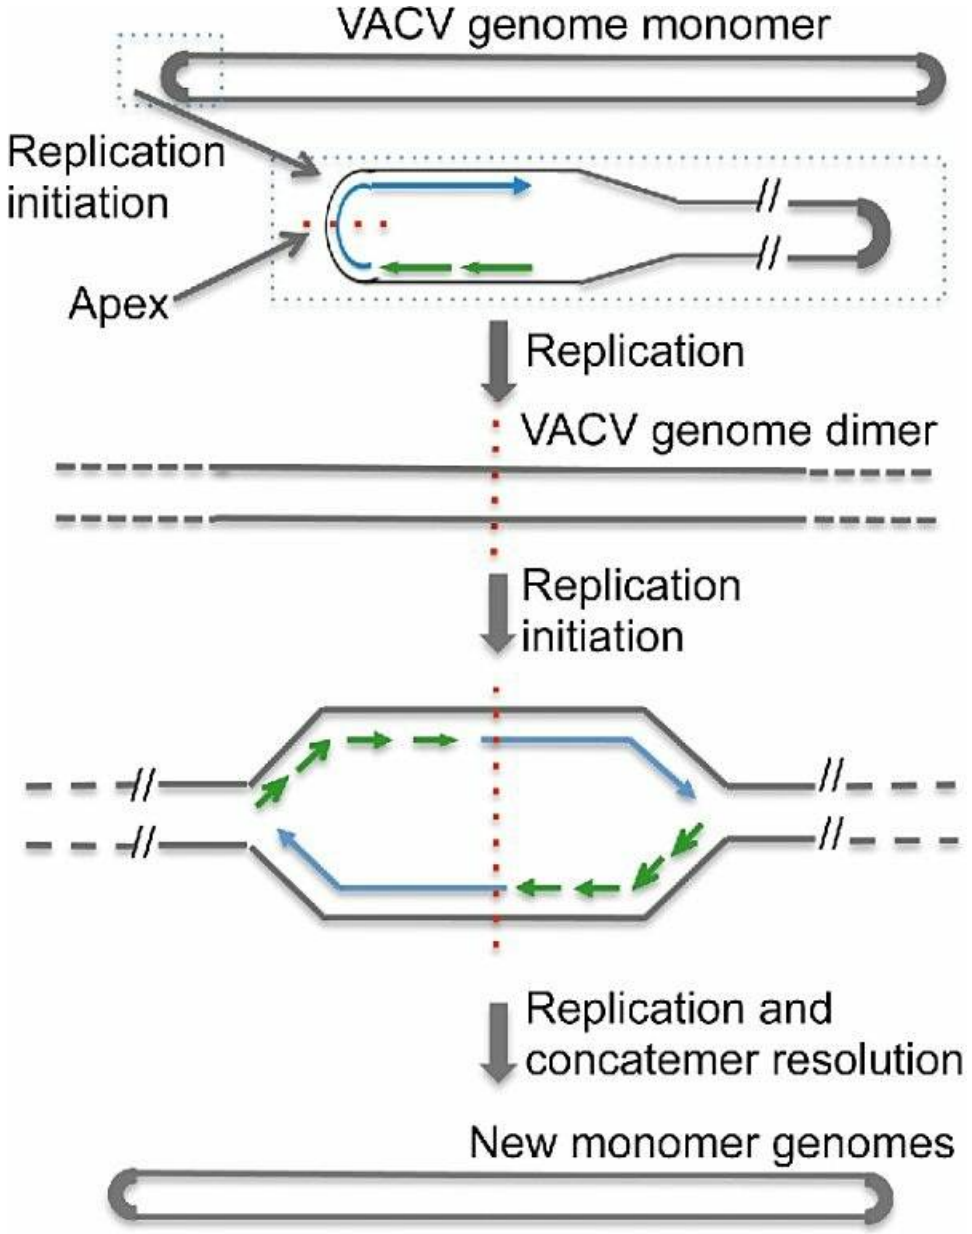

FIGURE 16.12 Model depicting replication origins at the terminal hairpin and concatemer junction. The VACV genome monomer with hairpin ends that is packaged in virus particles is shown at the top. DNA synthesis initiating within one hairpin is shown below. Replication results in the formation of a dimer by conversion of the incompletely base-paired hairpins into completely base-paired concatemer junctions. In this model, the concatemer junction serves as a bidirectional origin. Finally, the concatemers are resolved into unit genomes by the Holliday junction resolvase. Leading strands are shown as *blue arrows* and lagging strand fragments as *short green arrows*. The apex of the concatemer junction is indicted by *red dashes*. Mapping vaccinia virus DNA replication origins at nucleotide level by deep sequencing. *Proc Natl Acad Sci U S A* 2015;112(35):10908–10913. Ref.[645])

Enzymes Involved in DNA Precursor Metabolism

Some POXVs encode several enzymes involved in the synthesis of deoxyribonucleotides to enhance DNA replication in resting cells with suboptimal precursor pools, whereas others lack some or all of these. Inactivation of these enzymes has been used for construction of oncolytic poxviruses that selectively kill proliferating cancer cells.[439] In OPXVs, these enzymes include a TK,[43] thymidylate kinase,[674] ribonucleotide reductase,[665,715] and dUTPase.[100] VACV and some OPXVs also contain a gene encoding an inactive guanylate kinase.[264,673] Leporipoxviruses are missing genes encoding the large subunit of ribonucleotide reductase and thymidylate kinase,[119,782] and MOCV is missing genes for all of the enzymes involved in DNA precursor metabolism perhaps contributing to its limited host range.[635] FWPV encodes a protein related to human deoxycytidine kinase that is not present in the other POXVs.[364] Entomopoxvirus Melanoplus sanguinipes lacks all of the previously described POXV genes involved in nucleotide metabolism but has a thymidylate synthetase homolog.[2] However, a TK gene is present in other entomopoxviruses.[276,419]

POXV TKs are 20 to 25 kDa and related in sequence to corresponding eukaryotic enzymes (35% to 70% amino acid identity). The structure of VACV TK is similar to human TK, but there are differences in the association with dTTP that might be exploited for antivirals.[216] The enzyme exists as a tetramer, has ATP and Mg^{2+}-binding domains, and is susceptible to feedback inhibition by dTDP or dTTP.[79] The TK gene is regulated by an early promoter, as befits its role in increasing precursors for DNA replication.[774] Although the TK gene is not required for virus growth in tissue culture cells, deletion mutants are severely attenuated *in vivo*.[109]

Thymidylate kinase catalyzes the next step in TMP metabolism. The VACV gene encodes a 23-kDa protein that can complement *Saccharomyces cerevisiae* mutants deficient in the homologous enzyme.[317] The protein is expressed early in infection and is not required for virus replication in tissue culture. VACV thymidylate kinase has a 42% identity with its human homolog but differs in substantial ways and has broader substrate specificity.[39,117]

Ribonucleotide reductase, an enzyme that converts ribonucleoside diphosphates to deoxyribonucleoside diphosphates, is synthesized soon after VACV infection.[667] The small catalytic subunit and the large regulatory subunit resemble their eukaryotic counterparts structurally (70% to 80% identity) and functionally.[305,666] Catalytic activity is inhibited by hydroxyurea preventing DNA replication, and drug-resistant mutants generate direct tandem repeats of the gene encoding the catalytic subunit.[669] Mutation of the large subunit prevents induced ribonucleotide reductase activity in tissue culture cells without affecting replication.[138] However, the mutant virus was mildly attenuated in a mouse model. In contrast to OPXVs, many chordopoxviruses only encode the large subunit, which complexes with the cellular small subunit to form active ribonucleotide reductase.[243]

Hydrolysis of dUTP by the VACV dUTPase provides dUMP, an intermediate in the biosynthesis of TTP, and might also minimize dUTP incorporation into DNA.[100] The protein is synthesized early in infection[668] and is nonessential for virus replication in dividing cells.[546] The dUTPase is important in quiescent cells, particularly in the absence of the viral uracil DNA glycosylase.[181] The structure of VACV dUTPase is similar to the human homolog.[603]

Viral Proteins Involved in DNA Replication

Genetic and biochemical studies led to the identification of viral proteins that carry out genome replication.[159,377] The VACV DNA polymerase holoenzyme consists of the 116 kDa catalytic subunit E9 with a heterodimer of A20 and D4, which promotes processive DNA replication.[128,214,328,693] The core enzyme belongs to the B family of replicative polymerases, has 3′ proofreading exonuclease activity, and is the target of several inhibitors two of which (cidofovir and brincidofovir) are promising therapeutics for smallpox. Important features of these proteins were derived from high-resolution structures of E9 in complex with the N-terminal domain of D4 and of D4 in complex with the N-terminal domain of A20.[712]

In addition to serving as a processivity factor, D4 is a functional uracil DNA glycosylase[95,697] with structural features common to Family I enzymes.[623] These enzymes function in DNA repair by removing uracil residues that have been introduced into DNA, either through misincorporation of dUTP or through the deamination of cytosine. Mutagenesis studies demonstrated that the requirement for DNA replication is independent of its glycosylase activity.[183] Nevertheless, VACV mutants with enzymatically inactive UDG are attenuated in mice indicating that the repair function is beneficial, consistent with the preservation of the catalytic site in all POXV orthologs.

The VACV 49-kDa A20 protein has no nonpoxvirus homologs, and a role in DNA replication was first suggested by a yeast two-hybrid analysis, which demonstrated an interaction with the DNA replication proteins D4 and D5 and also H5.[328,440] The association of A20 and D4 with DNA polymerase imparts processivity.[159]

D5, a 90-kDa protein, has both nucleic acid-independent nucleoside triphosphatase[225] and primase activities[180,330] that are essential for DNA replication.[93,180] Helicase activity is predicted but not yet demonstrated. As previously noted, the triphosphatase domain of D5 also contributes to release of DNA from the core.[357]

VACV I3 is a 34-kDa phosphoprotein that forms octameric complexes on single-stranded DNA[729] and is essential for VACV genome replication.[269]

VACV encodes a functional ATP-dependent DNA ligase that is not essential for replication in tissue culture, although it imparts resistance to DNA-damaging agents and is important for virulence.[148,353] The ability of VACV to replicate in the absence of the viral DNA ligase depends on the recruitment of cellular DNA ligase I, which is responsible for joining Okazaki fragments.[527] However, replication of ligase-deficient VACV is greatly reduced and delayed in resting primary cells, correlating with initial low levels of ligase I and subsequent viral induction and localization of ligase I in virus factories.[527] By encoding its own ligase VACV can “jump-start” DNA synthesis in resting cells and enhance replication.

B1 is a 35-kDa serine/threonine protein kinase that is expressed early in infection, packaged in virions and fosters viral DNA replication by phosphorylating the cellular protein called barrier to autointegration factor (BAF).[518] B1 is a homolog of cellular protein kinases, which can substitute for the viral enzyme. An early protein encoded by the H5R gene is a substrate for the B1 kinase,[64] and interactions between these proteins was demonstrated by the yeast two-hybrid system.[440] H5 is a multifunctional protein with a role in DNA replication[94] as well as transcription, mRNA processing, and morphogenesis.

Each of the viral proteins involved in DNA replication plus the FEN-1–like nuclease G5, the telomere-binding protein I1, and components of the intermediate and late transcription systems were identified by mass spectrometry of proteins cross-linked to newly replicated viral DNA.[634] In that study, the cellular protein Top2B was found in equal abundance with and dependent on the VACV DNA ligase. Top2A and PCNA were identified at lower abundance than the viral proteins.

Photolyases, which protect DNA from ultraviolet radiation by excision of cyclobutane pyrimidine dimers, are encoded by avipoxviruses and leporipoxviruses as well as entomopoxviruses.[70,501,690]

While it is generally believed that VACV DNA synthesis is mediated exclusively by viral proteins, there is evidence that cytoplasmic activation of the ATR/ATM arms of the DNA damage response promote genome replication.[558]

Concatemer Resolution

The replication of the POXV genome involves the formation of concatemers and their resolution into unit–length molecules.[54,492] The concatemer junction consists of a precise duplex copy of the hairpin loop present at the ends of mature DNA genomes.[457] The conversion of circular plasmids containing concatemer junctions into linear molecules with hairpin termini when transfected into POXV-infected cells allowed determination of the structural and sequence requirements for resolution of concatemer junctions.[443,458] The minimal requirement for resolution is two copies of the sequence T_6-$N_{7–9}$-T/C-A_3-T/A present in an inverted repeat orientation on either side of an extended double-stranded copy of the hairpin loop.

In supercoiled plasmids, the concatemer junction can form a cruciform structure resembling a four-way Holliday junction (HJ) recombination intermediate.[200,457] This suggested that the putative concatemer resolving enzyme would be a HJ resolvase. Bioinformatic analyses led to the discovery of motifs and structural elements that are critical for activity of *Escherichia coli* RuvC HJ resolvase in ORFs that are conserved in all POXV genomes.[248] Moreover, the RuvC homolog encoded by the VACV A22R ORF specifically cleaves HJs.[248] Like RuvC, A22 is a dimer in solution and when bound to HJ structures but exhibits less cleavage sequence specificity.[157,250] A VACV-inducible A22 null mutant was defective in processing concatemers into unit–length genomes with hairpin ends under nonpermissive conditions, indicating that the enzyme is required for resolution, although additional proteins may also be involved in determining site specificity.[249]

Type I DNA topoisomerases form a covalent link with DNA and relieve supercoils during replication, transcription, recombination, and other activities. POXVs encode a type 1 topoisomerase that has served as a model for this class of enzymes.[647,659,805] The topoisomerase is unusual in that it exhibits some sequence specificity.[656] *In vitro*, the topoisomerase can carry out a variety of reactions including strand transfer, transesterification, recombination, and cleavage and ligation of a variety of DNA structures including a HJ.[520,632] A VACV topoisomerase deletion mutant has impaired early transcription, but DNA replication and concatemer resolution still occur.[162] The topoisomerase is regulated by a late promoter, which is consistent with a role in transcription or DNA processing.

Homologous Recombination

Recombination can occur during coinfection[231] and has occurred naturally between SFV, which produces benign fibromas in rabbits, and myxoma virus (MYXV), the agent of myxomatosis, to form malignant rabbit fibroma virus,[83] and between individual capripoxviruses.[257] Recombination between the terminal sequences of POXV DNA may explain variations in the number of tandem repeats as well as translocations and mirror image deletions.[442,493] Most extraordinarily, field and vaccine strains of FWPV carry a near full length and apparently infectious integrated avian retrovirus genome.[291] The existence of families of related proteins in poxviruses suggests the occurrence of gene duplications in the past. Moreover, experimental evolution studies reveal the occurrence of transient gene duplications that enhance expression, referred to as an accordion model.[217,669] Viral genomes rapidly eliminate direct repeats with the formation of intra- and intermolecular recombination products.[48]

Recombination can also occur between viral genomic DNA and transfected subgenomic DNA fragments, and this has been exploited to map and construct mutations and to insert genes for expression.[480] Single- and double-crossover products resulting from recombination between transfected plasmids and viral genomes[689] and inter- and intramolecular plasmid or bacteriophage DNA recombinants[224,529] have been detected in POXV-infected cells.

Recombination does not require postreplicative gene products.[456,781] There is evidence that the DNA polymerase participates directly in recombination and that the 3′ exonuclease and DNA joining activities are involved.[242] The protein encoded by the G5R gene, which is conserved in all POXVs and expressed early in infection, belongs to the FEN1 family of exo/endo nucleases.[165,329] Deletion of VACV G5R reduces the yield of infectious virus by two orders of magnitude.[636] Although the amount of viral DNA produced in the absence of G5 is similar to that made by wild-type virus, the mean size is approximately one-fourth of the genome length. Experiments with transfected plasmids show that G5 is required for double-strand break repair by homologous recombination, suggesting a similar role during VACV genome replication.[636]

The chordopoxviruses, except for avipoxviruses, encode homologs of serine recombinases.[1] However, only the crocodile POXV contains all amino acids that comprise the catalytic active site, and deletion of the VACV F16 homolog had no effect on replication in cultured cells.[637]

VIRION ASSEMBLY

Overview

The initial stages of virion assembly occur in virus factories. Assembly can be divided into the following stages: (a) formation of membrane crescents and spherical immature virions (IVs) containing the core protein precursors, genome, and an outer spicule layer; (b) loss of the spicules, organization of the core, and conversion to a brick-shaped mature virions (MVs); (c) enclosure of some MVs by two additional membranes to form wrapped virions (WVs) also called intracellular enveloped virions (IEVs); and (d) movement of WVs to the periphery and exocytosis to form EVs.[150] A thin section transmission electron microscopic image of a cell

infected with VACV and enlarged pictures of virions at successive stages of assembly and egress are shown in Figures 16.13 and 16.14, respectively. Deep etch electron microscopy revealed that the outer spicule layer is a honeycomb lattice composed of the D13 protein viewed on edge (Fig. 16.15).[292,709]

External scaffold of spherical immature poxvirus particles is made of protein trimers, forming a honeycomb lattice. *J Cell Biol* 2005;170(6):971–981; permission conveyed through Copyright Clearance Center, Inc. Ref.[709])

Formation of Crescent and IV Membranes

Microscopic images showing crescents composed of a single bilayer open to the cytoplasm and with no apparent connection to cellular organelles led to the idea that the viral membrane forms *de novo*.[167,292] Such an open architecture, however, is contrary to the idea that stable membranes have sealed ends and arise from preexisting membranes; the latter perception led to a series of now discounted reports proposing that the IV has a double membrane. An alternative explanation for the failure to see connections between cellular and viral membranes is that they are transient. Supporting this explanation are experiments showing that normal-looking IVs are absent and

connections between ER and viral membranes persist when expression of any one of five VACV proteins (A6, A11, A30.5, H7, and L2) are repressed.[433,775] Under these conditions, crescent-like membranes containing viral proteins are connected to the ER membrane and appear to bud into expanded ER lumens where spherical IV-like structures accumulate (Fig. 16.16). The five conserved proteins are referred to as viral membrane assembly proteins (VMAPs). L2, A30.5, and A11 have C-terminal hydrophobic domains, whereas A6 and H7 do not. The structure of A6, however, suggests that the C-terminal domain forms a cage that could enclose glycerophospholipids.[537] During a normal infection, L2, A30.5, and A11 localize at the edges of viral crescents, which might coat and protect the single viral membrane, as well as on the adjacent ER.[431,432] A model for viral membrane formation is that following insertion of viral proteins A17 and A14 into the ER, the VMAPs create or stabilize ER scissions possibly in collaboration with cellular proteins leading to the formation of the single membranes of the crescents and IVs.[477] A17 and A14 are major interacting components of the IV membrane[737] and small vesicles accumulate and crescent formation is reduced or abrogated if synthesis of either is repressed.[592,593,727,792]

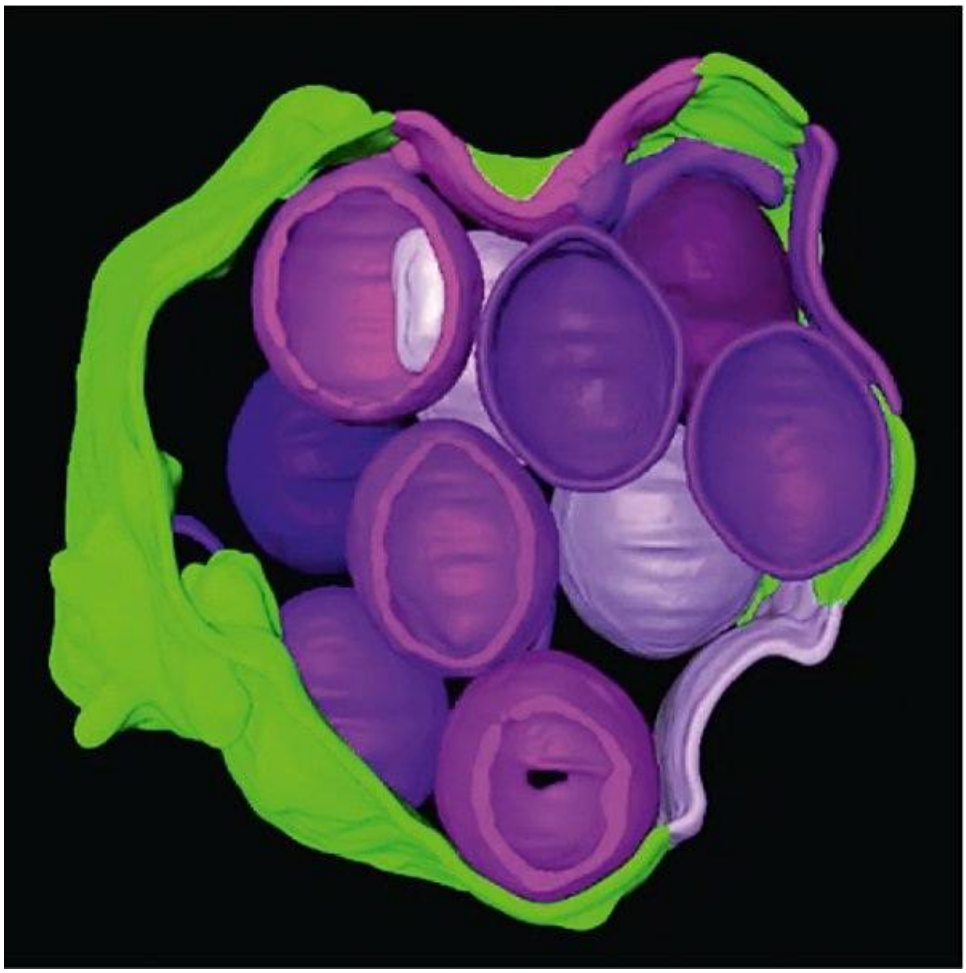

FIGURE 16.16 Three-dimensional rendering of a cluster of crescent and IV-like structures associated with ER. Cells were infected with an A30.5R deletion mutant and sections prepared for transmission electron microscopy and tomography. Curved

viral membranes are colored *violet* and smooth ER is *green*. Crescent-like membranes are continuous with ER, and IV-like forms are in lumen. (Reprinted with permission from Weisberg AS, Maruri-Avidal L, Bisht H, et al. Enigmatic origin of the poxvirus membrane from the endoplasmic reticulum shown by 3D imaging of vaccinia virus assembly mutants. *Proc Natl Acad Sci U S A* 2017;114(51):E11001–E11009. Ref.[775])

Additional biochemical and microscopic studies support an ER origin of the viral membrane. Blockade of the COPII ER exit pathway by dominant negative inhibitors of the Sar1 GTPase[318] and the drug brefeldin A[735] have no effect on formation of IVs or MVs ruling out a post-ER membrane origin. However, none of the viral proteins incorporated into purified MVs have a signature of ER translocation, such as signal peptide cleavage or glycosylation. However, a heterologous signal peptide fused to the N-terminal region of a VACV membrane protein was cleaved and the truncated protein localized in IVs and MVs providing evidence for a functional pathway between the ER and viral membranes.[319]

Several proteins in addition to A17, A14, and the VMAPs that are required for the formation of crescents and IVs have been identified. The formation of masses of electron dense "viroplasm" resembling the interior of IVs with few or no crescent membranes represents a characteristic phenotype of cells infected with conditional lethal F10 kinase,[726,765] H5,[194] and G5[163] mutants. H5 and G5 have other roles, so their action in crescent formation may be indirect. F10 phosphorylates the A14 and A17 IV membrane proteins,[73,197] and the kinase activity is required for its function in morphogenesis.[562,710]

In the presence of the antibiotic rifampicin, irregular viral membranes that lack the honeycomb lattice accumulate (Fig. 16.17).[482,497] Within minutes after removal of the drug, the single membrane bilayer becomes coated with the protein forming the honeycomb and assumes a crescent shape (Fig. 16.17) even in the presence of RNA or protein synthesis inhibitors, suggesting that rifampicin directly interferes with assembly.[270] The gene responsible for resistance of mutant viruses to rifampicin was mapped to the D13L ORF, which encodes a 65-kDa protein,[46,134,713] and a recent structural study shows a direct interaction of D13 and rifampicin.[252] When expression of D13 is repressed, morphogenesis of the viral envelope is blocked at the same stage as occurs with rifampicin.[825] The D13 protein forms trimers that assemble to form the honeycomb lattice, which gives the IVs a spherical shape (Fig. 16.15).[709] The structure of D13 is similar to the capsids of other viruses and phage suggesting a common origin.[41,320] D13 interacts with the N-terminal region of A17 to form the scaffold.[76] The A17 protein resembles cellular reticulon proteins and also contributes to the curvature of the IV membrane.[220]

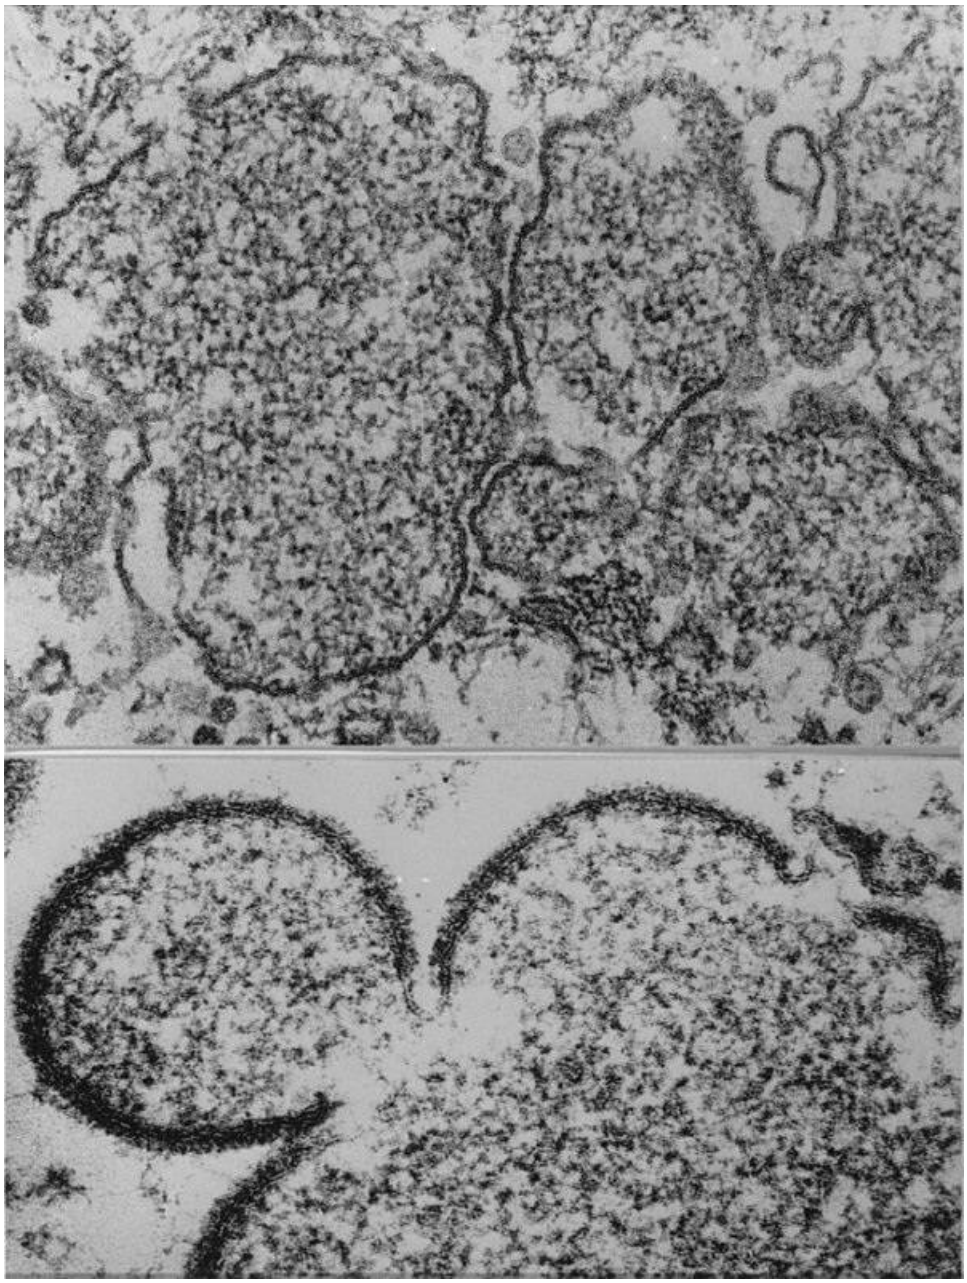

FIGURE 16.17 Electron micrographs of thin sections of cell infected with VACV in the presence of rifampicin. Upper panel: HeLa cells were fixed and sectioned at 8 hours after infection in the presence of rifampicin. **Lower panel:** Cells were fixed and sectioned at 10 minutes after removal of rifampicin. Note the thin uncoated single membrane bilayer loop connecting the more rigid crescent-like membranes that have acquired the D13 honey-comb lattice layer. (Reprinted from Grimley PM, Rosenblum EN, Mims SJ, et al. Interruption by rifampin of an early stage in vaccinia virus morphogenesis: accumulation of membranes which are precursors of virus envelopes. *J Virol* 1970;6(4):519–533. Ref.[270])

Association of the Genome, Core Proteins, and Transcription Complex With IVs

Electron micrographs show DNA nucleoids that appear to be entering IVs before complete membrane closure.[472] When morphogenesis is interrupted at a pre-IV stage, the viral DNA concatemers are processed normally, but mature DNA accumulates in large crystalloid structures.[270] Although concatemer resolution occurs in the absence of viral morphogenesis, DNA processing is required for morphogenesis.[249] A DNA packaging role for the A32 protein was predicted because of sequence similarity to the products of gene I of filamentous single-strand DNA bacteriophages and to the IVa2 gene of adenovirus, both of which are ATPases involved in DNA packaging.[365] This hypothesis was confirmed by the finding that repression of A32 synthesis blocked VACV genome packaging.[126] DNA packaging also fails to occur under nonpermissive conditions in cells infected with a *ts* mutant that mapped to the I6 telomere-binding protein of VACV.[193,275] Mutation of a second telomere-binding protein encoded by the I1 ORF, however, causes a defect at a later stage of morphogenesis.[275,358] Conditional lethal mutants of the A13 protein, which is a component of the virion membrane, also display a defect in genome packaging and DNA crystalloids associated with membrane accumulate.[738] How the membrane protein, telomere-binding protein and ATPase enable genome incorporation is unknown.

The dense viroplasm that is engulfed during the extension of the crescent into the IV contains unprocessed core proteins. Insight into the association of the core proteins with the crescent membrane has been obtained through use of conditional lethal VACV mutants. Eight core proteins A15, A30, D2, D3, F10, G7, J1, and F17 are each required for the association of crescent membranes with the granular viroplasm.[707,779] Similar phenotypes occur when expression of the A10 and E6 core proteins are repressed.[92,289,582,826] However, the mechanism enabling the association of core proteins with the membrane remains to be determined.

Packaging of the transcription apparatus is dependent on RAP94, the RNA polymerase-associated protein required for transcription of early genes.[824] When expression of RAP94 is repressed, morphologically normal but noninfectious virus particles form. These particles contain the genome and structural proteins as well as the early transcription factor VETF but lack the vRNAP, poly(A) polymerase, capping enzyme, topoisomerase, NPH I, and NPH II. Such a specific effect could be explained by the presence of a multienzyme complex that associates with promoter-bound VETF through RAP94. Physical association of RAP94 with NPH I[466] and VETF[809] have been demonstrated. Moreover, the cryo EM structure of the vRNAP holoenzyme[271] shows that VETF, capping enzyme, and NPH I interact directly with RAP94.[271] Repression of synthesis of VETF, however, leads to a more severe defect with accumulation of immature virus particles.[311,312] Association of VETF with promoter sequences in the genome would facilitate packaging of the transcription complex, which would be poised to initiate transcription of early genes.

Removal of the D13 Scaffold and Proteolytic Processing of Virion Proteins

Transition of spherical IVs to more compact and barrel-shaped MVs involves loss of the D13

scaffold (Fig. 16.15). Disassembly of the D13 scaffold correlates with processing of A17 by the I7 protease; when I7 expression is repressed, D13 is retained on aberrant virus particles.[76] Disassembly of the scaffold and transition to MVs fails to occur when expression of A9 is repressed[812] and with a ts A6 mutant at the nonpermissive temperature.[449] There is also some accumulation of IVs and delayed formation of MVs when the H3L ORF is deleted.[164,395]

In addition to processing of A17, at least five core proteins (A3, A10, A12, G7, and L4) undergo proteolytic cleavages. Processing of A17 depends on formation of the IV membrane,[583] whereas cleavage of core proteins occurs at a later step in morphogenesis.[350,481] In each case, cleavage occurs at the consensus sequence AG↓X.[750] The I7 protease is responsible for cleavage of the above proteins based on the phenotype of ts mutants[342,464] and conserved cysteine protease active site mutants.[31,113] The product of the G1L ORF contains a motif HXXEH that is found in some metalloproteases and conserved in all chordopoxviruses. Conditional lethal G1 mutants are blocked in morphogenesis, but processing of the known membrane and core proteins is not affected.[32,288] Nevertheless, mutagenesis of the putative active site abrogates the ability of G1 to complement a null mutant and G1 itself appears to be proteolytically processed.[390]

Intramolecular Disulfide Bond Pathway

The cytoplasmic domains of some MV membrane proteins contain intramolecular disulfide bonds. Because disulfide bonds usually form in the ER, this raised the possibility that POXVs encode novel oxidoreductases. Indeed, A2.5, E10, and G4 form a unique cytoplasmic disulfide bond pathway.[633,641,642,778] The atomic structure of G4 has been solved; the protein crystallized as a dimer that buried the Cys-X-X-Cys active site, which could protect the reactive disulfides from reduction in the cytoplasm.[40,700] Repression of any one of the three redox proteins results in a block in virion maturation. Nine of the eleven EFC proteins have intramolecular disulfides formed by the cytoplasmic redox system (Table 16.2). Both the entry proteins and the redox system are conserved in all POXVs suggesting their codevelopment. Some core proteins also contain intramolecular bonds, which form by a different mechanism within the developing virion and are reduced following infection.[412]

Occlusion of MVs

The MVs of some chordopoxviruses (e.g., CPXV, ECTV, raccoonpox virus, and FWPV) become occluded in dense protein matrices[247] within the cytoplasm, which are referred to as A-type inclusions (ATIs) to differentiate them from virus factories, which are sometimes called B-type inclusions.[345] Presumably, ATIs that are released following degeneration of infected cells protect the enclosed MVs from the environment. There is, however, suggestions that loss of the ATI protein enhances the dissemination of virus within a host,[343] which may account for the absence of ATI by VARV and MPXV. The major ATI protein of CPXV is a 160-kDa myristoylated species that may represent up to 4% of the total cell protein at late times after infection.[241,536] Early EM images revealed polyribosomes decorating ATIs.[323] Follow-up studies demonstrated local translation of ATI mRNAs around the inclusions, which could prevent premature ATI aggregation and inclusion of MVs within factories.[348]

CPXV A26 mutants form inclusions without virions implicating a role for the latter

protein.[444,736] A26 has a bridging role between the ATI protein and A27, which is tethered to MVs through interaction with A17.[303] Although VACV does not form ATIs, a homologous truncated protein is encoded by some strains.[27,175] Interestingly, neither the A26 nor A25 is present in EVs.[736]

Entomopoxvirus virions are also occluded.[71] Following ingestion by a larval host, infectious particles may be released in the alkaline pH of the gut. The sequences of homologous occlusion proteins, called spheroidin or spherulin, have been deduced from the ORFs of several entomopoxviruses.[2,608] These proteins are cysteine-rich, have a mass of approximately 100 kDa, and lack homology to fusolin, an abundant 50-kDa spindle body protein of entomopoxviruses,[169] the A-type inclusion protein of chordopoxviruses, or the polyhedrin protein of baculoviruses.

FORMATION OF EV

Overview

The EV is an extracellular form of POXV that consists essentially of a MV with an additional membrane that is important for virus dissemination.[90,539] For OPXVs, the extra membrane is frequently formed by an intracellular MV wrapping process followed by exocytosis,[540] whereas FPXV exits the cell predominantly by budding.[89]

Wrapping

Some MVs are wrapped by an additional double membrane (Fig. 16.14) that is important for intracellular movement and EV formation. Both the trans-Golgi and endosomal cisternae have been implicated in the formation of the wrapping membrane.[294,616,720] The discovery of retrograde transport of the F13 protein from endosomes to the trans-Golgi apparatus implicates both membrane compartments.[286,664] Eight viral proteins have been associated with either the wrapping or EV membrane (Table 16.5). Of these, A36 and F12 are associated exclusively with the outermost WV membrane that fuses with the plasma membrane and therefore are not retained in the EV. With the exception of E2, F12, F13, and K2, the proteins have a transmembrane anchor. A56, A33, A34, B5, and K2 are glycosylated and exposed on the outer EV surface, whereas F13 is palmitoylated, has a putative phospholipase motif that is essential for its role in wrapping, and is on the inner surface.[273,596,620] F13 is the target of TPOXX (Tecovirimat, ST-246), a therapeutic against smallpox licensed by the US Federal Drug Administration in 2018.[272] F12 associates with E2,[207] and A36[336] and K2 associates with A56.[732] Complex interactions between the A33, A34, and B5 proteins determine the composition of the EV membrane.[469] A33 has unique C-type lectin domains that could interact with other viral or cell proteins.[372,701]

Deletion of any of the genes encoding WV or EV membrane proteins, except A56 and K2, results in a small plaque phenotype indicating decreased virus spread. A56 and K2 are also located on the plasma membrane and deletion mutants have a syncytial phenotype that can be explained by the abrogation of A56/K2 binding to the A16/G9 components of the EFC.[759] Studies with mutant VACVs indicate that several proteins are required for efficient wrapping and

that severe effects are caused by repression or inactivation of the A27 MV protein,[591,769] the F13 protein,[80] and the B5 glycoprotein.[219,790]

Intracellular Movement and Exocytosis

The movement of MVs to the wrapping sites depends on microtubules, but the viral attachment protein is not known. Whether A27 is required for movement as well as wrapping *per se* is disputed.[605,769] Movement of WVs to the periphery of the cell occurs on microtubules.[253,300,586,772] A36 exposed on the surface of the WV interacts with the cargo-binding domain of the light chain of kinesin (KLC), a microtubule motor protein.[332,771] Movement is enhanced by interactions of the F12/E2 complex, which binds predominantly to KLC isoform 2,[124] whereas A36 binds KLC isoform 1.[246]

When the WVs arrive near the periphery of the cell, their migration through the dense cortical actin is facilitated by the action of F11 in preventing RhoA signaling.[36,154] The outer of the two wrapping membranes fuses with the plasma membrane to liberate the EV with one more membrane than a MV (Fig. 16.14). The externalization of VACV resembles vesicle exocytosis, but the detailed mechanism has not been determined. A role of the ESCRT machinery has been suggested.[301]

Only a minority of the externalized virus is found in the medium, whereas most adhere to the cell surface. The ratio of adherent to released virions varies in different VACV strains,[538] and the high amount of released EVs for the IHD-J strain is due to a single amino acid substitution in the putative lectin-binding domain of A34.[82] Mutations in A33, B5, and A36 also enhance release,[351,677] and the host Abl-family tyrosine kinases and host phosphoinositide 5-phosphatase SHIP2 are involved.[446,577] On cell monolayers, adherent EVs can mediate efficient cell-to-cell spread due to actin tails discussed below, whereas the released EVs provide long-range dissemination.[81]

Actin Tail Formation

Efficient cell-to-cell spread of EVs depends on their location at the tip of motile, actin-containing microvilli, which have been visualized by fluorescence and electron microscopy[156,295,694] (Fig. 16.6). The proteins encoded by the A33R, A34R, and A36R ORFs are required for the formation of the actin-containing microvilli, and their absence results in a small plaque phenotype.[595,604,791,794] Nucleation of the actin tails depends on tyrosine phosphorylation of the A36 protein of OPXVs and functional homologs of other POXVs by Src or Abl family kinases.[389] The phosphorylated A36 protein interacts with the adaptor protein Nck, which results in the recruitment of the Ena/VASP family member N-WASP to the site of actin assembly.

VIRUS–HOST INTERACTIONS

Tropism and Host Range

Individual POXVs frequently have a narrow host range capable of maintaining their survival in the wild, although they may occasionally infect and cause disease in other species. Indeed, the eradication of smallpox would not have succeeded if there were a wild animal reservoir. Occasionally, infection of an unnatural host, for example, the European rabbit by MYXV,[232] results in a high mortality. Tropism and virulence are frequently based on the genus- and species-specific properties of defense genes rather than the essential ones conserved in all or most POXVs. This is reflected in the broader species specificity for cultured cells than whole animals. Where restriction occurs, it is usually at a post-entry step.[441] An interesting example of tropism is the ability to infect primary mouse fibroblasts and mice by MYXV only if the IFN response is abrogated.[763] Under certain nonpermissive conditions of OPXV infection, viral macromolecular synthesis may be inhibited. Examples are the abortive VACV infection of drosophila cells restricted at the stage of viral DNA replication[69] and Chinese hamster ovary cells restricted at the stage of intermediate protein synthesis, which can be overcome by the CPXV gene encoding a 77-kDa protein.[308,568,686] CPXV CP77 is related to a family of VACV host range proteins that have ankyrin repeats and include C7 and K1[545] and which have overlapping functions.[393,569,819] In addition, VACV K1L deletion mutants are blocked at the stage of early protein synthesis in rabbit RK13 cells and VACV double K1L and C7L mutants exhibit a similar defect in human cells. A human genome-wide RNAi screen and coprecipitation studies identified human sterile alpha domain-containing 9 (SAMD9) and the paralog SAMD9L as IFN-induced host restriction factors that are antagonized by the C7 family of proteins.[404,452,661,663] Members of this family of host range genes are present in other POXV genera including sheeppox virus, Yaba-like disease virus (YLDV), MYXV, and swinepox virus (SWPV).[405,448,450] VACV strain modified virus Ankara (MVA), which was extensively passaged in chicken embryo fibroblasts, is unable to replicate in most mammalian cells due to gene loss or mutation,[34] which prevents late stages of morphogenesis.[703] The virus proteins lost from MVA that counteract the putative host restriction factors have been identified as C12 and C16.[407,543] C12, also known as serine protease inhibitor 1, is a host range gene for rabbitpox virus and other VACV strains.[470,651] A human genome-wide RNAi screen identified three host proteins (IRF2, FAM111A, and RFC3) as restriction factors for rabbitpox C12 deletion mutants.[522]

Effects on the Cytoskeleton

Infection of tissue culture cells with VACV and other OPXVs results in profound morphological changes consisting of rounding, cell–cell dissociation, and migration. These cytopathic effects involve alterations in microtubules, actin, and intermediate filaments.[235,461,551,615] VACV induces cell motility[606] that requires F11 protein-mediated inhibition of RhoA signaling.[471,743]

Effects on Host Macromolecular Synthesis

A rapid and profound reduction in cell protein synthesis follows VACV infection.[223,484] Several factors may contribute to the switch from host to viral protein synthesis, and the relative contribution of each factor may depend on the virus multiplicity, cell type, and time of analysis. Inhibition of host protein synthesis frequently remains incomplete until after DNA replication, suggesting a major role of a viral intermediate or late protein. The primary factor in the shut off of host protein synthesis is a profound reduction in cellular mRNA. After several hours, most of

the mRNA present in the cytoplasm of infected cells is viral[86,808] due to accelerated degradation of host mRNAs[65,585,628] coupled with active virus transcription and inhibition of host RNA synthesis and transport.[542,561,786] The accelerated degradation of host and viral mRNAs is initiated by the expression of the viral decapping enzymes D9 and D10[531–533,655,684,685] and completed by host cell exonuclease activity.

VACV also hijacks cellular translation initiation factors to expression sites within cytoplasmic factories, which may contribute to suppression of cell protein synthesis.[347] The abundance of the cellular translational repressor 4E binding protein decreases during VACV infection enhancing translation of viral mRNAs.[760] VACV protein WR 169 is a protein synthesis inhibitor excluded from virus factories that may also contribute to host shut-off.[695] At high virus multiplicities, inhibition of host protein synthesis can occur in the absence of viral gene expression, implicating a virion protein.[438,475,547] Other studies suggested that small poly (A)-containing RNA molecules are involved.[116] VACV also inhibits nuclear DNA replication.[340,634] This effect may be indirect, although a role for VACV-encoded deoxyribonucleases was suggested.[198]

The VACV protein WR C16 (CPN C10) binds to prolyl hydroxylase domain-containing protein 2 (PHD2) to stabilize HIF-1α and induce a hypoxic response under normoxia[437] that results in reprogramming of central energy metabolism.[436]

Interactions With the Ubiquitin-Proteasome System

Ubiquitylation is a posttranslational modification that regulates cellular processes by several mechanisms including protein degradation. The exploitation of the ubiquitin–proteasome system by POXVs has been reviewed.[58] Studies with inhibitors suggested that OPXVs require the ubiquitin proteasome system for uncoating cores and DNA replication.[611,714] In addition, VACV exploits the proteasome to degrade cellular factors that restrict virus replication; out of 265 cell proteins reduced greater than twofold during infection, 70% were degraded in a proteasome-dependent manner.[679] A few POXVs encode ubiquitin-like genes, but many more encode modulators of the ubiquitin–proteasome system, including E3 ubiquitin ligases,[314,424,505] and ankyrin/F-box-like proteins.[335,680,681,687,776] Some of the ankyrin/F-box–like proteins interact with the SKP1 component of the SCF ubiquitin ligase complex to commandeer the cell proteasome machinery. Although many of these modulators of ubiquitin are required for virulence, the functions of most remain unknown. One exception is VACV C9; the ankyrin repeat domain binds IFITs and the F-box interacts with SCF ubiquitin ligase complex, which together mediate the degradation of the IFITs.[410] POXVs also encode BTB-kelch proteins that are predicted Cullin 3 E3 adapters.[47,61,240,363,785] The VACV BTB-kelch protein A55 binds Cullin 3 directly and with high affinity.[245,521] VACV C6 binds to histone deacetylase (HDAC)4 and mediates its proteasome-dependent degradation by a mechanism not yet defined.[414,679]

Stimulatory Effects on Cell Pathways

To enhance their replication, POXVs may stimulate certain host pathways, for example, MAPK and P13K/Akt.[29,678,764] FWPV,[135] SFV,[654] Yaba virus,[511] and MOCV[559] induce hyperplasia and tumors. VACV protein B14 is a MAPK activator.[721] In the case of OPXVs and leporipoxviruses,

the hyperplastic effect is due to secretion of a homolog of epidermal growth factor, which binds to ErbB receptors and enhances virulence.[108,133,399,519,696,734] A gene encoding a mitogenic polypeptide with homology to mammalian vascular endothelial growth factor is present in the ORFV genome and may account for the extensive vascularization of lesions and virulence.[613,788] VACV protein A49 activates the wnt signaling pathway by binding β-TrCP and thereby stabilizing β-catenin.[178]

VIRAL DEFENSE MOLECULES

Overview

The first line of host defense against viruses consists of nonspecific, innate mechanisms involving IFNs, chemokines, cytokines, signaling pathways, complement activation, and natural killer cells. Subsequently, antigen-specific cytotoxic T lymphocytes (CTLs) and antibodies become important. However, POXVs encode multiple proteins that help evade innate and adaptive immune responses. These may be grouped according to their site of action, inside or outside the infected cell, structural similarity, or which host defense pathway they antagonize. Secreted proteins may be related to cellular soluble binding proteins (BPs) for specific cytokines or IFNs, or cellular receptors that have lost their transmembrane anchor sequences and have been termed viroceptors.[740] Numerous intracellular proteins interfere with signaling or effector pathways. In contrast to the highly conserved mechanisms of entry, gene expression, and genome replication that are employed by all POXVs, there is considerable diversity in POXV defense genes, which are adapted to specific hosts. Many of these genes were acquired from their hosts and retain recognizable motifs despite extensive modification, whereas others may represent acquisition of new functions by proteins.

Extracellular Defense Proteins

Secreted defense molecules have been reported for many poxviruses, and 12 have been described for VACV (Table 16.7). Some may also bind to both infected or uninfected cells via interactions with other viral proteins or cell surface glycosaminoglycans. Secreted proteins may not only protect the infected cell from immune attack but also diminish the inflammatory response more widely to aid virus spread and transmission.

TABLE 16.7 VACV secreted proteins

Cop[a]	WR[b]	kDa	Time[c]	Properties	References
A39R	163/4[d]	50-55	L	Related to semaphorin SEMA7A, virulence factor, restricts NK cell response	(149,251,403)
A41L	166	30	E	Chemokine-binding protein, virulence factor	(42,506)
A53R[d]	186[d]	20	L	TNF-binding protein, CrmC VACV strain Lister, USSR, and Evans	(12,572)
—	—	18	L	TNF-binding protein, CrmE, VACV strain USSR, secreted and on cell surface, virulence factor	(572,609)
B8R	190	42	E	IFN-γ–binding protein, virulence factor	(16,488,512,691,706)
B16R[d]	197	50–60	L	IL-1β–binding protein, virulence factor, regulates body temperature	(14,15,688)
B19R	200	60–65	E	Type I IFN-binding protein, secreted and on cell surface by binding GAGs, virulence factor	(19,146,468,705)
C3L	025	35	E	Complement control protein (VCP), virulence factor, binds C3b and C4b, inhibits complement activation, secreted and on cell surface, binds to A56	(187,261,327,367,368)
K2L	033	48–50	E	Serine protease inhibitor, fusion inhibitor, binds A56 on cell and EV surface	(106,768)
C11R	009/210	19	E	Vaccinia growth factor (VGF), virulence factor	(84,99,108,696)
—	013	13	E	IL-18–binding protein, virulence factor	(88,676,704)
C23L	001/218	35	E/L	Chemokine-binding protein, binds CC chemokines, virulence factor	(17,122,265,575,630,670)
M2L	031	33	E	Binds B7.1 (CD80) and B7.2 (CD86) T-cell costimulatory proteins to block T-cell activation	(679,767)

[a]Copenhagen (COP) ORF name.

[b]Western Reserve (WR) ORF number.

[c]Time of synthesis: E, early; L, late.

[d]Gene fragmented and nonfunctional.

Complement Regulatory Proteins

VACV and other OPXVs encode a secreted complement control protein (VCP), consisting largely of tandem, inexact copies of a 60-amino acid short consensus repeat found in cellular complement regulatory proteins, that inhibits the classical and alternative pathways of complement activation by binding and inactivating C4B and C3B and accelerating the decay of C3 convertases.[4,367,368,445,602] Although VCP is secreted, some of it is retained on the surface of infected cells by binding to heparin-like molecules[244] and to the VACV A56 protein.[187] Both the VACV and ECTV complement control proteins contribute to virulence.[262,326] Interestingly, the VARV ortholog of VCP is more potent than the VACV version in inhibiting human complement[400,599] and strain variation in the MPXV ortholog may contribute to differences in virulence.[394,401] Although the VACV B5 EV membrane protein also has short consensus repeats, there is no evidence that it has complement inhibitory activity. Host proteins incorporated into the EV membrane may also inhibit complement activation.[749]

IFN-Binding Proteins

Type I IFN BPs encoded by VACV and other OPXVs are present in the supernatants and on the surface of cells and are important for virulence.[146,188,705] Glycosaminoglycans help retain the IFN BPs to the surface of infected and uninfected cells so enabling virus spread to cells not rendered resistant to virus infection by IFN signaling.[19,468] The VACV type I IFN BP (Copenhagen B19, WR B18/200) and orthologs are Ig family proteins with limited sequence similarity to regions of the IL-1 receptor family[672] but not to the ligand-binding subunits of IFN receptors. Nevertheless, these proteins neutralize human IFN-α, -β, and -ω and have broad

species specificity.[705] MYXV encodes a protein important for virulence that is related in sequence to VACV B18 but is smaller, membrane bound and apparently cannot bind IFN.[55] Antibodies that bind the ECTV-type I IFN BP greatly attenuate infection *in vivo* showing the importance of these soluble virus proteins for disease progression.[804]

Proteins that bind to type II IFNs are secreted by POXVs of several different genera. The IFN-γ BPs of MYXV and OPXVs are related in sequence to the extracellular domain of the IFN-γ receptor.[16,488,741] Deletion of the MYXV and VACV IFN-γ BP attenuate disease in rabbits.[487,691,706] Because of the low affinity of the VACV IFN-γ BP for mouse IFN-γ compared to human IFN-γ, this cytokine would have a more profound inhibitory effect on VACV in mice compared to humans, which may be important for interpreting disease models.[728] The type I IFN inhibitor encoded by Yaba monkey tumor virus also inhibits type III IFN.[315]

IL-18 BPs

IL-18 induces IFN-γ and acts in synergy with IL-12 to induce NK cell activation, T-cell activation, and Th1 response polarization. MOCV, OPXVs, Yaba monkey tumor virus, and some other POXVs encode secreted proteins with amino acid similarity to the mammalian IL-18 BP and which bind and inactivate IL-18.[88,451,502,676,704,799,800] Despite limited sequence identity, similar amino acids of the human and viral residues interact with IL-18.[371] The MOCV IL-18 BP is secreted as a full-length form that binds cell surface glycosaminoglycans through the C-terminal tail and a furin-cleaved form with only the IL-18 binding domain.[801] ECTV and VACV IL-18 BP deletion mutants exhibit decreased virulence compared with wild-type virus.[88,574,704]

Soluble Tumor Necrosis Factor BPs

Tumor necrosis factors (TNFs) bind to their cognate receptors and induce pro-inflammatory responses or death of virus-infected cells. Leporipoxviruses,[624] OPXVs,[12,309,413,572,609] and yatapoxviruses[107] encode up to four soluble TNF receptors with varying binding specificities, time of expression during infection, and presence on the cell surface.[554–556] The VACV CrmE protein shares structural features with mammalian type 2 TNF receptors,[266] whereas the tanapox and Yaba-like virus TNF BPs have sequence similarity with MHC class 1 molecules.[107,564,811] CPXV and ECTV also encode a soluble homolog of CD30, another member of the TNF receptor family, which inhibits interaction of CD30 with its ligand.[524,610] Some OPXV TNF BPs also bind chemokines via a distinct C-terminal domain (see below).

Soluble IL-1β Receptor Homologs

IL-1β mediates a broad-spectrum response to virus infection by binding to a high-affinity cell receptor leading to activation of NF-κB. OPXVs encode homologs of the IL-1 receptor that bind IL-1β.[13,15,688] Depending on the virus dose and route of inoculation, deletion of the gene can reduce or enhance virulence. Expression of the IL-1β BP by VACV prevented induction of a febrile response.[13] In some VACV strains and all sequenced VARVs, the corresponding gene is rendered nonfunctional by frameshift mutations.[221]

Chemokine Inhibitors

A principal role of chemokines (CKs) is to coordinate the activation and migration of leukocytes to sites of virus infection by establishing concentration gradients on endothelial cells. CKs bind to endothelial cells via a glycosaminoglycan (GAG)-binding domain and to CK receptors on leukocytes via a CK receptor–binding domain. POXVs encode soluble CK BPs, transmembrane CK receptors, and CK mimics. The soluble CK BPs lack sequence similarity to CK receptors and interfere with the CK response in two ways. One group, typified by CC type CK BPs from CPXV, VACV, and MYXV (vCKBP/vCCI and M-T1), bind to CKs via the CK receptor binding domain and so prevent CKs binding to CK receptors on leukocytes.[18,265,670] The second group, exemplified by VACV protein A41[42,506] and MYXV M-T7,[378] bind to CKs via the GAG-binding domain. This prevents the establishment of CK concentration gradients to diminish leukocyte recruitment to sites of infection. Another group of CK BPs (CrmB and CrmD) were identified first as TNF BPs, but also bind CKs by a C-terminal domain.[20] Orthologs of either or both are expressed by CPXV, ECTV, and VARV. Blocking both TNF and CK binding to cognate receptors simultaneously has synergistic anti-inflammatory benefit, and antibody against ECTV CrmD alone can protect against mousepox.[20] Secreted CK BPs are encoded by OPXVs, leporipoxviruses, and parapoxviruses.[17,112,122,265,385,575,629,630,670] The structures of several POXV CK BPs have been solved and the binding sites determined.[37,42,821]

Several POXVs encode homologs of the CK receptor CCR8. The Yaba-like disease virus protein is inserted into the plasma membrane, binds human CCL1, and activates signal-regulated kinases.[499] A recombinant VACV expressing the Yaba-like disease virus CCR8 homolog is attenuated in mice.[498]

CK homologs are encoded by MOCV and FWPV. The MOCV-encoded homolog is predicted to be a CK antagonist based on the absence of the conserved N-terminal region[635] and binding specifically to the CCR8 CK receptor and competitively inhibiting binding of I-309, the natural ligand.[416] Other reports, based mainly on chemotaxis assays, suggested a broader activity.[170,186,370]

Other Cytokine-Binding Proteins and Homologs

Some parapoxviruses encode a secreted protein that binds granulocyte–macrophage colony-stimulating factor and IL-2.[184,185] ORFV encodes an IL-10 homolog with a high degree of identity to ovine IL-10.[236,325] The ORFV IL-10 suppresses macrophage activation and exerts an immunosuppressive effect.[787] Some chordopoxviruses secrete a semaphorin homolog with proinflammatory properties that interacts with plexin C1.[3,149,251,403]

Secreted Inhibitors of NK and T-Cell Activation

NK cells and CTLs have important roles in combating OPXV infections.[228,528] CPXV and MPXV encode a secreted class I MHC-like protein that acts as a competitive antagonist of the NKG2D activating receptor and inhibits NKG2D-dependent killing by NK cells.[120] Another secreted CPXV protein called M2, which is conserved in VARV, MPXV, and some VACVs, binds the T-cell costimulatory ligands B7.1 (CD80) and B7.2 (CD86) to compete with binding of CD28 and CTLA4 and thereby diminish T-cell activation.[767] CPXV lacking M2 induced

stronger antiviral $CD4^+$ and $CD8^+$ T-cell responses. The B22 protein homologs of VARV and MPXV render human T cells unresponsive to stimulation of the T-cell receptor by MHC-dependent antigen presentation, and MPXV and ECTV deletion mutants are attenuated in monkeys and mice, respectively.[22,584]

Intracellular Defense Proteins

Poxviruses encode many intracellular proteins that target innate immunity. These vary between poxvirus genera and antagonize diverse signaling pathways or antiviral factors. Often these proteins are encoded in the terminal regions of the genome, are expressed early during infection, and are nonessential for virus replication in cell culture. These proteins may affect virus virulence *in vivo* and modulate the development of virus-specific immunological memory.[11] It is not uncommon for a single virus to encode multiple proteins that target a single pathway. These diverse proteins are grouped here according to the pathways they target.

Inhibitors of Cell Pattern Recognition Receptor and Cytokine Stimulated Signaling Pathways

Pattern recognition receptors (PRRs) detect pathogen-associated molecular patterns (PAMPs) and thereafter activate innate immune signaling pathways leading to the expression of cytokines, CKs, and IFNs. Viral PAMPS include cytoplasmic DNA, single-stranded RNA with triphosphate ends, dsRNA, and viral proteins. POXVs interfere with these innate immune defenses at multiple levels including blocking interaction of the PRR and PAMP, inhibiting the signaling pathways, targeting the up-regulated cytokines, CKs and IFNs, and blocking the signaling pathways these host factors activate or the function of antiviral proteins they induce.

Inhibitors of RNA and DNA Sensing

To diminish recognition of viral RNA by PRRs, POXVs either synthesize viral mRNAs that are indistinguishable from host mRNAs by encoding capping, methylating, and polyadenylating enzymes, or minimize the level or availability of dsRNA produced by convergent overlapping transcription (predominantly late during infection). dsRNA is sequestered by the dsRNA-binding protein E3[129] and reduced by the decapping enzymes D9 and D10 that remove the 5′-caps from dsRNAs leading to their degradation and, consequently, diminishing the PKR- and RNase L-mediated antiviral responses.[408,411]

POXVs synthesize DNA in the cytoplasm that may be detected by DNA sensors such as cGAS, DNA-PK, IFI16, DAI, AIM2, RNA polymerase III, DDX36, DDX41, and Mre11. In response, POXVs have evolved countermeasures. DNA-PK is targeted by VACV proteins WR C16 (CPN C10)[549] and C4[627] that bind the Ku heterodimer to diminish DNA binding by this PRR. Evidence for additional downstream inhibitors[255] was followed by the discovery of poxins (VACV protein B2) in a wide range of poxviruses. These are 2′-3′-cGAMP nucleases that destroy this second messenger produced by cGAS after its engagement with dsDNA, and so prevent STING-TBK1-IRF3 activation.[212] RNA polymerase III-mediated sensing is counteracted by the dsRNA-binding protein E3.[426,744] Many other POXV inhibitors target the IFN regulatory factors (IRFs), NF-κB, and AP-1 pathways that are activated by these and other PRRs such as

toll-like receptors (TLRs), RIG-like receptors (RLRs), and NOD-like receptors (NLRs).

Inhibitors of NF-κB Signal Transduction

The NF-κB complex comprises a family of dimeric transcription factors that have a central role in responding to viral infections and mediating an inflammatory response. NF-κB exists in an inactive complex with IκBα in the cytoplasm until the latter is phosphorylated by Iκ kinase (IKK) complex, polyubiquitylated, and then degraded by the proteasome. POXVs can trigger NF-κB activation but use a variety of mechanisms to suppress this. Modified VACV Ankara (MVA), a highly attenuated strain of VACV used as a safe smallpox vaccine and as a vector for other vaccines, has suffered multiple deletions and lost the ability to prevent NF-κB activation due to dsRNA triggering of PKR in some cells.[418,515,652] Restoration of the N1L or M2L genes prevents induction of NF-κB by the PKR or ERK2 pathway, respectively.[254,297,418,784] The importance of NF-κB for innate immune signaling is underscored by the many inhibitors that POXVs express to inhibit its activation. This is illustrated well by VACV, which encodes greater than 10 inhibitors of this pathway (A46, A49, A52, A55, B14, C4, E3, K1, K7, M2, and N1) that act at different stages (Fig. 16.18) (for review[671]) and additional inhibitors remain to be identified.[702] Protein A46 binds to the TLR/IL-1R (TIR) domain of TLRs and the signaling adaptors TRAM, TRIF, MAL, and Myd88 to block signaling.[91,692] Proteins A52[91,287] and K7[625] act downstream of NF-κB and each binds TRAF6 and IRAK2 to inhibit TLR/IL-1R-induced signaling. A46, A52, and K7 inhibit TLR/IL-1R-induced NF-κB signaling but not TNF-induced signaling, whereas other VACV inhibitors act at or downstream of the convergence of these pathways and so have broader inhibitory activity. Protein B14 binds to IKKβ, to block IKKβ phosphorylation and so prevent phosphorylation of IκBα.[66,137] ORFV protein 024 also prevents phosphorylation of IKKβ and IKKα but does not bind the IKK proteins.[201] Protein N1 also inhibits NF-κB activation although the report that it binds to the IKK complex[204] is disputed.[137,153] Mutation of the N1 dimerization interface abrogates NF-κB inhibition,[177] but its mechanism of action remains unknown. Protein C4 also inhibits the pathway at or close to the IKK complex.[218] Protein A49 mimics IκBα and, via a motif conserved between these proteins, binds to the E3 ligase β-TrCP.[425] This prevents ubiquitylation and proteasomal degradation of IκBα and so IκBα remains bound to NF-κB subunits in the cytoplasm. A49 is an inducible inhibitor of NF-κB that requires activation by phosphorylation.[504] The kinase IKKβ activates both NF-κB signaling and A49 to inhibit NF-κB signaling.[504] Protein K1, a host range protein with ANK repeats, also prevents the degradation of IκBα.[652] The translocation of p65 into the nucleus is inhibited by VACV protein A55, which binds to the importin KPNA2.[521] Proteins M2[254] and E3[496] inhibit activation of NF-κB via the ERK2 and PKR pathways, respectively. NF-κB inhibitors A46,[229,230] A49,[503] A52 and B14,[267] K7,[341] and N1[35,153] are structurally related and have a Bcl-2 fold. A surprising feature of VACV NF-κB inhibitors is that, where tested, each one contributes to virulence despite the presence of other inhibitors[59,61,67,136,218,287,425,692] suggesting multiple functions.

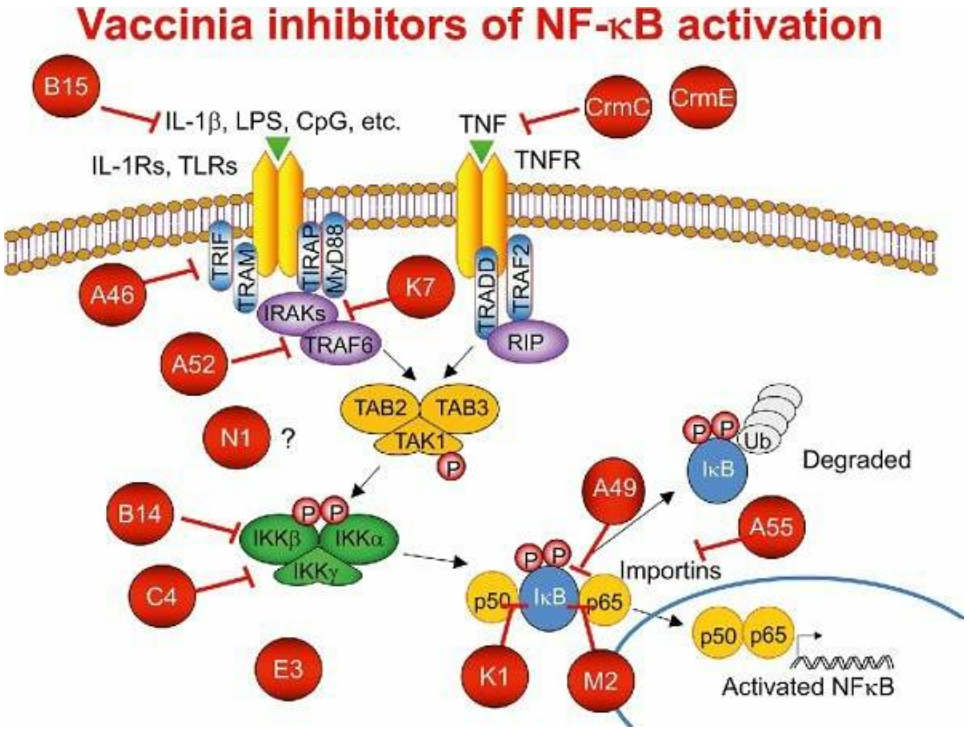

FIGURE 16.18 VACV inhibitors of NF-κB. Schematic showing simplified pathway of NF-κB activation following engagement of IL-1, TNF, or TLR ligands with their cognate receptors. Individual VACV proteins that inhibit activation of the pathway at specific places are indicated with *red circles*. Note B15 is from VACV strain WR. CrmC and CrmE are from VACV strains Lister, USSR, and Evans. Protein E3 binds dsRNA. The site of action of N1 is uncertain.

Other OPXVs contain orthologs of several of these VACV inhibitors and some additional inhibitors. For instance, VARV protein G1 and its orthologs (CPXV 006, ECTV 002, and MPXV 003) have ANK repeats and bind to the NF-κB p105 subunit and to SCP1 to inhibit pathway activation.[465,467] ECTV ANK proteins 002, 005, 154, and 165 also interact with SCP1, stabilize IκBα, and prevent p65 nuclear translocation.[111,745,746] Another group of ANK proteins have a C-terminal BC domain (ECTV 010, CPXV 016 and 019, raccoonpox virus 011, and skunkpox virus 202) and bind to cullin 2 and inhibit NF-κB activation or other signaling pathways.[514] NF-κB inhibitors in other POXV genera include ORFV protein 121 that binds to and inhibits the phosphorylation and nuclear translocation of NF-κB,[202] MC160, that inhibits TNFα-induced NF-κB activation by association with Hsp90 to increase IKKα degradation and by interaction with procaspase-8,[508] and MYXV protein MO13 that binds NF-κB.[566]

Inhibitors of IRF-3 Activation

The IRF-3 pathway is also targeted by several POXV proteins, and several of these are also inhibitors of NF-κB. VACV dsRNA-binding protein E3 prevents PKR-dependent activation of IRF-3 and mitogen-activated protein kinases.[822,823] VACV protein A46 binds to TRIF and TRAM and thereby prevents activation of IRF-3 and IFN-β expression.[692] Four additional

VACV Bcl-2 proteins, N1, K7, C6, and N2, each inhibit IRF-3 activation at or downstream of the kinases TANK-binding kinase 1 (TBK1) and IKKε that function at the convergence of several pathways leading to IRF-3 activation. N1 associates with TBK1,[204] and K7 binds directly to the DEAD-box helicase DDX3 that promotes activation of the IRF-3 pathway at the level of TBK-1 and IKKe.[625] C6 binds to the TBK-1 adaptors TANK, SINTBAD, and NAP1 to restrict IRF-3 activation,[739] and N2 acts after IRF-3 nuclear translocation to inhibit *ifnb* gene transcription within the nucleus.[234] The concerted inhibition of both IRF-3 and NF-κB activation by many POXVs restricts the production of pro-inflammatory cytokines, CKs, and IFNs. Additional POXV inhibitors target IFN-induced signaling and the function of IFN-stimulated gene (ISG) products with antiviral activity.

Inhibitors of IFN Pathways

Secreted proteins that bind type I, II, or III IFNs and block IFNs binding to their cellular receptors have been described above. A notable feature of these extracellular viral proteins is their ability to block the action of IFNs whether these are produced by the infected cell or uninfected cells recruited to the site of infection. POXVs also encode proteins that prevent IFN signaling and the function of IFN stimulated gene (ISG) products. The VACV dual specificity H1 phosphatase inhibits phosphorylation of the STAT1 and STAT2 transcription factors and block type I and II IFN-mediated immune responses.[406,423,500] MYXV inhibits type I IFN by blocking the activity of Janus kinase Tyke2, upstream of STATs.[762] VACV protein C6 associates with STAT2 and inhibits type I IFN signaling after STAT1-STAT2 phosphorylation, dimerization, nuclear translocation, and binding of the IFN-stimulated gene factor 3 (ISGF3) complex to promoters bearing the IFN-stimulated response element (ISRE).[698] Further analysis showed that C6 binds and induces the proteasomal degradation of histone deacetylase (HDAC)4, and that HDAC4 is needed for type I IFN signaling. Following IFN stimulation, HDAC4 is recruited to the ISRE-bearing promoters and is needed for the recruitment of STAT2.[414]

Inhibition of IFN-Stimulated Gene Products

IFNs induce the expression of hundreds of ISGs and several of these are antagonized by POXVs. The first examples were PKR and 2′5′-oligoadenylate synthetase (OAS). These host proteins are up-regulated by IFN but require dsRNA for their activation. Once activated by dsRNA present during infection, PKR phosphorylates eukaryotic translation initiation factor 2 alpha (eIF2α) to block protein synthesis. OAS synthesizes 2′-5′-linked oligoadenylates that activate RNase L, which then cleaves rRNA, tRNA, and mRNA and thereby also prevents protein synthesis. The action of both proteins is antagonized by VACV protein E3[129] and also by related dsRNA-binding proteins from other POXV genera, such as MYXV protein M029.[563,565] E3L deletion mutants show host range restriction and enhanced apoptosis, RNA degradation, and IFN sensitivity.[62,356] The C-terminal domain of E3 contains the dsRNA-binding domain and the N-terminal segment contains a Z-DNA–binding domain important for virulence.[374] The antiviral action of PKR is also antagonized by a truncated viral version of eIF2α (e.g., VACV K3 and MYXV M156), which inhibits eIF-2α phosphorylation by PKR.[171,172,567] Deletion of K3L increases the IFN sensitivity of VACV.[63,383] Thus, E3 and K3 proteins have overlapping roles in blocking IFN action.

The VACV C7-like family of host range genes encoded by several POXV genera mediate resistance to the IFN-induced antiviral factor SAMD9.[405,450,661,662,819] VACV protein C9 induces resistance to IFN treatment by binding to components of the SCF (CUL1, SKP1, and F-box) and signalosome/deneddylation complexes and to IFITs and inducing their proteasomal degradation.[409,410] VACV induces greater than twofold down-regulation of 265 cellular proteins during infection, and the majority including many ISGs are degraded by proteasome-mediated proteolysis.[679] VACV strategies to interfere with IFN is the subject of a recent review.[675]

Apoptosis Inhibitors

POXVs encode a variety of proteins that inhibit apoptosis by different mechanisms to prevent activation of the extrinsic pathway, for example, TNF, Fas ligand, or intrinsic pathway mediated by mitochondria. CrmA, a viral member of the serine protease inhibitor (serpin) superfamily initially described as an inhibitor of IL-1β converting enzyme caspase 1,[570] blocks apoptosis activated through Fas and TNF receptors[205,355,463,716] and potently inhibit caspase-8, the apical caspase in these pathways.[828] CrmA deletion mutants replicate normally in most cell lines without inducing apoptosis but do induce apoptosis in a pig kidney cell line.[420,571] The effect on virulence caused by deletion of CrmA or related SPI-2 has varied in different animal models.[355,718]

MOCV encodes two FLIP proteins with death effector domains (DEDs).[635] DEDs are also present in cellular FADD and procaspase-8 and mediate their interaction following the binding of TNF or FasL to their receptors. One of the MOCV DED proteins, MC159, has been shown to bind FADD and protect transfected cells against death effector filament formation and apoptosis induced by Fas and other members of the TNF receptor superfamily.[72,310,391,494,717,730]

Some POXVs encode Bcl-2-like proteins (e.g., VACV F1, MYXV M11, ORFV 125, FPV 039, deerpox virus 022) that prevent cytochrome c release from mitochondria by preventing Bak and Bax activation.[28,49,50,121,210,226,373,557,777] Those encoded by VACV are shown in Figure 16.19. F1 is also a caspase 9 inhibitor indicating that it is a multifunctional apoptosis inhibitor.[818] VACV protein N1 is another Bcl-2 antiapoptotic protein[153,177] although a relatively weak inhibitor compared to some other VACV proteins.[754] M1, a VACV ankyrin repeat protein, encodes an inhibitor of apoptosis that associates with the apoptosome.[601]

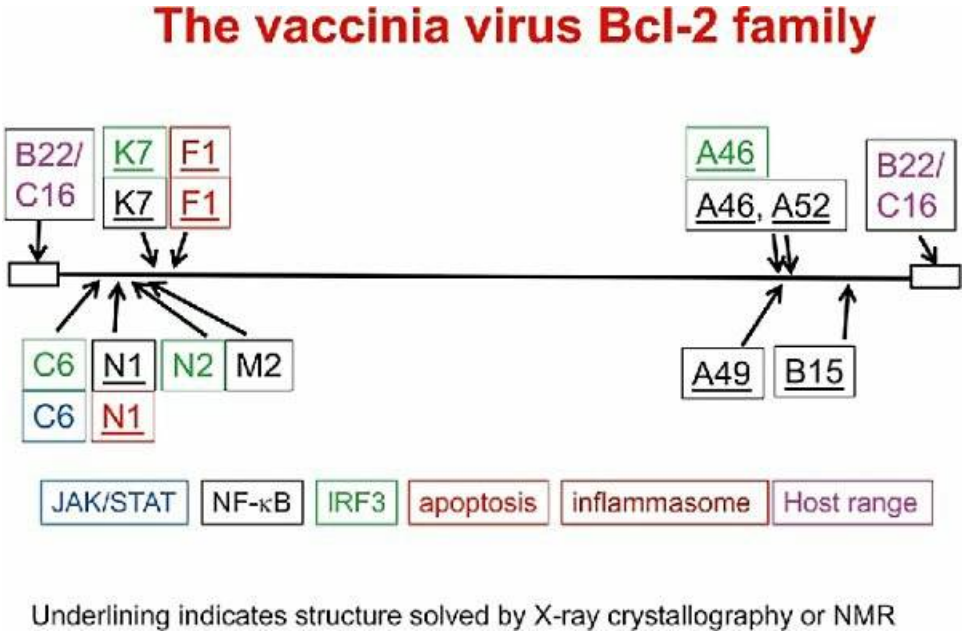

FIGURE 16.19 The VACV Bcl-2 family. The VACV genome is depicted as a *black line* with the inverted terminal repeats as *black boxes*. The positions of VACV CPN genes encoding Bcl-2–like proteins are shown with *arrows* and the function(s) of the encoded proteins indicated by *color*. Note several proteins have multiple functions. Proteins *underlined* have had their structure solved by x-ray crystallography or nuclear magnetic resonance. Note B15 CPN is B14 in strain WR. C16/B22 are diploid due to being in the ITR.

Several POXV proteins prevent apoptosis by additional mechanisms. GAAP (Golgi Anti-Apoptotic Protein) is encoded by CMLV, some strains of VACV, and eukaryotes and can inhibit apoptosis mediated by extrinsic and intrinsic pathways.[278] The ECTV p28 protein contains a RING finger motif that is required for virulence in mice,[643] acts upstream of caspase 3 to block UV-induced apoptosis,[96] and has been shown to be an E3 ubiquitin ligase.[314] Over expression of the SFV ring finger protein N1 can also block apoptosis induced by UV light.[97] MOCV encodes a selenocysteine-containing protein, MC66, that is homologous to cellular glutathione peroxidase and which can protect cells against the cytotoxic effects of hydrogen peroxide, which could be produced by inflammatory cells and UV irradiation.[653] A putative glutathione peroxidase is also encoded by FWPV.[3] The MYXV M-T4 localizes to the ER of infected cells and is required for virulence and to prevent induction of apoptosis in a rabbit CD4+T cell line or primary rabbit lymphocytes.[57,298] The MYXV M-T5 protein has a single ankyrin motif, is related to OPXV host range genes, and is required to prevent apoptosis in a rabbit CD4+ T-cell line.[486] VACV E3L deletion mutants induced apoptosis in HeLa cells through failure to inhibit PKR and RNase L as discussed above.[356,388]

Inhibitors of Antigen Presentation

CPXV encodes two proteins that down-regulate MHC class I presentation by distinct mechanisms. CPXV203 retains fully assembled MHC class I by exploiting the KDEL-mediated

ER retention pathway, whereas CPXV12 binds to the peptide-loading complex and inhibits peptide loading on MHC class I molecules.[114,115] The VACV A35 protein inhibits MHC class II antigen presentation by an unknown mechanism.[578,579]

Additional POXV Defense Proteins

The VACV β-hydroxysteroid dehydrogenase contributes to virulence by inhibiting an effective inflammatory response.[573] The mechanism of action of many other POXV proteins that are not required for replication in cell culture but reduce virulence in animal models remain to be determined.[56,209,227,644,682,683]

ADAPTIVE IMMUNE RESPONSE TO POXVIRUSES

Adaptive humoral and cell-mediated immune responses are important in clearing poxvirus infections, and knowledge in this area helps to understand the efficacy of vaccines and the design of new ones. Not surprisingly given their large size and complexity, there are numerous antigens, and consequently protective antibodies are directed toward both the MV and EV forms. As in other areas, most information has been obtained for OPXVs, and this has been the subject of several reviews.[11,479,491,646,803]

ANTIVIRALS

In view of the large number of viral proteins involved in cytoplasmic replication, there are many potential targets for antivirals, and some have been investigated over the years.[176] Two potent antivirals have reached the stage of clinical testing. Cidofovir is an acyclic nucleoside analog that is incorporated into the growing DNA strand and inhibits the 5′-to-3′ chain extension and 3′-to-5′ exonuclease activities of VACV DNA polymerase.[30] Cidofovir (Vistide) has been approved to treat cytomegalovirus retinitis in AIDS patients. An orally available derivative of cidofovir, Brincidofovir, is being tested for both cytomegalovirus and poxvirus applications. The other antiviral is ST-246, which inhibits the wrapping of MVs and formation of EVs by targeting the F13 protein[339] and has been approved under the name TPOXX (Tecovirimat) as a treatment for smallpox and monkeypox.[272]

EXPRESSION VECTORS

Several attributes of POXVs have led to their extensive use as expression vectors.[474] These

include relative ease of formation and isolation of recombinant viruses, capacity for large amounts of DNA, relatively high cytoplasmic expression, and wide host range. Expression has been achieved either by using POXV promoters or by employing bacteriophage RNA polymerases and cognate promoters. Recombinant viruses have been used for the synthesis of proteins *in vivo* or *in vitro* and as vaccine candidates to prevent infectious disease and treat cancer.[434] In particular, there has been a recent emphasis on the attenuated MVA primarily for safety reasons[755] and the combination of MVA with DNA priming.[23]

INTRODUCTION

The family *Poxviridae* is extensive, with member species infecting insects (*Entomopoxvirinae*) and vertebrates (*Chordopoxvirinae*). This chapter focuses on vertebrate poxviruses (Table 17.1). Genera of poxviruses with species described to cause human illness are *Orthopoxvirus*, *Parapoxvirus*, *Yatapoxvirus*, and *Molluscipoxvirus*. The majority of human pathogenic poxvirus infections are zoonoses; only variola virus (VARV) and molluscum contagiosum (MCV) virus are sole human pathogens. The appearance and general structure of poxvirus virions is depicted in Figure 17.1.

TABLE 17.1 Host range and geographic distribution of genera and unclassified members of the subfamily *Chordopoxvirinae*

Genus and Species	Reservoir Host	Geographic Distribution	Other Infected Hosts
Orthopoxvirus			
Camelpox virus	Camels	Africa, Asia	Nil
Cowpox virus	Bank voles *Clethrionomys glareolus*, long-tailed field mouse *Apodemus sylvaticus*	Europe, western Asia	Cats, cattle, humans, zoo animals
Akhmeta virus	Rodents?	Europe	Cattle?
AK2015 (from Alaska)	?	Northern United States (Alaska)	?
Ectromelia virus	Rodents	Europe	Nil
Horsepox virus	?	Central Asia	Horses
Monkeypox virus	? Unknown—likely rodent	Western and central Africa	Monkeys, zoo animals, humans, prairie dogs
Raccoonpox virus	Raccoons	(Eastern) United States	Nil
Skunkpox virus	Skunks	(Western) United States	Nil
Taterapox virus	Gerbils (*Tatera kempi*)	Western Africa	Nil
Uasin Gishu virus	?	Eastern Africa	Horses
Vaccinia virus	?	?	Humans, rabbits, cows, river buffaloes (*Bubalis*)
Variola virus	Humans	Eradicated (formerly worldwide)	Nil
Volepox virus	California vole (*Microtus californicus*)	Western United States	Nil
Parapoxvirus			
Ausdyk virus	Camels	Africa, Asia	Nil
Bovine popular stomatitis virus	Cattle (beef)	Worldwide	Humans
Orf virus	Sheep, goats	Worldwide	Ruminants, humans
Pseudocowpox virus	Cattle (dairy)	Worldwide	Humans
Red deer poxvirus	Red deer	New Zealand	Nil
Seal parapoxvirus	Seals	Worldwide	Humans
Capripoxvirus			
Sheeppox virus	Sheep	Asia, Africa	Nil
Goatpox virus	Goats	Asia, Africa	Nil
Lumpy skin disease virus	? African cape buffalo	Africa	Cattle (*Bos taurus, Bos indicus*)
Suipoxvirus			
Swinepox virus	Swine	Worldwide	Nil
Leporipoxvirus			
Myxoma virus	*Sylvilagus brasiliensis*	South America, western United States	*Oryctolagus*, other leporids
	Sylvilagus bachmani		
Fibroma virus	*Sylvilagus floridanus*	Eastern United States	*Oryctolagus*
Hare Fibroma virus	*Lepus capensis*	Europe	Nil
Squirrel fibroma virus	*Sciurus carolinensis*	Eastern United States	? Woodchuck
Western squirrel fibroma virus	*Sciurus griseus*	California	Nil
Yatapoxvirus			
Tanapox virus		Eastern and central Africa	Humans
Yaba poxvirus	? Primates	Western Africa	Humans
Molluscipoxvirus			
Molluscum contagiosum virus	Humans	Worldwide	Nil

Genus and Species	Reservoir Host	Geographic Distribution	Other Infected Hosts
Unclassified			
Crocodilepox	Crocodiles	Australia, South Africa	Nil
	Caimans	Florida	Nil
	Quokkas		
Cotia poxvirus	? Mice	Brazil	Nil
Squirrelpox virus	Grey squirrel	? Europe	*Sciurus vulgaris* (red squirrel)
Deerpox virus	? *Odocoileus hemionus* (North American mule deer)	North America	*Odocoileus hemionus* (North American mule deer)[121]
Mucocutaneous disease			
Avipoxvirus			
Many species	Birds	Worldwide	
NY014		Northern United States	
Murmansk virus	Root vole	Russia	
Salmon gill poxvirus	Salmon	Norway	
Eptestipox virus	*Eptesicus fuscus* (big brown bat)	United States	
Batpox virus	*Miniopterus schreibersii bassani* (Southern bent-wing bat)	Australia	
Batpox virus	*Pteropus scapulatus* (Little red flying fox)	Australia	
Batpox virus	*Eidolon helvum* (fruit bat)	Africa	
Hypsugopoxvirus	*Hypsugo savii* (insectivorous bat)	Europe	
Western grey kangaroo poxvirus, WKPV	*Macropus fuliginosus*	Australia	
Eastern grey kangaroo poxvirus, EKPV	*Macropus giganteus*	Australia	
Cetacean poxvirus	Dolphins	Europe	
Sea otter poxvirus	*Enhydra lutris kenyoni*	United States	

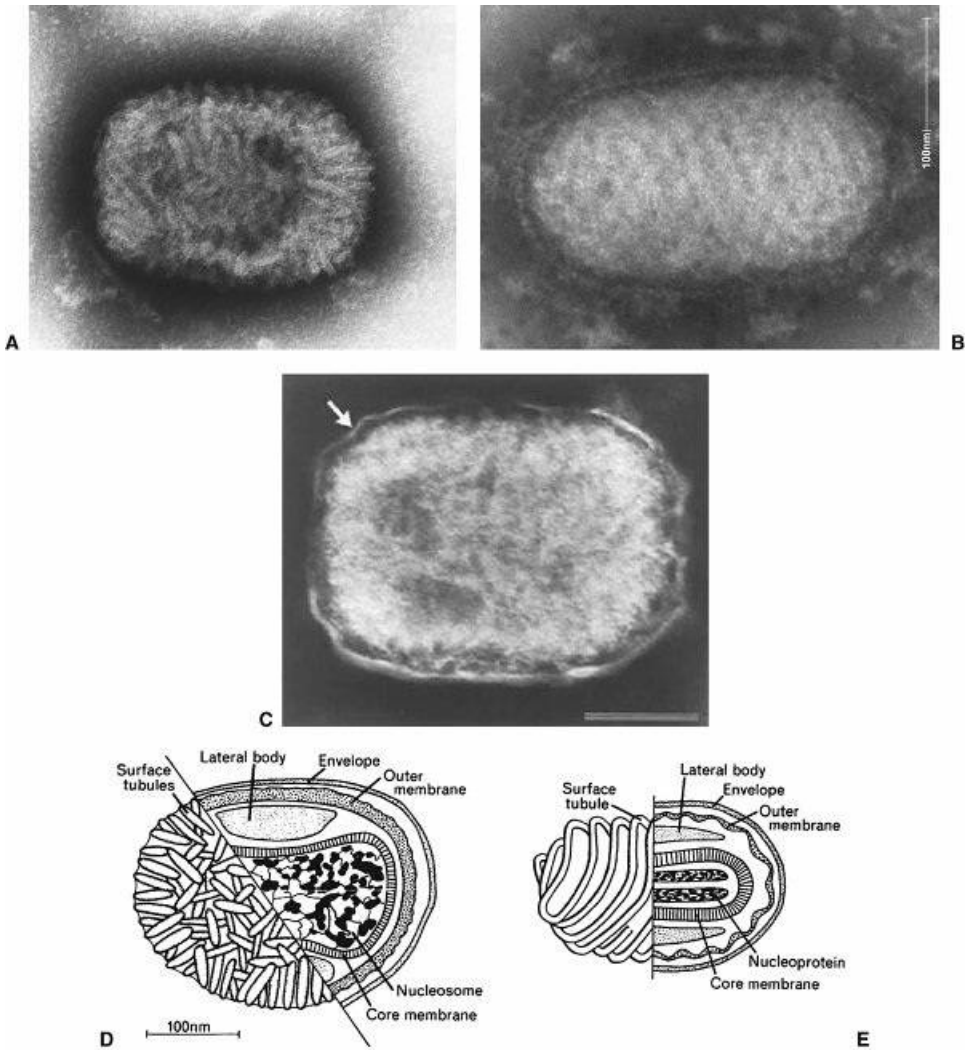

Figure 17.1 Negative stain electron microscopic appearance of orthopoxviruses **(A)**, parapoxviruses **(B)**, and yatapoxviruses **(C)**. Schematic diagram of structure of orthopoxvirus virion in **(D)** and of parapoxvirus virion in **(E)**. The structure of the yatapoxvirus and molluscipoxvirus virions is similar to that of the orthopoxvirus virion. As seen in **(C)**, clinical material from the yatapoxvirus tanapox often contains virion forms with enveloped virions (extracellular enveloped virions [EEVs]; see *arrow*). Knobby, brick-shaped virion forms, consistent with mature virions (MVs), are more often seen in clinical material from orthopoxvirus infections. Parapoxviruses are ovoid and smaller, with a distinctive criss-cross filament pattern derived from the wrapping of a surface tubule **(B)**. *Bars* indicate 100 nm. **D:** Drawing of a brick-shaped virion typical of an orthopoxvirus. Viral genome DNA and several proteins within the core are organized as a nucleosome. The core has a 9-nm-thick membrane with a regular subunit structure. By negative stain techniques, the virion core assumes a dumbbell shape with large lateral bodies occupying the concavities. The core and lateral bodies are enclosed within a lipoprotein structure, the outer membrane, which is 12 nm thick. The outer membrane surface appears to consist of irregularly shaped tubules that produce the knobby or mulberry-like M form seen in **(A)**. The majority of infectious virions remain cell associated; others acquire an additional envelope

composed of host cellular membrane and virus-specific proteins. These associate on the cell surface to spread to neighboring cells or are released as EEVs to allow more distant spread. **E:** Schematic drawing of parapoxvirus virion showing wrapping pattern of the outer protein tubule, which appears to wrap around the virus. ORTHOPOXVIRUSES

History

The orthopoxviruses are perhaps best known for their most notorious member, VARV, the causative agent of human smallpox. Smallpox was a febrile rash illness with a variable mortality rate extending to 30% to 40% in some outbreaks. The disease was understood to be a sole human pathogen; extensive experimental studies infecting closely related species failed to produce a viral infection that could be sustained in other host species. Recognition that an infectious agent that caused lesions on the skin and mucosal surfaces on cows and their caretakers could be used to prevent VARV infection was published by Jenner in 1798.[121] The viruses, cowpox- and later likely horsepox,[191] and vaccinia were used in the 19th and 20th centuries to prevent VARV infection; the use of the former virus (cowpox), the Latin for cow being vacca led to the term “vaccination.” Previously, material derived from convalescent smallpox patients, usually scab material, was used either as an intranasal or percutaneous preparation (termed inoculation) to prevent smallpox in humans.[73] Ultimately, this, in part, led to our early understanding of the genus *Orthopoxvirus* (where at least cowpox virus, CPXV) was used to cross-protect against smallpox.[15] In addition, the unsuccessful use of infectious material from “spurious” lesions[159] for smallpox vaccinations, which were later recognized to be of parapoxvirus origin (termed paravaccinia or pseudocowpox), led to the recognition of this distinct group of poxviruses. Vaccinia virus (VACV), however, is the most comprehensively studied of the orthopoxviruses.

The history of smallpox and its eradication program has been chronicled in detail[73] and is available from the World Health Organization (WHO) Web site. Perhaps the earliest, most reliable accounts of smallpox are from China in the fourth century AD; contained in writings that distinguish the disease from measles, report that smallpox was endemic in the region, and report the disease was introduced from the west in 48 AD.[73] Early practices from the 10th to the 18th centuries to control disease included quarantine, intranasal insufflation with powdered smallpox scabs, and cutaneous inoculation with pulverized smallpox scabs. With the recognition that vaccination with cowpox or vaccinia would diminish iatrogenic VARV cases, improvements in

disease control were seen. By 1953, smallpox had been eliminated from Europe. The development of freeze-dried vaccine preparations permitted vaccination in areas outside the cold chain. Largely through the global efforts in improvement of public health surveillance and disease control methods and the design and implementation of WHO-sponsored vaccination programs, the disease smallpox was declared eradicated in 1980 by the WHO. The last naturally occurring cases of smallpox occurred in the Indian subcontinent in 1975 and in the Horn of Africa in 1977. Remaining stocks of VARV were subsequently moved to two designated WHO Collaborating Centers for Smallpox and Other Poxvirus Infections with maximum containment laboratory facilities. The dismantling of population-based vaccination programs began in 1980. The eradication of smallpox and the discontinuation of vaccination programs likely contribute to the increase in observations of other human orthopoxvirus infections since 1980. Also, it has enhanced the concerns that if unknown stocks of VARV exist and were to be used, the effects on our current population would be profound.

Infectious Agent

By electron microscopy, the orthopoxviruses are large brick-shaped particles; as with all other poxviruses, the virus replicates and matures within the cytoplasm of the host cell. The viral steps involved in entry, fusion, morphogenesis, and release of virus are described in Chapter 16 as well as in a number of detailed reviews.[181,219] By light microscopy, cytopathic effects in monkey kidney cell lines are apparent and profound. Cell rounding and detachment from neighbor cells is followed by formation of elongated cellular lamellipodia[227]; ultimately, cells detach from the substrate. Similar to other poxvirus genomes, the nuclear material is a covalently closed double-stranded genome. Genome length ranges from 170 to 250 kilobase pairs, and its composition is 34% G+C. The central 90 kbp of the central region is highly conserved and contains virion structural genes and enzymes responsible for its DNA replication and mRNA transcription; the terminal regions are varied across species and encode genes involved in the host–pathogen interaction. In addition to nucleic acid-based techniques, classification of orthopoxviral species has also been accomplished based on various biological properties (Table 17.2). These include the presence (or absence) of acidophilic-type inclusion (ATI) bodies, cytoplasmic structures containing collections of virions, and seen in cowpox, ectromelia, raccoonpox, volepox, and skunkpox infections. However, as additional sequence information becomes available, classification of viruses is becoming more complex. For instance, phylogenetic analysis of strains within species was initially supportive for at least two clades of CPXV.[92] A recent analysis, using additional CPXV genome sequences, demonstrates four distinct clades.[39,78] Current information is supportive of two clades of monkeypox virus[47,158] and two or three clades of VARV.[68,155,197] The majority of the orthopoxviruses appears to have a broad host range, although the spectrum of disease may vary, depending on what host is infected. This is exemplified by cowpox, which causes discrete localized lesions on the udders of cows but appears to cause a systemic disease in cats. The exception is VARV, which as we understand the virus, was a sole pathogen of humans and humans appeared to be the sole host. A review on the cellular host range of poxviruses is available.[171,193,197,265]

TABLE 17.2 Biologic properties of orthopoxviruses that can infect humans

Property	Variola	Monkeypox	Vaccinia	Cowpox
Host range	Narrow	Broad	Broad	Broad
Pocks of the chorioallantoic membrane (CAM)	Small, opaque, white	Small, opaque, hemorrhagic	Strains vary; large, opaque, white or hemorrhagic	Large, hemorrhagic
Ceiling growth temperature on CAM (°C)	37.5–38.5	39	41	40
Rabbit skin lesion	Small transient, nontransmissible	Indurated, hemorrhagic	Strains very; indurated nodule, sometimes hemorrhagic	Large, indurated hemorrhagic
Lethality for:				
Mice	Low	High	High to very high	Variable
Chick embryo	Low	Medium	Very high	High
A-type inclusion bodies	No	No	No	Yes
B-type inclusion bodies	Yes	Yes	Yes	Yes
Genome DNA size (kbp)	186	191	192	220

Pathogenesis and Pathology

Orthopoxvirus infections can be classified as systemic or localized (at the site of virus entry) illnesses. Generalized disease usually manifests with rash. The type of infection that results is dependent on the species of orthopoxvirus, the route of entry, and the genus/species of susceptible animal and its immune status. For this chapter, infections of humans and models to understand infections of normal host humans are largely described. In some cases, understanding of the natural pathogenesis is limited due to the lack of data on the disease pathogenesis in its natural host. The most obvious example is VARV. Although clinical descriptions of disease are well notated from early medical writings, the specifics of human pathogenesis are largely derived from inferences evaluating other (e.g., ectromelia, which causes mousepox infection in mice, rabbitpox in rabbits, and monkeypox in nonhuman primates) orthopoxvirus virus species infections of various animal models.[36,44,84,129] Other respiratory challenge animal models of orthopoxvirus disease are the intranasal vaccinia and intranasal or aerosol CPXV challenges of mice.[101,167] These appear to primarily cause upper and lower respiratory infection; virus antigen predominates in the sinuses, intranasal passages, trachea, airways, and lungs. Some evidence of viremic spread is suggested by occasional lesions in the skin or bone marrow.

Nonetheless, the use of animal models of systemic or localized disease, in combination, will be useful in determining efficacy of various therapeutic and/or prophylactic disease mitigation and prevention strategies. Intranasal or aerosol challenge models have been developed using many of the orthopoxviruses in different animal species to represent a respiratory route of infection. Different routes of exposure result in differences in disease pathogeneses, involve some different sets of viral proteins, and provide information relevant to understanding disease acquired via contact versus respiratory routes of transmission.[254] Contact transmission has been classically modeled in the footpad model of infection of mouse species with ectromelia,[69] and more recently, in the dermal ear model with vaccinia, which also provides a model for understanding the immune response to multiple puncture immunization in eliciting (vaccination) protection against smallpox. Models of specific disease manifestations in various immunocompromised hosts have also been developed in order to evaluate the effect of various host factors in both disease pathogenesis and response to, containment of, and clearance of pathogen.

Systemic Disease Pathogenesis

Entry

The cellular receptor used by poxviruses for entry into their host cells is unknown. Member viruses have a broad tropism for entry into tissue culture cells; usually it is the later steps that inhibit completion of the viral maturation process to produce infectious progeny and affect "host range".[171,200] A summary of *in vitro* research on *in vitro* (orthopoxvirus) viral entry and fusion mechanisms is available.[180,181] The portal of entry for orthopoxvirus infection is usually considered to be percutaneous (via contact) or the respiratory tract. Oral routes of exposure have also been reported if very large doses of ectromelia virus (ECTV) are administered[72] to mice; this has been proposed to be a potential route of exposure for cats to cowpox and squirrels to monkeypox.[75] However, investigations associated around a laboratory-associated outbreak in a mouse colony suggested that the natural route of transmission is through abrasions in the skin after exposure to infected animals or contaminated fomites.[263] The route of infection also affects the disease course. Inoculation of variola, when unsuccessful as a form of disease prevention and caused iatrogenic disease, demonstrated a compressed time from infection to illness with respect to that seen with respiratory acquired disease. Transmission of human smallpox is thought to occur via an upper respiratory route of infection, which is consistent with the typical time frame of disease; infection via contact with contaminated fomites has also been observed. The exposure route/portal of entry for human monkeypox infection may be either percutaneous or upper respiratory; the clinical disease course varies with route of infection.[215] To model a respiratory route of exposure, a variety of aerosol challenges with various orthopoxviruses have been used to infect various animal species; these may produce initial stages of disease that occur in lower portions of the respiratory tract than seen in natural human infection. An alternative exposure route has been intranasal challenges.[84,94,116,167,217,267] For one North American orthopoxvirus, volepox, mechanical arthropod vectors have been suggested as a route of transmission to California voles[213]; this has not been observed in other orthopoxviruses, although it is a route of transmission, and portal of entry, for fowlpox and *Capripoxvirus* and *Leporipoxvirus* species. Importantly, in rabbitpox virus challenge studies, natural respiratory/airborne transmission appeared to occur over 12 feet.[267]

Site of Primary Replication

When the skin is the portal of entry, studies with ectromelia have suggested that the virus needs to be introduced to the dermis if systemic infection is to eventually ensue.[218] Virus replicates in the Malpighian layer of the epidermis, and dermal infection consisted of fibroblasts and histiocytes; the latter were likely responsible for subsequent movement of virus to the lymphatics to initiate the course of events required for systemic illness.

When the respiratory tract has been used as portal of entry, in experimental aerosol infections, likely dependent on particle size, a combination of upper and lower respiratory tract infection has occurred. Viral replication occurred in alveolar macrophages and small bronchioles, then moving to regional pulmonary lymph nodes. Epidemiologic understanding of the natural human infections with VARV to cause smallpox suggests that the common method of transmission was via a respiratory route. Primary infection is believed to have occurred within the mucosal surfaces of the nasopharyngeal tract, then moving to the regional lymphatics by extrapolation from that seen with ectromelia and rabbitpox virus studies. A recent review of aerosolized rabbitpox virus infection in rabbits is available.[262]

Virus Spread

Our understanding of orthopoxvirus spread after initial infection and spread to regional lymphatics comes again from studies of ectromelia in mice, rabbitpox in rabbits, and monkeypox in nonhuman primates. The use of fluorescent-antibody stains of fixed tissues and titers of infectious virus in organs at various time points in disease has provided the majority of this information. With reporter viruses expressing firefly luciferase gene, live imaging and progression of viral spread is monitored with imagers limiting the need for serial sacrifice.[5,163,274] Virus moves from the regional lymphatics to the bloodstream to cause a primary viremia, then multiplies in the spleen, liver, bone marrow, and other reticuloendothelial organs. After this, a second viremic period ensues, followed by seeding of distant sites, specifically the skin, and generation of the characteristic generalized rash. Virus particles are mostly cell associated during viremic phases of disease. In ectromelia, the virus replication in the macrophages of the liver spreads to the parenchymal cells of the liver causing necrosis; similar pronounced replication and effect of virus is found in spleen and bone marrow. In certain inbred mouse species, the disease is so pronounced at this stage that mortality ensues prior to development of rash.[36]

Experimental challenge studies of monkeypox virus infection, which clinically resembles smallpox more than mousepox, have been done in several species of animals, including nonhuman primates, and have demonstrated infectivity and pathogenesis through a number of routes of infection, including aerosol, intranasal, or parenteral administrations.[44,113,185,275] Initially, after aerosol infection in cynomolgus macaques, there is regional lymph node uptake and replication of virus in lymphoid organs, followed by viremia. An eruption begins, with lesions forming macules, papules, vesicles, pustules, and crusts to scar formation from days 6 to 23 of infection. Areas of inflammation and cell necrosis have been seen in tonsils, lymph nodes, digestive tract, testes, ovaries, kidneys, liver, and lungs. Epithelial degeneration, necrosis, and intracytoplasmic bodies have been seen in skin and mucous membranes. Based on the infection and transmission of MPXV in prairie dogs observed during 2003 U.S. outbreak, several studies characterized prairie dogs as a model for MPXV/systemic orthopoxvirus disease pathogenesis.[112,114,116] MPXV infection in prairie dogs closely resembles that of human symptoms including a prodromal period and skin lesions making it an attractive model to check the effect of vaccines and antivirals.[131,244] Similarly, other potential reservoir hosts of MPXV, dormice, Gambian rats and African rope squirrels, were susceptible to MPXV infection.[70,115,234] As a mouse model, the CAST/EiJ strain was identified to be highly susceptible to MPXV infection and useful to study MPXV pathogenesis.[4] Use of high doses of variola in nonhuman primate challenges, via parenteral route of administration, produced a severe illness with hemorrhagic manifestations of disease.[120] Apoptosis and a disregulated cytokine response are believed to be responsible for what has previously been referred to as the “toxemia” of smallpox. Despite several attempts, other rodent animal models to study VARV pathogenesis, like prairie dogs and CAST-EiJ mice, did not replicate classical systemic orthopoxvirus illness signs and symptoms, although CAST-EiJ manifest adaptive humoral responses to infection.[40,80]

Pathology

Cytoplasmic inclusion bodies are a typical histopathological feature of orthopoxvirus infections.

Two morphologies (Fig. 17.2) are manifest: A-type inclusion bodies, where virions are clustered within an intracytoplasmic structure (Fig. 17.2D), or B-type inclusions (Guarneri bodies), which are perinuclear and contain the viroplasm and maturing viral particles. Not all orthopoxviruses form A-type inclusions; a longer predicted form of the A-type protein (ATI) (130–160 kD vs. 90 kD) appears to be required. In cowpox, the A-type inclusion is termed a Downie body; in ectromelia, it is termed a Marchal body. The North American orthopoxviruses also form A-type inclusions. Notably, VARV, MPXV, VACV, and horsepox virus encode truncated ATI open reading frames and do not form inclusion bodies. In animal studies, loss of ATI or inclusion body formation was correlated to enhanced virulence/pathogenesis.[130]

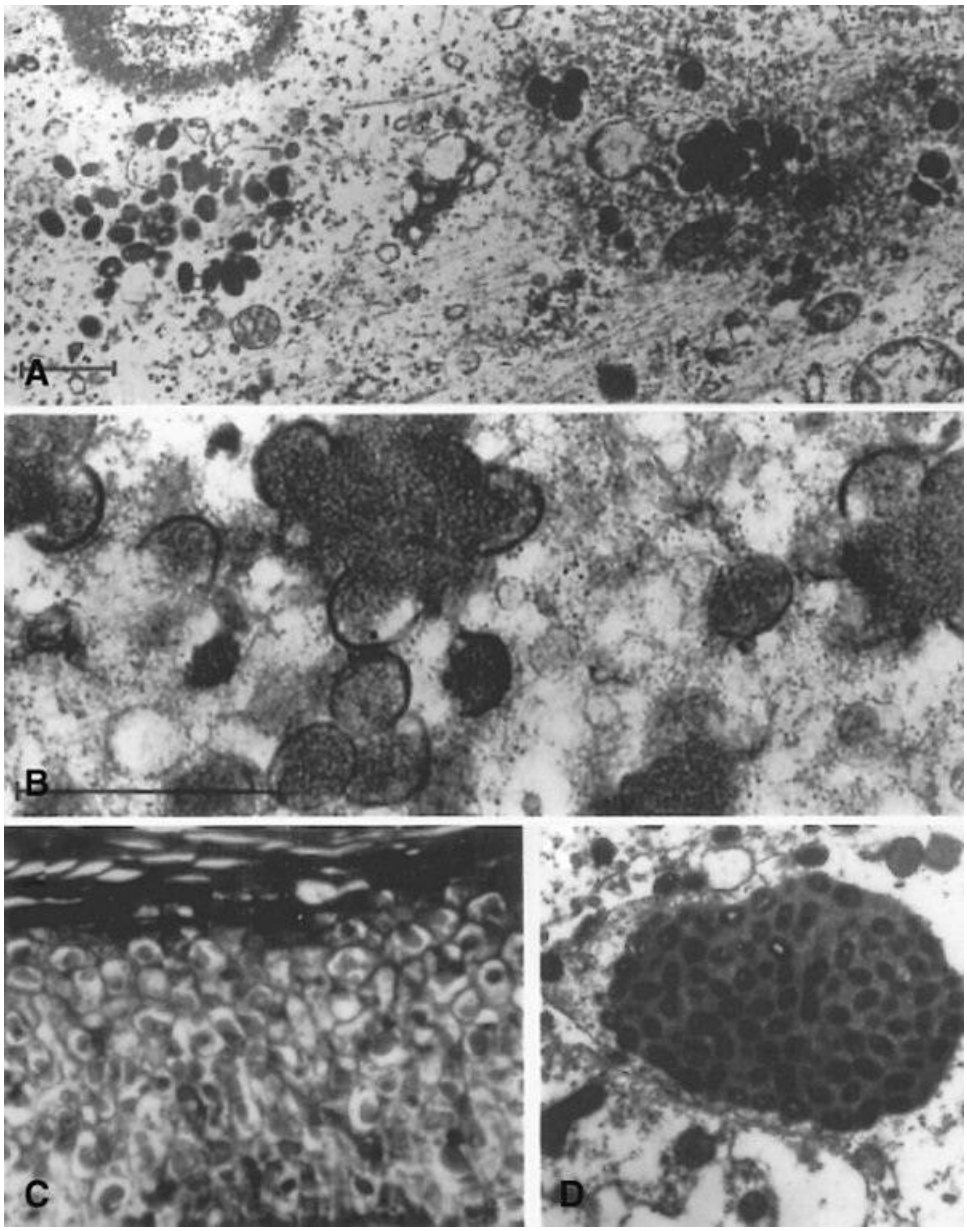

Figure 17.2 Cytoplasmic inclusion bodies produced by poxviruses. A and **B:** Electron micrographs of viral cytoplasmic factories that manifest by light microscopy

as B-type inclusions; these structures are basophilic by hematoxylin-and-eosin staining. In **(A)**, rounded structures, the immature virions (IVs), are seen on the right, and the nonenveloped intracellular virions (IMVs) are seen on the left. In **(B)**, a higher-power magnification demonstrating the IVs and the earlier crescent-shaped progenitor forms. **C and D:** A-type inclusion bodies (ATIs) visualized by light microscopy **(C)** and electron microscopy **(D)**. **C:** Hematoxylin-and-eosin staining of mouse skin demonstrating eosinophilic intracytoplasmic structures in the skin of a mouse infected with ectromelia. **D:** Electron micrograph of mature cowpox virions within an ATI. In humans, it is the rash that has been extensively studied during smallpox disease pathogenesis. The viral lesion primarily develops in the epidermis, although early changes of capillary dilation, endothelial cell swelling, and perivascular cuffing with lymphocytes, macrophages, plasma cells, and eosinophils are seen in the papillary layer of the dermis prior to development of the rash lesion. Subsequently, within the epidermis, the cells of the Malpighian layer swell and vacuolate to undergo ballooning degeneration. B-type inclusions could be seen in the cytoplasm. The cytoplasm continues to enlarge, loss of nuclear material is noted, and coalescence of vacuoles via cell rupture creates reticulating degeneration of the middle and upper layers of the stratum spinosum. In the next stages, the vesicle is formed. Cells of the lower stratum spinosum and basal layer exhibit nuclear condensation and nuclei fragment. The cavity of the vesicle (later the pustule) thus develops adjacent to the dermis, permitting the “deep-seated” feel of the smallpox pustular lesions. The cavity retains some cellular remnants that create a multiloculated appearance, also adding to the firmness of the lesion. When polymorphonuclear cells move into the cavity, pustulation occurs. High titers of virus are found within the lesions.[31] In mucosal surfaces, the absence of a horny layer allowed the necrosis caused by proliferation of virus within the epithelium to create ulcers and led to liberation of large quantities of virus into the oropharynx.[228]

Evaluation of other organs in human smallpox has been done in select autopsies from cases where death was attributed to ordinary or hemorrhagic forms of smallpox.[31] Some of the observations from autopsies of ordinary smallpox case deaths have been that, unlike ectromelia, liver and spleen do not show as extensive evidence of viral replication and necrosis that is seen in ectromelia infection of susceptible mice. In general, mild pathological changes are seen in the lungs. This is in contrast to the more severe lung pathology seen in apparent cowpox infection of captive felines, which caused death and was associated with severe bronchopneumonia.[166] Similarly, pulmonary disease has been seen in respiratory rabbitpox infection of rabbits, where in

addition to subpleural nodules, focal areas of consolidation were noted.[88]

The pathology of the localized lesions of cowpox in humans has been studied. The lesions are characterized by a marked inflammatory and erythematous response.[17] The bulk of the lesion is caused by hypertrophy and proliferation of the basal cell layer of the epidermis, together with massive inflammatory infiltration. Infection usually spreads into follicles, and typical A-type inclusions are usually seen.

Immune Response: Primary Infection

Early responses to virus infection are the production of interferons, nitric oxide, and elicitation of natural killer (NK) and macrophage cellular functions prior to the development of adaptive, antigen-directed B- and T-cell responses. Both complement pathways are also activated by the host in response to virus infection. Studies of ECTV infection in various mice deficient in one or more immune response pathways demonstrate the importance of IFN-γ, granzymes A and B, perforin, and CD4 and CD8 T cells in clearance of primary infection. Antibody is also essential.[45,46,198] Additional studies in other orthopoxviruses demonstrate successful clearance of a primary orthopoxvirus infection to be dependent on the adequate production of interferon-γ and Th1 cytokines[208] to promote an effective cytotoxic T-lymphocyte (CTL) effector response. Experiments where high levels of IL-4 are produced early in infection, expressed from recombinant challenge poxvirus, show delayed or inhibited ability of the host to clear the recombinant poxvirus and evade antiviral inhibition.[7,118,239] In secondary infection, as in the circumstance of infection post vaccination with a heterologous orthopoxvirus, antibody alone may be sufficient.[199] This latter finding has also been demonstrated in vaccine provided protection for monkeypox infection.[63]

Macrophages and NK cells are involved in early responses to infection and are used for clearance of orthopoxvirus infections.[71,128] The secreted interferons are needed for containment of primary orthopoxvirus infections.[163,222] The cellular secretion of tumor necrosis factor is another host response to orthopoxvirus infection. Viral infection can induce apoptosis, and the poxviruses have a number of strategies to inhibit apoptosis, which are also involved in host range, that have been reviewed[97,265] and are described in Chapter 16. One of the strategies that the orthopoxviruses have evolved is soluble secreted proteins to bind the host cytokines, complement C3b and C4b, chemokines, interferons, and their receptors. These include viral proteins that bind TNF, IL-1β, and IFN-γ via secretion of an ortholog of the mammalian protein that lacks its intermembranous and signaling portions. The orthopoxviral proteins that bind the type I interferons, as well as those that bind IL-18 (which regulates IFN-γ) and the chemokines, have apparently evolved to develop a structure distinct from the mammalian receptors for these immune response proteins; the IL-18–binding proteins have similarity to the mammalian IL-18 regulatory-binding proteins.

Studies designed to better define the pathogenesis of adverse effects of current replicative vaccinia used as smallpox vaccine in individuals with atopic dermatitis (AD) provide additional information about the early steps in viral pathogenesis and the normal and aberrant host innate immune responses, as well as factors important in containment of viral infection to produce localized disease. In AD, there is an abundant Th2 response.[21] Human skin explant models have been developed to understand eczema vaccinatum (EV), the dissemination of vaccine virus in individuals with AD.[107] In human AD skin, an abundance of Th2 cytokines IL-4 and IL-13 (with

respect to normal skin) diminish the effectiveness of an innate immune response to VACV, in a STAT-6–dependent manner, allowing increased replication of virus. In normal skin, viral replication is inhibited by cathelicidins. In human keratinocytes infected by vaccinia, the cathelicidin LL-37 is down-regulated through the effects of IL-4 and IL-13.[108] Limited animal models for AD have been developed to study pathogenesis of OPXV infections. ECTV infection in an AD mouse model developed EV with large skin lesions and high viral loads, and disease could be treated with antivirals and antibodies. The use of the replication-deficient modified vaccinia Ankara (MVA) for preexposure vaccination and protection from lethal ECTV challenge has been demonstrated in this model.[2]

The orthopoxviruses have strategies to inhibit intracellular antiviral effects of the interferons.[243] All orthopoxviruses sequenced to date have a homolog of the vaccinia E3L protein, and most have a homolog of the K3L protein. The E3L gene is truncated in MPXV and Volepox, even though MPXV is still pathogenic in humans. E3L homologs bind dsRNA and have at least two functions: one is to inactivate the IFN-induced dsRNA-dependent protein kinase (PKR) and the other is to inactivate 2′5′-oligoadenylate synthetase. K3L mimics eIF-2α, which prevents eIF-2α phosphorylation and inhibits autophosphorylation (activation) of PKR. Interestingly, this gene is absent from most strains of MPXV. E3L inhibition of PKR also interferes with its proapoptotic functions[19,138,152] to affect cellular host range of VACV. VACV lacking E3L, grown in nonpermissive cells significantly expand the K3L region of genome, after continuous passages, to compensate for the lack of E3.[64] This type of genomic accordion (expansion or reduction of genomes based on the selective pressures) is documented in other cases, as well, demonstrating an effective mechanism to overcome host cell inhibition by poxviruses.[67] Of note, one set of monkeypox clinical samples, associated with the emergence of monkeypox in South Sudan, contained a sizeable genomic duplication of multiple ORFs; the significance of this is unknown.[184] A number of orthopoxvirus proteins have also been identified that interfere in various intracellular steps of the IL-1R and TLR signaling pathways, ultimately regulating the NF-κB pathway[179] and interferon regulatory factors (IRFs). Two vaccinia proteins appear to act early in the pathway and target multiple nonoverlapping TLR pathways; A52R and A46R both block NF-κB activation. A VACV with A52R deleted appears attenuated *in vivo*. A46R inhibits TRIF-dependent signaling to inhibit IRF3 activation and TRIF-dependent gene induction.[247] TRIF may have an additional role in inhibition of vaccinia replication in the macrophage.[105] The product of the vaccinia A52 ORF has the ability to block NF-κB activation via a number of pathways. Additional vaccinia proteins (K1L and N1L) block specific steps further downstream in the signaling pathway for NF-κB activation.[60,241]

The orthopoxviruses also express proteins that interfere with various steps in apoptosis.[205] The vaccinia F1L protein interferes with mitochondrial components of the apoptotic cascade[264] through interaction with Bak. The serpin, SPI-2 (vaccinia) or crmA (cowpox), inhibits caspases 1 and 8; the latter effect protects target cells against CTL lysis induced by the Fas pathway.

The host–pathogen relationship of orthopoxviruses is complex and involves many host and viral factors. Using siRNA or genetic screens using insertional inactivation, requirement of host proteins and exploitation of host cell pathways for OPXV infection were characterized.[18,164,176,210,242] These studies demonstrate a multitude of different mechanism adopted by OPXV for establishing successful infection. Host responses to pathogenic and nonpathogenic orthopoxvirus infections examined using microarray techniques[33,93] provide

additional information regarding complex host–pathogen interactions. In variola parenterally infected nonhuman primates, which models aspects of the second viremia and subsequent disease course in severe forms of smallpox,[120] peripheral blood mononuclear cell transcripts showed an increase in interferon-associated gene transcripts not evident in animals that rapidly succumbed to infection.[226] There was also a significant up-regulation of Ig gene transcripts. Overall, there were minimal TNF-α and NF-κB responses.

Immune Response: Vaccination

The protective effects of smallpox vaccination and correlates of protection remain an area of active investigation.[76] Vaccinia strains provided an effective strategy for use as a live viral vaccine to prevent smallpox and to facilitate disease eradication. Smallpox disease was declared eradicated 40 years ago, at a time when the current advances in immunology were not available to dissect the mechanisms of protection. Although some studies demonstrated high levels of neutralizing antibody after vaccination or smallpox infection were protective,[229] other studies have demonstrated the level of CD8+ T-cell memory correlates with protection from subsequent viral disease.[268] A number of studies have demonstrated long-lived Ig and T-cell responses to smallpox vaccination[99,100]; individuals vaccinated in childhood demonstrate long-lived B-cell memory response, a longer duration of CD4 T-cell memory than CD8 T-cell memory,[3,51] which may be important for long-term B-cell memory.

However, previous remote childhood smallpox vaccination was not completely protective against acquisition of the related disease monkeypox when it was introduced in the United States in 2003.[127] Studies with ECTV infection in mice demonstrate the requirement of a virus-neutralizing antibody response, even in the absence of CD8+ T cells, in order to control a pathogenic virus challenge after immunization.

Release From Host

For smallpox, data on virus shedding show infectious virus in the oropharyngeal secretions, with lesser amounts in the urine and conjunctivae.[230] Levels of virus in oropharyngeal secretions were highest just after rash onset between 3 to 4 days post fever onset, the clinical manifestation of the secondary viremia; however, virus could be detected up to 2 weeks post fever onset in cases with more pronounced rash (confluent disease). Virus could be detected in urine over approximately the same time period during illness. In localized orthopoxvirus infections, such as vaccination with VACV (smallpox vaccination), virus can be found at the lesion until the scab separates.[143]

Epidemiology

Of the orthopoxviruses that infect humans, only VARV is not a zoonotic infection. Interhuman transmission of VARV occurred through the inhalation of large airborne respiratory droplets, containing infectious virus from infected persons. Transmission usually required prolonged face-to-face or other close contact, although airborne transmission over longer distances had been reported.[73] Transmission via fomites or contact with the infectious material from the rash also occurred. Aggregate data, collected during the smallpox eradication campaign, suggest a secondary attack rate of 58.4% in unvaccinated close or household contacts and a secondary

attack rate of 3.8% in previously vaccinated close or household contacts.[73] Case fatality rates for variola major varied with the type of disease manifest, but aggregate rates of 10% to 30% in various outbreaks have been recorded. Severity of disease correlated with rash burden and was also more severe in children and pregnant women. Variola alastrim minor, a variant of VARV with a case fatality rate of less than 1%, but manifest with apparent similar epidemiologic features of human-to-human transmission.

Monkeypox has a more complex epidemiology; two genetically discrete virus clades have been described,[47,158] with apparent distinct clinical and epidemiologic parameters. Identification of human infections, in Western and Central Africa, was first made in 1970. Investigations in 1980s in the Congo Basin country Zaire, now the Democratic Republic of Congo (DRC), demonstrated that human-to-human transmission of monkeypox was less than that of smallpox. The secondary attack rate in unvaccinated contacts of monkeypox cases were calculated to be 9.3% versus 37% to 88% for smallpox.[123] Prior smallpox vaccination (3–19 years previously) appeared to be 85% protective at preventing disease acquisition in contacts and also ameliorated disease severity. Overall, although the majority of cases identified acquired disease from a presumed animal exposure(s), only 28% of cases were ascribed to person-to-person transmission. A case fatality rate of approximately 10% was observed in unvaccinated persons; the majority of fatalities and severest disease manifestations was observed in children younger than the age of 5. Serosurveys suggested that subclinical infection may have occurred in up to 28% of close contacts of monkeypox patients in some communities, which may have contributed to the rarity of sustained generations of human-to-human transmission in household and other close contact situations.

Because the majority of cases were believed to have acquired disease through animal exposures, case–control studies were attempted in the 1980s to determine the source of infection. These were not definitive because the population appeared to have multiple daily contacts with the same animals in settlements, forests, or cleared agricultural areas. Among primary cases, recent close contact via hunting, skinning, killing, cooking, or playing with carcasses was identified to *Cercopithecus, Colobus*, and *Cercocebus* primate; *Cricetomys* terrestrial rodent; and *Funisciurus* and *Heliosciurus* squirrel species. Ecologic studies, usually using convenience samples of animals collected in areas surrounding human cases in West and Central Africa, demonstrated orthopoxvirus and sometimes monkeypox-specific seroprevalence in various members of these species but were not reported for *Cricetomys* species. This work has been comprehensively reviewed.[123] Virus was only found in one euthanized, moribund squirrel species *Funisciurus anerythrus*. The prevailing hypothesis was that squirrel species were the likely reservoir of disease. Near the end of the 1980s, disease surveillance and associated studies waned after modeling studies based on the epidemiologic observations of secondary attack rates from human-to-human exposure suggested that limited number of transmission events were feasible, even with low population immunity provided by waning immunization rates in the populations of Central Africa. The virus had not, therefore, adapted to survive solely through human infection and would not manifest with the same human-to-human transmission dynamics of smallpox. This work also led to the recommendations to not continue routine smallpox vaccination in individuals considered at risk for monkeypox infection.

A re-emergence of disease was noted in 1996 in the DRC; a salient observation from a series of investigations was that more cases were derived from secondary human-to-human contact (88%) than seen in 1981 to 1986 investigations (28%). This was, in part, attributed to a larger

population of humans fully susceptible to disease because of the cessation of routine smallpox vaccination in 1980 after smallpox eradication. Another observation was that disease epidemiology showed more cases in the older child/young adult population.[111] Disease mortality (1%) was observed to be lower than previously seen in 1981 to 1986. This may have been due to a smaller demographic of very young children (ages 0–4 years) being infected, may have been due to technical limitations on the investigations, or may have been due to the inclusion of chickenpox cases in the case definition. Whereas previous ecologic serosurveys of animal populations had implicated tree squirrels as having significant orthopoxvirus seroreactivity, these investigations were the first to show orthopoxvirus seroprevalence in terrestrial rodents (*Cricetomys emini*) and in one domestic pig (*Sus scrofa*) sampled. Outbreaks of monkeypox, some with apparent high interhuman transmissibility,[150] and ongoing surveillance documents an increased incidence of monkeypox in regions of the Congo Basin.[216] In addition, MPXV was detected in several West African countries in the 21st century after the absence of reported cases for several decades (Fig. 17.3).[22,214]

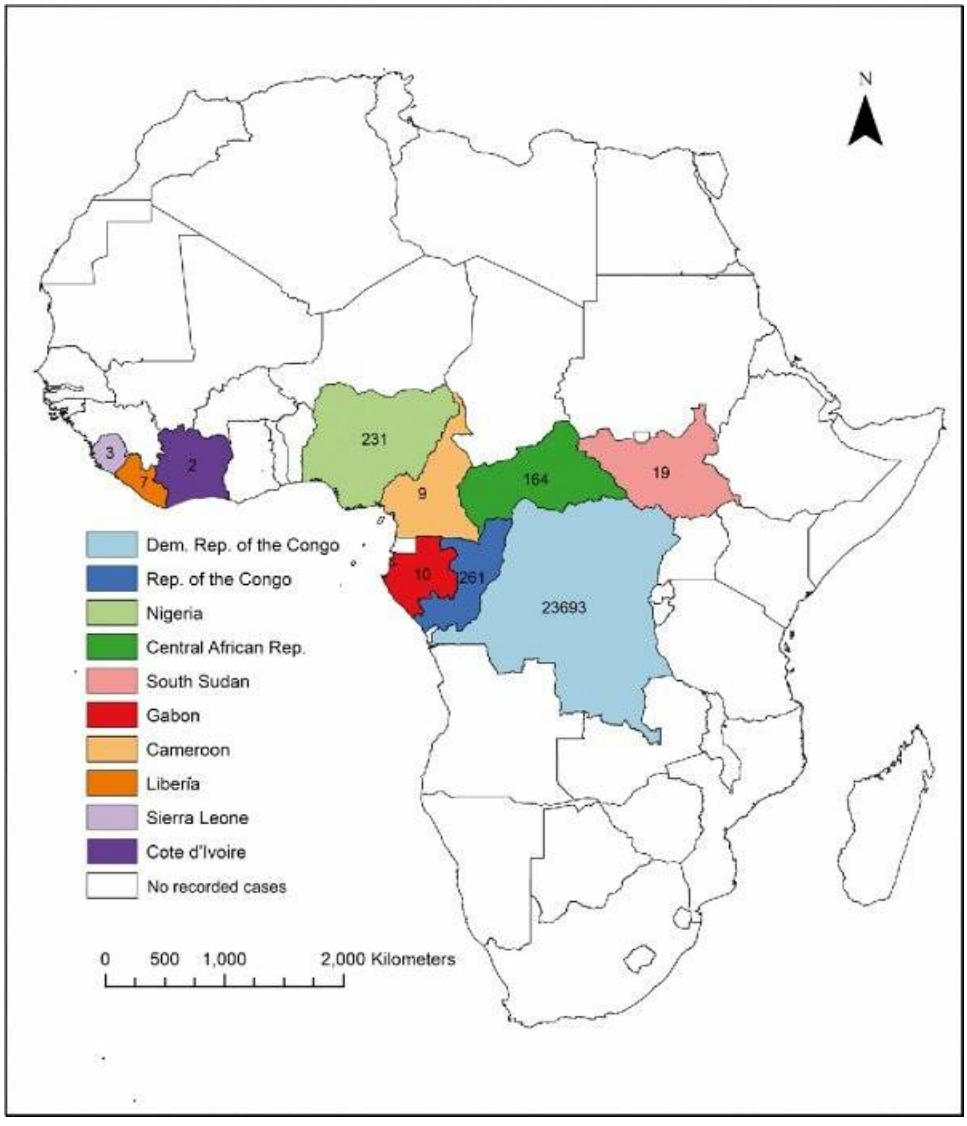

Figure 17.3 Human monkeypox cases reported from Africa between 1970 and 2018. (Reprinted from Beer EM, Rao VB. A systematic review of the epidemiology of human monkeypox outbreaks and implications for outbreak strategy. *PLoS Negl Trop Dis* 2019;13(10):e0007791. https://creativecommons.org/licenses/by/4.0/.)

Monkeypox virus was introduced to the United States (U.S.) in 2003 via a consignment of wild-captured animals from the West African country of Ghana. The virus was identified as belonging to a distinct clade of monkeypox, which included previous West African monkeypox isolates and isolates derived from earlier outbreaks in primate colonies. Detailed comparison of the clinical and epidemiologic characteristics of the U.S. cases (imported from West Africa) with DRC cases from 1981 to 1986 demonstrated significant differences in human disease manifestation[158]; pronounced rash and more severe illness were seen in the Congo Basin cases. Controlling for age and vaccination status, disease severity remained more extreme in the Congo Basin than in the U.S. case patients. Monkeypox-related mortality and human-to-human transmission were only seen in the Congo Basin, but a recent outbreak of MPXV WA clade in Nigeria demonstrated human-to-human transmissions.[270] In addition, travel-related monkeypox cases spread to the United Kingdom, Israel, and Singapore from MPXV outbreak in West Africa demonstrating, again, the potential risk for introduction outside the endemic area.[66,189,258] In toto, these data are suggestive of at least two populations of monkeypox viruses being maintained in Africa.

Cowpox

Cowpox is a virus found in Europe and Asia that is maintained in rodents; in Britain, these are bank voles and woodmice (Table 17.1).[23,41,43] The domestic cat is one common source of human infection,[24] and this probably explains the occurrence of cases in children; 26% of 54 cases identified between 1969 and 1993 were in children younger than 12 years.[17] Most feline and human cases occur between July and October, with only occasional cases between January and June. Human cases occur in which no source is traced, but despite detailed investigations, only three human cases in Britain since 1968 have been traced to a bovine source, and no case of bovine cowpox has been detected since 1976.

Cowpox virus has a wide host range, and an interesting finding has been the occurrence of cowpox in a variety of captive exotic species in European zoos. Susceptible animals have included cheetahs, lions, anteaters, rhinoceros, elephants, and okapi, and infection has occasionally been transmitted to animal handlers.[16,203,204] Recent outbreaks of human infections with CPXV in Europe have been traced to rat populations used in the pet trade.[38] A large number of novel CPXV infections and associated strains have been recently recognized and isolated in Germany and from Europe. Additionally, two OPXVs similar to CPXV, but phylogenetically distant, have been identified from Georgia and Italy.[78,90,261]

Vaccinia

The origin of vaccinia is unknown, and no natural host for the virus is known. However, a number of vaccinia variants have been described. Buffalopox has been described in India; human infection results from contact with infected animals. It is not known whether buffaloes are a

reservoir or whether other wildlife is involved, as with cowpox. Similarly, there have been increasing reports of VACVs infecting cattle handlers in Brazil. Cantagalo virus has been classified as a vaccinia variant, but other similar nonidentical vaccinia-like viruses have also been reported in the region.[53,56,57,153,252] VACV infections were detected in Colombia among cattle handlers, and DNA sequence confirmed distinct strain but most closely grouped with VACV strains from Brazil.[257] Studies have begun to investigate the disease ecology of these viruses.[1]

Other Orthopoxviruses

A number of novel orthopoxviruses have been identified in the past years. These include NY-014,[145] the causative agent of a renal transplant patients' slowly progressive rash illness, and Alaskapox, the cause of a localized rash illness in an Alaska resident.[246] Little is understood about the exposure related to these infections, and the genomes have been characterized.[82,245]

Clinical Features

Variola: Smallpox

Naturally acquired VARV infection caused a systemic febrile rash illness; the course of clinical features is schematically diagrammed in Figure 17.4. For ordinary smallpox, the most common clinical presentation, after an asymptomatic incubation period of 10 to 14 days (range, 7–17), was fever, which quickly rose to about 103°F, sometimes with dermal petechiae. Associated constitutional symptoms included backache, headache, vomiting, and prostration. Within a day or two after incubation, a systemic rash appeared that was characteristically centrifugally distributed (i.e., lesions were present in greater numbers on the oral mucosa, face, and extremities than on the trunk). Lesions were commonly manifested on the palms and soles. The rash lesions were initially macular and then advanced to the papular stage, enlarging and progressing to a vesicle by day 4 to 5 and a pustule by day 7; lesions were encrusted and scabby by day 14 and then sloughed off. Skin lesions were deep seated and in the same stage of development in any one area of the body. Images of the classic presentation of ordinary smallpox are depicted in Figure 17.5. Milder and more severe forms of the rash were also documented. Less severe manifestations (modified smallpox or variola sine eruptione) occurred in some vaccinated individuals, whereas hemorrhagic or flatpox types of smallpox are believed to have developed as a result of an impaired immune response of patients.

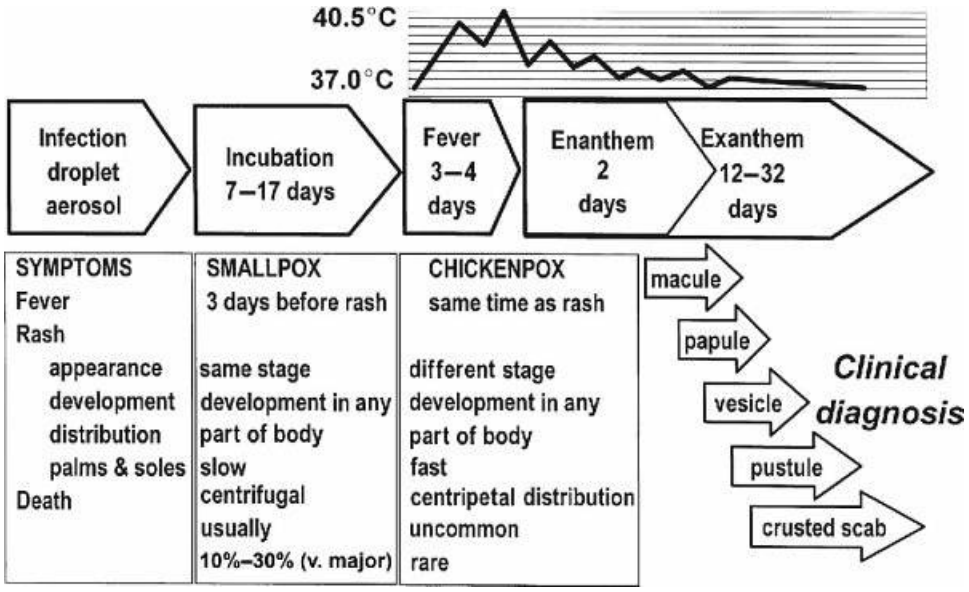

Figure 17.4 The clinical development of discrete ordinary smallpox. After respiratory droplet exposure and infection, an asymptomatic incubation period of 7 to 17 days precedes prodromal symptoms of high fever and malaise. Subsequently, rash develops 2 to 4 days after the prodrome. The fever diminishes at the onset of rash development. The characteristics of smallpox and chickenpox rash are contrasted.

Figure 17.5 The rash of smallpox. The smallpox recognition card used during the Intensified Smallpox Eradication Programme of the World Health Organization, showing the nature and distribution of the rash of ordinary smallpox. (Reprinted with permission from Fenner F, Henderson DA, Arita I, et al. *Smallpox and its Eradication*. Geneva: World Health Organization; 1988.)

Variola major smallpox was differentiated into four main clinical types: (a) ordinary smallpox (~90% of cases) produced viremia, fever, prostration, and rash; mortality rates were generally proportionate with the extent of rash and ranged, using the WHO classification, from less than 10% for ordinary discrete to 50% to 75% for the rarer ordinary confluent presentation; (b) (vaccine) modified smallpox (5% of cases) produced a mild prodrome with few skin lesions in previously vaccinated people and had a mortality rate of less than 10%; (c) flat smallpox (5% of cases) produced slowly developing focal lesions with generalized infection and had an approximate fatality rate of 80%; and (d) hemorrhagic smallpox (<1% of cases) induced bleeding into the skin and the mucous membranes and was invariably fatal within a week of onset. Notably, prior vaccination did not appear to protect from mortality associated with the more severe flat or hemorrhagic forms of disease. A discrete type of the ordinary form, with typical febrile prodrome and rash, resulted from alastrim variola minor infection.[73]

The WHO established a system for classifying smallpox case types on the basis of disease presentation and rash burden. The hemorrhagic and flat types are briefly described previously. The ordinary type was subgrouped into three categories, which were based on the extent of rash on the face and the body: confluent, semiconfluent, and discrete. In ordinary confluent disease, no area of skin was visible between vesiculopustular rash lesions on the trunk or the face. In ordinary semiconfluent and discrete disease, patches of normal skin were visible between rash lesions on the trunk and face, respectively. Disease modified by vaccine presented with sparse numbers of lesions. Survival from infection conferred lifelong immunity.

Monkeypox

In humans, clinical disease is believed to result from either respiratory, percutaneous, or permucosal exposures. Classical descriptions from the active surveillance program in Zaire, now the DRC, have historically provided most of our understanding of human monkeypox. Following an incubation period of 7 to 17 days (mean, 12 days), a prodrome of fever, headache, backache, and fatigue begins. The cutaneous eruption evolves similar to that of smallpox. Lesions evolve in the same stage in any one part of the body from macules, papules, vesicles, pustules, and then crust and scar. This is apparently more common in unvaccinated individuals[123]; in previously vaccinated individuals, pleomorphic presentation of rash lesions was observed. Following resolution of the rash, hypopigmentation is followed by hyperpigmentation of the scarred lesions. Pronounced lymphadenopathy clinically distinguishes monkeypox from smallpox. Lymphadenopathy in the facial area: cervical, postauricular, submandibular, and inguinal can be quite pronounced. Images of the typical presentation of human monkeypox in the DRC are in Figure 17.6.

Figure 17.6 Human monkeypox. The day 8 appearance of monkeypox rash on a 7-year-old girl from the Democratic Republic of Congo. Prominent lymphadenopathy is apparent at the angle of the chin and in the inguinal areas. (Reprinted with permission from Breman JG, Kalisa R, Steniowski MV, et al. Human monkeypox, 1970–79. *Bull World Health Organ* 1980;58(2):165–182.)

Vaccinia Virus

Multiple-puncture VACV infection, using a bifurcated needle, is currently used in the smallpox vaccination regimen used for laboratory workers using replication-competent orthopoxviruses[201,224] and public health care personnel and military in the United States. Most commonly, the infection progresses through a standard course of events from vesicle to pustule (Fig. 17.7). However, of all vaccines used today, the smallpox vaccine, composed of live replicative VACV, has one of the highest rates of adverse events.[50] Major complications include progressive vaccinia, EV, generalized vaccinia, postvaccinial encephalitis, accidental infection, and carditis (Fig. 17.8). Recently, replication-deficient Modified Vaccinia Ankara vaccine (JYNNEOS) was approved by the U.S. Food and Drug Administration (FDA) as smallpox vaccine for smallpox and monkeypox preexposure vaccination; previously, the vaccine had been approved for use to prevent smallpox in Europe (Imvamune) and Canada (Imvanex).

Figure 17.8 Severe complications of vaccination. A: Eczema vaccinatum in the unvaccinated contact of a vaccinated sibling. **B:** Progressive vaccinia, previously known as vaccinia necrosum, in a child with a congenital defect in cell-mediated immunity. **C:** Generalized vaccinia 10 days after vaccination. **D:** Ocular vaccinia. (Reprinted with permission from Fenner F, Henderson DA, Arita I, et al. *Smallpox and its Eradication*. Geneva: World Health Organization; 1988.)

Progressive vaccinia, previously called vaccinia necrosum or vaccinia gangrenosum, is a rare and often fatal vaccine complication in persons with severe deficiencies of cellular immunity.[32] In 1968 in the United States, there were 5 cases among 6 million primary vaccinees and 6 cases

among 8.6 million revaccinated persons[146]; 4 of these 11 patients died. Progressive vaccinia is characterized by progressive, often painless growth and spread of the vaccine virus beyond the inoculation site, often leading to necrosis, sometimes with metastases to other body sites.[79] The possibility of progressive vaccinia should be considered if the vaccination site lesion continues to progress and expand without apparent healing more than 15 days after vaccination.[188] Initially, limited or no inflammation is present at the inoculation site, and histopathological examination shows an absence of inflammatory cells.[132]

EV can occur in people with a history of AD (eczema), irrespective of disease severity or activity. This complication is the clinical result of local spread or dissemination from the primary vaccination site in such persons or the result of the skin of an individual with AD contacting the unscabbed vaccination site of another person.[79,187] A localized or generalized papular, vesicular, or pustular rash anywhere on the body or localized to previous eczematous lesions is the clinical presentation of EV. Systemic illness with fever, malaise, and lymphadenopathy may occur. In the national U.S. surveillance of smallpox vaccination that was done in 1968, there were 66 cases (no deaths) of EV among 14.5 million vaccinees (4.6 cases per million) and 60 cases (one death) among their several million contacts.[146] In one study, early vaccinia immune globulin (VIG) administration reduced mortality from 30% to 40% to 7%.[134]

Generalized vaccinia is a nonspecific term that is used to describe a vesicular rash that develops after vaccination. Excluding dissemination associated with EV and progressive vaccinia, it has been extremely rare to document virus in these lesions.[133] True generalized vaccinia is believed to represent the end product of viremic spread of virus, and no predisposing factors have been identified. Generalized vaccinia was estimated to occur in about 242 of every 1 million primary vaccinations[146]; likely many of the historic reports also included allergic and inflammatory responses to the vaccine.[259]

Postvaccination encephalomyelitis (PVEM) is a rare but serious complication that usually occurs in primary vaccinees. The frequency of its occurrence differed widely from country to country and with the strain of VACV used in the vaccine. The incidence of PVEM was lower with the NYCBOH VACV strain (the U.S. vaccine strain) than with the strain used in other countries.[73] No predisposing factors for PVEM are known, although host factors are believed to be important; the pathophysiology of PVEM is not well understood. Patients have variably displayed clinical and diagnostic features suggestive of a postimmunization demyelinating encephalomyelitis or direct viral invasion of the nervous system. This postvaccination reaction typically occurs 11 to 15 days following vaccination. Symptoms of PVEM include fever, headache, vomiting, confusion, delirium, disorientation, restlessness, drowsiness or lethargy, seizures, and coma. The cerebral spinal fluid can demonstrate elevated pressure but generally has a normal cell count and chemistry profile.[248] Infants younger than 2 years old can also develop a rare, postvaccination encephalopathy (PVE) similar to PVEM. Acute onset of PVE occurs earlier in the postvaccination period (6–10 days after vaccination), presents with the same symptoms as PVEM, and may also include hemiplegia and aphasia. Diagnosis of PVE or PVEM is one of exclusion because there are no specific diagnostic tests to confirm the diagnosis of this complication, and there are many other infectious and toxic etiologies that can result in similar clinical symptoms. Accidental infection occurs when virus from the vaccination site is transferred to another site or to another person via intimate skin contact. This usually occurs in primary vaccinees rather than revaccinees. Accidental self-inoculation, which most commonly

occurs on the face, mouth, lips, or genitalia, is usually not serious and requires no specific treatment. Inoculation of the eye or eyelid is more serious and can be sight threatening if not evaluated and treated appropriately. In the 5 years between 1963 and 1968, ocular vaccinia was observed in 348 persons, 259 were vaccinees, and 66 were contacts of vaccinees. Of these, 22 had evidence of corneal involvement and 11 experienced permanent defects.[146,225]

Cardiac adverse events had not been reported before 2003 in any person vaccinated with the NYCBOH strain. Myocarditis and pericarditis were documented in 18 of 230,734 primary vaccinees immunized with the NYCBOH strain in 2002 and 2003.[98] Arrhythmias and myocardial ischemia have also been described recently, but the association with vaccination is not as clear. A review of the development of the current U.S. licensed replicative vaccine, derived from the NYCBOH strain and known as ACAM2000, and associated adverse events, has been published.[87]

VACVs in the Indian subcontinent (buffalopox), Brazil (Cantagalo virus, and related strains Aracatuba virus, Belo Horizonte virus, Passatempo virus, and others) and Colombia have been described to cause human infection in handlers of buffalo or cattle.[57] Up to 10 lesions have been described on the hands or arms of the human handlers; fever, lymphadenopathy, backache, and fatigue have also been associated symptoms. Transmission is believed to occur via unprotected contact with active lesions present on animal teats and udders. Interhuman transmission of buffalopox to family members has been reported to occur via contact.[142]

Cowpox

Cowpox also causes localized lesions in humans (Fig. 17.9D), and lesions in cows are typically found on their teats and udders (Fig. 17.9A). Most information is available from a detailed analysis of 54 human cases investigated during 1969 to 1993.[17] Lesions are generally restricted to the hands and face, and most patients (72%) have only one lesion. Multiple lesions may be caused by multiple primary inoculations, autoinoculation, and rarely by lymphatic or viremic spread. Occasionally, a very severe infection, and death, may occur usually in immunosuppressed individuals.[81]

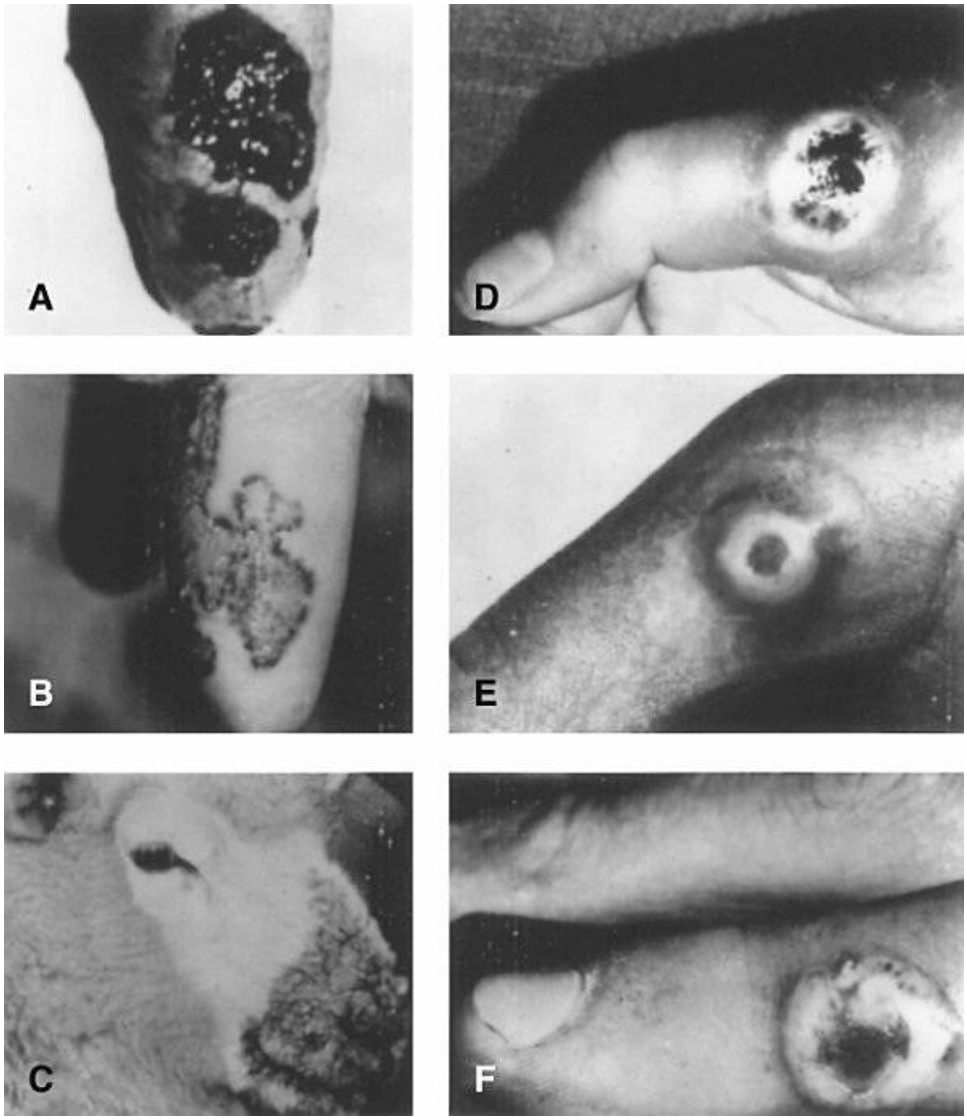

Figure 17.9 Cowpox, pseudocowpox, and orf virus infections of animals **(A–C)** and the lesions caused by these viruses on the digits of humans **(D–F).** A: A Cowpox ulcer on teat of cow, 7 days after onset of symptoms. B: Pseudocowpox (milker's nodule) virus infection of cow teat. C: Orf virus scabby mouth in a lamb. D: Cowpox. E: Milker's nodule. F: Orf. (**A and B:** Courtesy of E. P. J. Gibbs; **C:** Courtesy of A. J. Robinson; **D:** Courtesy of A. D. McNae; **E and F:** Courtesy of J. Nagington.)

The lesion passes through macular, papular, vesicular, and pustular stages before forming a hard black crust. The lesion is usually quite painful, and erythema and edema are common at the late vesicular and pustular stages (Fig. 17.9A). There is usually lymphadenitis, fever, and general malaise, often referred to as "flulike." These features are usually severe in children, and absence from school or work is common; 16 of 54 patients (30%) were hospitalized. Most cases take 6 to 8 weeks to recover; in some cases, it may take up to 12 weeks. Scarring is usually permanent.

Diagnosis

Differentiating Smallpox From Other Diseases and Conditions

Prior to its eradication, smallpox as a clinical entity was relatively easy to recognize, but other exanthematous illnesses were mistaken for this disease. For example, the rash of severe chickenpox, caused by varicella-zoster virus, was often misdiagnosed as that of smallpox. However, chickenpox produces a centripetally distributed rash and rarely appears on the palms and soles. In addition, in the case of chickenpox, prodromal fever and systemic manifestations are mild, if they manifest at all; the lesions are superficial in nature; and lesions in different developmental stages may present in the same area of the body. Other diseases and conditions that could be confused with vesicular-stage smallpox include monkeypox, generalized vaccinia, disseminated herpes zoster, disseminated herpes simplex virus infection, drug reactions (eruptions), erythema multiforme, enteroviral infections, scabies, insect bites, impetigo, and MCV. Diseases confused with hemorrhagic smallpox included acute leukemia, meningococcemia, and idiopathic thrombocytopenic purpura. The Centers for Disease Control and Prevention (CDC), in collaboration with numerous professional organizations, has developed an algorithm for evaluating patients for smallpox. The algorithm assists in differential diagnoses of the vesiculopustular stage of rash. The algorithm and additional laboratory testing information are available at https://www.cdc.gov/smallpox/lab-personnel/laboratory-procedures /rash-testing.html. An evaluation of the algorithm has been published.[238]

Laboratory

A variety of diagnostic strategies are available for the laboratory diagnosis of orthopoxvirus infections. Negative stain electron microscopy cannot differentiate the virions of orthopoxvirus from those of yatapox or molluscipox, but the clinical and epidemiologic information will likely aid interpretation. Some of the classic methods for distinguishing orthopoxvirus species are depicted in Table 17.2. Protein-based diagnostics can be used to detect the genus, but for the most part cannot identify individual species.[54] An IgM capture serologic assay may provide a useful tool for assessing orthopoxvirus disease incidence[126] and may provide utility in assessing infectious etiologies of encephalitic symptoms associated with orthopoxviruses.[236]

The majority of tests which are able to differentiate orthopoxvirus species, however, rely on nucleic acid testing. Identification of orthopoxvirus species can be accomplished through morphologic observations of virus pock growth on chorioallantoic membrane of embryonated eggs. A number of nucleic acid test strategies have been developed and published; the majority are polymerase chain reaction (PCR) based.[144,156,157,196,233] More recently, whole genome high-throughput DNA sequencing methods are used to obtain genome sequences to more fully characterize these viruses.

Prevention and Control

Vaccination has been the historic tool for control of interhuman transmissible orthopoxvirus infections. The successful eradication of smallpox, declared in 1980 by the WHO, was largely due to the effective use of vaccinia vaccine strains worldwide in an extensive immunization program. Classical public health tools of surveillance and isolation of cases were supported by vaccination programs. Vaccination could also be used postexposure to provide protection; greatest protection was afforded if provided within days of contact to a patient[168] and if the

contact had previously been vaccinated.[103] For laboratory workers, vaccination is recommended in some countries[224] for those using any orthopoxvirus capable of causing disease in humans; in others, only for those working with the more human pathogenic orthopoxviruses. Because of the adverse events associated with the use of current VACV vaccine strains, evaluation of vaccination regimens using attenuated vaccinia strains[135,170,178] or subunit vaccines have been undertaken. In the United States, FDA approved MVA-based smallpox vaccine, a nonreplicating virus in mammalian cells with improved safety profile even in contraindicated individuals.

Recent work has also focused on the development of antiorthopoxvirus therapeutic strategies. Compounds with direct antiviral effects, as well as others that inhibit viral use of cellular functions, have been evaluated and demonstrate efficacy in various animal model systems of orthopoxvirus challenge.[29,109,136,147,207,211,212] At least two antiviral agents, with different mechanisms of antiviral action, are moving into advanced stages of research and development for orthopoxvirus treatment. A DNA polymerase inhibitor, cidofovir, and an orally bioavailable derivative brincidofovir™ of the parent compound have activity against orthopoxviruses in tissue culture, and in treatment of various orthopoxvirus-animal model challenges. ST-246 (Tecovirimat™ or TPOXX™), a novel compound which functions to inhibit later stages of viral maturation and egress, has been shown effective against orthopoxviruses in similar studies. TPOXX™ is now approved by FDA for smallpox treatment. These antivirals have been used investigationally with VIG, for the treatment of severe vaccinia infections related to vaccination.[8,9,260,273] Additionally, the efficacy of monoclonal antibodies to substitute for VIG in prophylactic treatment is currently under investigation.[182]

PARAPOXVIRUS

History

Parapoxvirus infections are widespread, worldwide in sheep, goats, and cattle. Human infections from these sources are a common occupational hazard for those in contact with infected animals or, less commonly, fomites. The current International Committee on Taxonomy of Viruses (ICTV) recognized that members of the genus *Parapoxvirus* are orf virus (ORFV), bovine papular stomatitis virus (BPSV), pseudocowpoxvirus (PCPV), and parapoxvirus of red deer in New Zealand (PVNZ). BPSV and PCPV are maintained in cattle, while ORFV is maintained in sheep and goats, but all three are zoonoses. A squirrel parapoxvirus had been described by electron microscopic morphology as a parapoxvirus, but genome sequencing suggests that it is an unclassified poxvirus.[249] Distinct parapoxvirus infections of, and viral species from, red deer in New Zealand[106,220] have been characterized. PVNZ has not been observed to infect humans. In the United States, a novel deer-associated parapoxvirus was characterized as the cause of cutaneous infections in two hunters. The viruses appear related to pseudocowpox viruses.[223] Other tentative members of the genus are camel contagious ecthyma virus or chamois contagious ecthyma virus, which causes a disease initially called Ausdyk or camel contagious ecthyma in camels; this may also be the virus responsible for cases of “camelpox” described in humans in the Middle East.[124] Another tentative member is seal parapoxvirus.[20,253] A poxvirus infection of reindeer[139] has been classified as an ORFV and demonstrated the ability of orf to cross species

barriers.

Human infection with ORFV is termed orf. Most commonly, the disease is transmitted from sheep or goats. The disease in animals is alternately referred to as orf, contagious pustular dermatitis, contagious ecthyma, or scabby mouth. Disease in sheep was recognized as early as 1787; the earliest known report of human disease was made in 1879. Human infection with PCPV is commonly called milker's nodule. The disease is transmitted from dairy cattle and is referred to as paravaccinia or pseudocowpox in these animals. Notably, this disease was not formally distinguished from that caused by the orthopoxvirus cowpox until the end of the 19th century, although Jenner did recognize "spurious" forms of cowpox on cow teats, described in the late 1700s as "pustular sores" lacking "bluish or livid tint".[121] Human disease with BPSV is termed *bovine papular stomatitis* and is transmitted from beef cattle; the disease name when virus infects cattle is the same. Initial descriptions of disease in beef cattle were published in 1884; transmission of infection, causing illness in humans, was described in 1953.[195] Subsequent reports demonstrated that humans could transmit disease to cattle.[42] Human disease with seal parapoxvirus is called sealpox and is transmitted from seals. Human infection of a seal handler was first reported in 1987[104]; the virus was first detected in seals and sea lions in 1969.[269]

Infectious Agent

By negative stain electron microscopy, parapoxviruses appear ovoid with a criss-cross surface appearance (Fig. 17.1), generated by the genus' characteristic outer spiral tubule structure. The particles of ORFV are 260 nm long by 160 nm wide; pseudocowpox virions appear a bit larger 300 nm by 190 nm. The viruses obtained from clinical materials grow most readily on primary ovine or bovine cell culture systems and do not grow in embryonated eggs. A few strains have been laboratory adapted to grow on VERO cells or MRC-5 cells; this has been associated with genome changes and attenuation of the virus.

The separation of the parapoxviruses into at least four distinct groups has been based on natural host range, pathology, and nucleic acid methods, including restriction endonuclease, DNA/DNA hybridization, and, most recently, partial or full gene or genome sequence analyses.[58,177,249] As with other poxviruses, the latter studies have shown that the parapoxviruses share extensive homology between central regions of their genomes but much lower levels of relatedness within the genome termini. The high G+C content of parapoxvirus DNA is in contrast to most other poxviruses (except for molluscipoxvirus) and suggests that a significant genetic divergence from other genera of this family has occurred. DNA sequencing of the genome of two parapoxviruses, species BPSV and ORFV, has allowed a detailed comparison with the fully sequenced genomes of other *Chordopoxviruses*. These studies have provided a genetic map of ORFV and BPSV and revealed that within the central core of the genome, 88 ORF are conserved with the other sequenced *Chordopoxviruses.*[58] This conservation is not maintained in the genome termini where insertions, deletions, and translocations have occurred. Studies have demonstrated a great degree of diversity within species via comparison of three complete orf genome sequences.[177]

Pathogenesis and Pathology

Most of the work on the pathogenesis of parapoxvirus infections comes from studies of orf and

paravaccinia viruses. Most animal models have used ORFV in sheep; however, there is detailed literature on the pathological appearance of human orf lesions. Infection occurs via cuts and scratches and remains localized. After entry through nonintact epithelium, virus replicates in the regenerating epidermal keratinocytes.[172] Lesions are produced by hypertrophy and proliferation of epidermal cells, often marked, and leukocyte infiltration. Histologic examination shows many small multilocular vesicles within the dermis; true macrovesicles rarely occur.[125,271] In the first 2 weeks, the epidermis shows ballooning degeneration in the keratinocytes, and the dermis shows newly formed thin-walled blood vessels with an inflammatory infiltrate. As the infection progresses, in weeks 2 to 3, the intraepidermal vesicles described previously are seen in some cases, with intraepidermal bullous lesions in others. At this point, keratotic material could be visualized on the skin surface. Viral particles were only visualized in the epidermis and were present in the greatest numbers in the first 2 weeks after infection.[125]

The immune response in natural human infection has been investigated.[271] There is a vigorous but short-lived cell-mediated response and a relatively poor and short-lived humoral response. This is consistent with the occurrence of second infections in 8% to 12% of individuals.[221,271] Studies of the immune response to orf infection in sheep have been reviewed.[95] Immunohistochemical studies of lesions demonstrate large numbers of neutrophils, lymphocytes (T and B), and dendritic cells surrounding virus-infected epidermal cells.[6] In comparison of primary versus reinfection lesions, the appearance of CD8+ T cells and B cells are later in primary infection than in reinfection; CD4+ T cells are the predominant cell present in either lesion. Virus replication is decreased in reinfection lesions with respect to that seen in primary lesions. Studies of cytokine response demonstrated γ-IFN mRNA+ cells and some TNF-α mRNA+ cells in reinfection, but not in primary infection. Cellular depletion studies[161] have suggested that CD4+ T cells, IFN-γ, and some CD8+ T-cell responses and some humeral components are necessary for host resolution of infection. Passive antibody transfer, however, does not appear to protect young animals from infection[35] nor does there appear to be a predominant neutralizing antibody response to orf infection.[52]

The parapoxvirus genomes are predicted to express several proteins involved in the host–pathogen interaction; the majority of those studied have been in the context of ORFV. ORFV expresses a homolog of the mammalian vascular endothelial growth factor (VEGF), which has been demonstrated to be a viral virulence factor. The absence of the orf protein produces an attenuated virus[232]; it is hypothesized that the viral protein stimulates keratinocyte growth likely to provide cell substrate for viral replication; in addition, it inhibits apoptosis.[232] The product of a viral gene, OVIFNR, a homolog of vaccinia E3L, prevents inhibition of host protein synthesis to permit virus utilization of the protein synthetic apparatus. The mechanism for this is protein binding to dsRNA formed during viral infection, preventing PKR kinase activation and subsequent eIF-2 phosphorylation. Other virally encoded proteins are postulated to evade or modulate the host immune response. These include proteins that inhibit GM-CSF and mimic IL-10. *In vitro* studies implicate the orf expressed IL-10 homolog in impairment of an effective immunologic memory response and is a virulence factor.[77,149] A chemokine-binding protein expressed by the virus can interfere with recruitment of dendritic cells to the site of orf infection.[148]

Epidemiology

Human infections with parapoxviruses are an occupational hazard of farm workers, abattoir workers, veterinary surgeons and students, and so on. It is most common in the lambing and calving seasons, and more commonly reported in sheep workers than in cattle workers; this probably reflects differences in animal husbandry. Of 191 cases with a known source surveyed from 1978 to 1995, 84% had an ovine source and 16% were from cattle. During the same period, 32 cases occurred in abattoir workers.[16]

Factors responsible for ongoing transmission have been attributed both to the environmental stability of ORFV in scab material (although infectivity wanes over time) and to the manifestation of chronic infections in some animals.[160] There is no known latency state for this or any other poxvirus. Transmission of virus to humans and to animals is via direct contact with lesions or with fomites.

Clinical Features

The progressive stages of human infection have been described in detail,[125,151,271] and illustrations have also been provided[45] (Fig. 17.9 B, C, E, and F). Lesions start as erythematous papules and progress to a "target" stage. This, seen 1 to 2 weeks after infection, has a red center surrounded by a white halo and an outer inflamed halo. This progresses to a nodular then papillomatous stage, which often has a "weeping" surface. In some patients, this may enlarge and persist for some weeks before resolving and may cause some concern. The lesion resolves via a crusting stage, which may last some weeks. Very large granulomatous lesions, usually in immunocompromised individuals, can occur.

Most patients have only one lesion, but multiple primary lesions may occur. Systemic reaction is relatively uncommon, and the lesion is often not particularly painful. Lymphadenopathy is present in some patients, and lymphangitis is also observed but is relatively uncommon. *Erythema multiforme* was reported in one-third of patients reported in one case series.[125] But, because many ordinary uncomplicated cases of orf go unreported, the actual incidence of *E. multiforme* is probably low.

Diagnosis

Differential

Differential diagnosis of parapoxvirus lesions can include ecthyma gangrenosum (a pseudomonas infection of immunocompromised persons), cutaneous anthrax, erysipeloid, and tularemia or tumor. Clinical diagnosis of uncomplicated cases in patients with a known animal contact should not cause difficulties but has been confused with anthrax. However, farmworkers and so on recognize the infection and tend not to seek medical attention for routine cases. Consequently, a disproportionately large number of reported cases have no known contact with infected animals. Of approximately 500 cases surveyed from 1978 to 1995, some 45% had no such contact. Clinical diagnosis of such cases, particularly if severe or prolonged, may be difficult. In particular, large weeping granulomatous or papillomatous lesions may be misdiagnosed as malignancies.

Laboratory

With negative stain electron microscopy, virions with the characteristic morphology of parapoxviruses are usually easily seen in lesion extracts, and this provides a rapid, certain diagnosis of the genus. The virus can be grown in cell culture, but this is not attempted routinely in laboratories that do not maintain primary ovine or bovine cultures.

A number of methods derived from limited or complete genomic analysis have been used for nucleic acid detection (PCR) and laboratory diagnosis of infection.[117,156,251] Species-specific and species-generic protein-based diagnostics for parapoxviruses have also been developed.[52]

Prevention and Control

Most workers at risk get infected at some stage, and reinfection is not uncommon. Individuals should take care not to spread infection by autoinoculation or to contacts, including animals. The vaccine used to control orf in sheep is fully virulent and has caused human infection. Work is underway to create live attenuated viruses that can be used as vaccines. Treatment options are limited; anecdotal reports have described the use of topical cidofovir,[169] or topical imiquimod. Other options may be topical formulations of interferon-modulating compounds such as imiquimod.

MOLLUSCUM CONTAGIOSUM

MCV virus causes a disease characterized by one or more benign, self-limited skin “tumor(s)” or papular eruption(s), occurs worldwide, and is regarded as a specific human infection.[28] There is no evidence of disease transmission between humans and other animals, although lesions resembling molluscum and containing pox virions have been detected in species other than humans (e.g., horses, chimpanzees).

Infectious Agent

Four subtypes of MCV, characterized by restriction endonuclease digests, have been described previously.[183] Disease presentation by all subtypes appears to be similar. The genomic sequence of both MCV subtypes, I and II, are determined.[237,277] The MCV genome encodes a number of novel gene products involved in its pathogenesis and evasion of the immune system, including, among others, an IL-18–binding protein and apoptosis inhibitors.[237,240] Attempts at propagating the virus in tissue culture have been unsuccessful.

Pathogenesis and Pathology

MCV does not cause systemic disease and remains localized at the site of inoculation. MCV lesions have long been known to have a distinctive pathology. Description of the characteristic molluscum bodies, or Henderson-Patterson bodies, was made in 1841 by Henderson and Patterson. A good review of the histopathological features of the infection is available[206] (Fig. 17.10A). The onset of infection occurs when virus begins replicating, extending upward, in the lower layers of the epidermis.[202] The asymptomatic incubation period is variable but can be

protracted. As the infection progresses, the epidermis hypertrophies and extends down into the underlying dermal strata. Characteristic inclusions (molluscum bodies) are formed in the prickle cell layer and gradually enlarge as the cells age and migrate to the surface. These cells are replaced by hyperplasia of the basal cell layer; few to no viral structures are seen in the stratum basale. The structure of the basement membrane remains intact; the hypertrophied epidermal cells, with their cytoplasm occupied by a large acidophilic granular mass (i.e., the molluscum body), project above the skin to appear as a tumor. Little to no inflammatory infiltrate is seen until late in disease, just prior to natural resolution of the lesion.

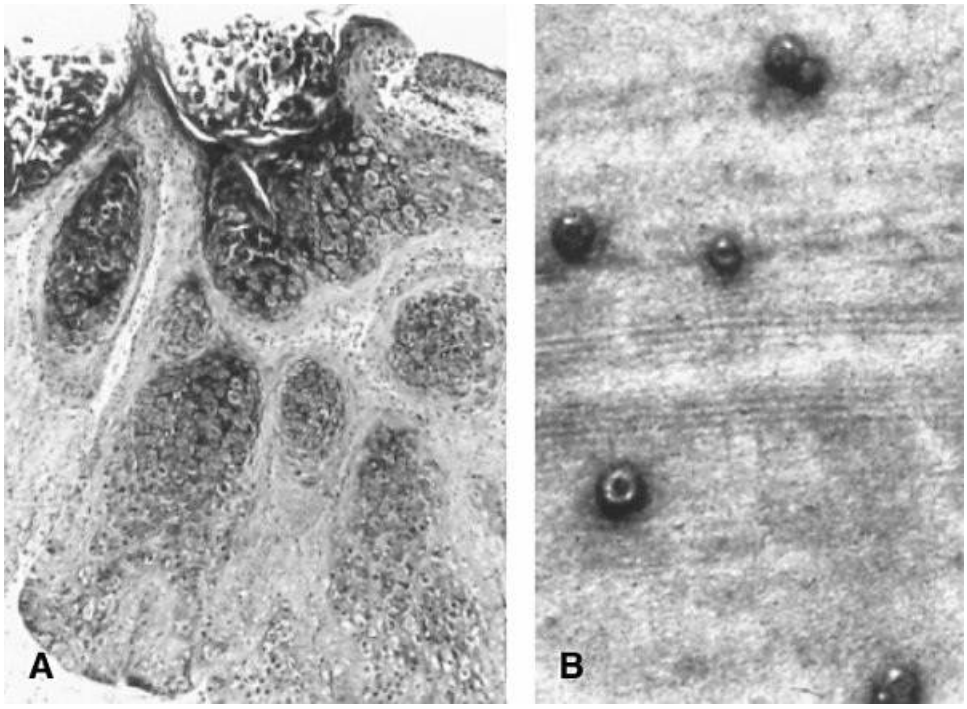

Figure 17.10 Molluscum contagiosum. A: Section of a skin lesion visualized by hematoxylin-and-eosin staining. **B:** Lesions of molluscum contagiosum in a human. (Courtesy of D. Lowy.)

Clinical Features

Molluscum infection occurs as a result of MCV coming in contact with nonintact skin. The characteristic lesion begins as a small papule and, when mature, is a discrete, 2- to 5-mm diameter, smooth, dome-shaped, pearly or flesh-colored nodule, which is often umbilicated (Fig. 17.10B). A cheesy, off-white or yellowish material is easily expressed from lesions. There are usually 1 to 20 lesions, but there may occasionally be hundreds. Because of multiple simultaneous infections or mechanical spread, the lesions may become confluent along the line of a scratch, and satellite lesions are sometimes seen.

In children, molluscum lesions occur mainly on the trunk and proximal extremities, and in adults, they tend to occur on the trunk, pubic area, and thighs; however, in all cases, infection can be transmitted to other parts by autoinoculation. In males infected with human

immunodeficiency virus (HIV), molluscum lesions appear to occur along the beard line, and with persons with infections involving the face, there have been reports of ocular involvement. Individual lesions last for about 2 months, but the disease usually lasts 6 to 9 months. More severe and prolonged infection tends to occur in individuals with impaired cell-mediated immunity, including persons with HIV infection.[85]

Diagnosis

The clinical appearance of molluscum lesions in normal cases is generally sufficiently characteristic to permit clinical diagnosis. Brick-shaped virions can usually be seen in large numbers if the cheesy material expressed from the lesion is examined by negative-stain transmission electron microscopy. The virus has not been cultured in standard tissue culture systems. The characteristic histopathology of molluscum lesions and PCR are described for use in identifying MCV infections.[156,250]

Epidemiology

MCV virus occurs worldwide, affecting mostly children and immunocompromised.[194] Traditional modes of transmission are associated with mild skin trauma such as abrasions, direct contact with a lesion, and, in some cases, fomites (e.g., shared towels); however, there is increasing evidence that the disease is sexually transmitted and that genital lesions are more common than lesions elsewhere on the body.[28] The disease presents a significant concern for individuals whose children are in day care or school situations, where potential transmission to other children may exist. Secondary spread of lesions may occur by autoinoculation (excoriation of primary lesions and spread to areas of normal skin) and shaving. No known animal reservoir exists.

Prevention and Control

The covering of lesions and the use of proper hand hygiene after contact with lesions should prevent transmission in most situations.

MCV infection is benign and recovery is usually spontaneous, but treatment may be sought for cosmetic reasons, particularly for facial or multiple lesions. Various treatments have been tried, including cryotherapy, mechanical curettage, and chemical treatments, such as podophyllin/podofilox, cantharidin, iodine, and tretinoin. Irritation has been a side effect of many of the chemical treatments. Topical application of a 3% Cidofovir antiviral cream or suspension has been reported to be beneficial, as has the use of potentially immune-modulating cimetidine or topical imiquimod therapy.[49] The absence of well-controlled trials makes it difficult to assess the efficacy of various therapeutic regimens. For individuals with AIDS and molluscum, the use of highly active antiretroviral therapy, with improvement of CD4 cell counts, appears to be efficacious.

YATAPOXVIRUSES

History

Human infection with tanapox virus, a species of the genus *Yatapoxvirus*, was first recognized in the Tana River area of Kenya in 1957 and was best characterized during post smallpox eradication surveillance efforts. An account of 264 laboratory-confirmed cases from Zaire (now the DRC), with color illustrations, is available,[122] as is information on the virus itself.[141] The genome of the virus has been sequenced. Yaba-like disease of monkeys is caused by the same virus that causes tanapox in humans[62] and was responsible for outbreaks in three primate centers where animal handlers were infected. There have been a few reports of human disease outside Africa that have been published and illustrate the need to consider poxvirus etiologies of illness in travelers returning from, and emigrants from, areas where the virus is endemic.[59]

Yaba monkey tumor virus (YMTV), the other member of the genus, was recovered from rhesus monkeys in Nigeria.[190] Although no naturally occurring human infections have been reported, the virus does cause disease if injected subcutaneously or intradermally in humans or nonhuman primates.[86]

Pathogenesis and Pathology

The pathogenesis of tanapox or Yaba-like disease is incompletely understood. The clinical features, described here, are suggestive of some systemic phase of disease. The ultimate skin lesion shows epidermal thickening with marked ballooning degeneration; eosinophilic inclusions are often visible. YMTV causes localized histocytic “tumors” at the site of inoculation. After inoculation into the dermis, an accumulation of proliferating spindle-shaped cells begins about 1 week later. This continues for 4 to 6 weeks, resulting in the formation of a “tumor.” The lesion can become superinfected with bacteria. Virus remains cell associated, and the lesion appears to regress as mononuclear cells move from the periphery into the lesion.[190]

The genomes of both species encode a novel TNF-binding protein, distinct from the receptor homolog expressed in orthopoxviruses. Studies of the protein expressed from tanapox demonstrate its high affinity for human, not murine or rabbit, TNF.[34,235] This and other unique immune-modulatory proteins expressed by one or both members of this genus likely affect their pathogenesis.

Epidemiology

Tanapox virus is restricted to Africa, principally to Kenya and the DRC, and is thought to have a simian reservoir.[61] Cases of direct primate-to-human transmission, via a break in skin, have been described in animal handlers, although such cases appear to be extremely rare.[96] Several factors have led to speculation that an insect or arthropod intermediary may be involved in transmission of tanapox virus to humans. Persons confirmed to have tanapox infection have denied contact with nonhuman primates but have reported arthropod and culcine mosquito bites prior to infection; in patients who developed multiple lesions, there was no evidence that the virus had been spread mechanically.[122] Furthermore, the seasonal variation of human tanapox infections follows the activity of local arthropod populations. No human-to-human transmission has been reported.

Clinical Features

Tanapox infection begins with a short febrile (38°C to 39°C) illness of 2 to 4 days that is sometimes accompanied by headache, backache, or prostration. The eruption of a lesion is often heralded by pruritis at the site of the outbreak. The lesion appears as a hyperpigmented macule, often with central elevation, and the macule then evolves to a papule, with palpable induration. Fever and systemic symptoms wane as the lesion manifests. The papule then becomes more "pock-like" but contains no fluid; umbilication or the formation of a pseudo-crust has been reported at this stage. Typically, the papule evolves into a firm, deep-seated, elevated nodule (Fig. 17.11A). At the end of the first week, the lesion is surrounded by erythema and indurated skin. Regional lymphangitis is common at this stage. During the next stage, lesions either ulcerate or become larger nodules (up to 2 cm in diameter) (Fig. 17.11B). In the African series, the maximum lesion size was usually reached within 2 weeks and then the local inflammatory response began to wane, and the lesion began to granulate. Resolution of lesions occurred within 6 weeks.[122]

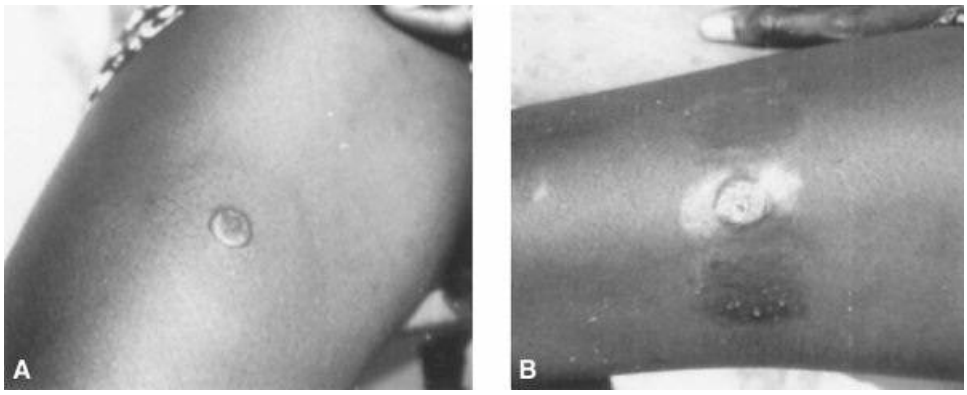

Figure 17.11 Lesions of tanapox in a Congolese youth. A: Day 10 of rash. **B:** Day 31 of rash. (Courtesy of Z. Jezek.)

Most cases (78% in one series) involve a solitary nodule; however, as many as 10 lesions on one individual have been described. Most lesions (72%) occur on the lower extremities, and the fewest occur in the face and areas normally covered by clothing. Infection appears to confer lifelong immunity.[122]

Diagnosis

The limited geographic distribution of tanapox virus and the patient's travel history should be considered in the diagnosis of tanapox infection. Unique clinical features that allow for the differentiation of tanapox from other orthopoxvirus infections are the nodular nature of the rash lesion, the paucity of lesions, the benign disease course, and the protracted course of rash resolution. The solid nodular/ulcerated lesions are larger and develop more slowly than those of monkeypox, but they are smaller and develop more rapidly than those of tropical ulcers.

Tanapox virus can be detected by electron microscopy, and the virions usually appear enveloped, but this finding would not exclude the possibility of infection with other

morphologically similar brick-shaped poxviruses; nucleic acid testing[59,276] on lesion extract could be used for that purpose. Tanapox virus grows in a number of cell lines (e.g., owl monkey kidney, Vero, MRC-5, BSC-1) but not on chorioallantoic membrane.

OTHER POXVIRUSES

This section discusses poxviruses of veterinary importance or of other interest.

Orthopoxviruses

Camelpox

Camelpox virus has a host range that is apparently restricted to *Camelus dromedarius*. The illness it causes is a systemic disease with generalized rash in dromedary camels. The disease is enzootic in camels. Geographically, the virus can be found anywhere in the native geographic distribution of the host in Asia and Africa. Case fatality rates as high as 28% in outbreaks have been noted,[124] young animals are more susceptible to severe disease manifestations, and extensive chains of transmission between camels could be documented. Another study in Somalia evaluated 295 cases of camelpox in 1,052 camels. The case fatality rate was highest in animals up to 1 year of age (13.5%), and only 2.8% in animals 4 years of age. The genome sequence shows a high degree of similarity with that of VARV[91]; despite this and the clinical similarity of camelpox disease in camels with smallpox in humans, camelpox is generally not considered to be a zoonotic disease of humans.[124] However, in human cases, (from India and South Sudan), localized lesions on the hands of camel handlers to a camelpox-like virus were reported.[26,137] Although virus was not isolated from the human lesions, genetic characterization of amplicons from one human lesion was similar to that of amplicons obtained from the camels' camelpox virus isolates. Additional surveillance is needed to understand the significance of these observations.

Camelpox disease has been experimentally studied using intradermal inoculation. By day 5, papules appear at the primary inoculation site and then form vesicles and pustules and crust by days 9 to 10. In camels, a generalized rash manifests between days 9 and 11, which is preceded by fever. The rash is most pronounced on the mouth, nose, eyes, and oral cavity. Fewer lesions are seen on the extremities. The illness can last for 2 to 5 weeks. Diagnostics historically involved evaluation of characteristic morphology on chorioallantoic membrane, in addition to electron microscopy and nucleic acid techniques. Nucleic acid PCR-based techniques are increasingly used.[26]

Prevention and control have been reported through the use of live attenuated camelpox viruses.[266] The sequences of these vaccine virus strains are not yet available, but genome restriction maps show similarity to the pathogenic strains.

Ectromelia

Ectromelia was first described in 1930.[165] The reservoir or natural hosts have been minimally characterized; virus has been reported from wild rodents.[89] Our epidemiologic understanding of this pathogen comes from studies of outbreaks of disease in captive mouse colonies; fundamental biological and genetic studies of this pathogen have provided a detailed understanding of factors involved in the host–pathogen interaction.

At least two forms of clinical "natural" disease may manifest. A rapidly fatal form that results in extensive necrosis of the liver and spleen and death occurs shortly after symptom onset; no rash is seen. Some animals do survive, however, and, if this is the case, a generalized rash can be seen (Fig. 17.12A). Characteristic organ pathology is imaged in Figure 17.12B and C. A more chronic form with ulcerating lesions of the feet tail and snout is seen in other animals. C57Bl/6 and AKR mice are highly resistant, whereas Balb/c and other inbred species are far more susceptible. Much is known about the host genetic determinants for disease presentation, and this has been reviewed.[69]

Pathology and diagnosis of mousepox. *Lab Anim Sci* 1981;31(5 Pt 2):599–608; permission conveyed through Copyright Clearance Center, Inc.)

Taterapox

This virus has been isolated once in the West African country of Dahomey, now known as Benin. The virus was isolated from an apparently healthy gerbil (*Tatera kempii*) in 1968, at the time of a human smallpox outbreak. Identification as an orthopoxvirus was accomplished after liver and spleen homogenates used to inoculate suckling mouse brain–induced illness, and infectivity was blocked via administration of hyperimmune vaccinia mouse ascitic fluid. The virus had biological properties most similar to those of variola alastrim minor. The sequence of the virus is closely related to that of variola.[68] Neither 1 nonhuman primate nor 12 gerbils showed signs of viral dissemination in organs after parenteral or intracerebral inoculation.[162] This suggests that this orthopoxvirus has evolved to have a "successful" parasitic relationship and further suggests that other "nonpathogenic" orthopoxviruses exist.

North American Orthopoxviruses

Raccoonpox, skunkpox, and volepox are the North American orthopoxviruses. In general, these too have been isolated from fairly asymptomatic animals or animals with localized lesions. The viruses have been propagated in monkey kidney cell lines; A-type inclusions are evident, whereas full-genome sequence information is not yet available. Raccoonpox was identified in the upper respiratory tissues of 2 of 92 healthy-appearing raccoons trapped in Maryland. Twenty-two of these animals appeared to have orthopoxvirus seroreactivity.[140] Volepox was isolated from a skin lesion on a vole (*Microtus californicus*) in the San Francisco Bay Area of California; serosurveys of voles suggested that the virus was enzootic. Experimental infection of seronegative voles demonstrated development of a localized lesion and antiorthopoxvirus seroconversion after challenge via footpad or tail inoculation.[213]

Capripoxviruses

The capripoxviruses are somewhat larger, by electron microscopy, than other poxviruses with dimensions of 300 × 270 × 200 nm. A number of strains of each species have been sequenced; the genome is approximately 154 kbp in size. Three species of capripoxvirus have been categorized. The diseases sheeppox, goatpox, and lumpy skin are caused by the viruses of similar names (Table 17.1). Representative strains of these viruses have been sequenced.

Lumpy skin disease was first identified in 1929 in Zambia; the virus infection has largely remained restricted to the African continent[186] but has emerged in the Middle East. Illness consistent with sheeppox is recorded as early as 2 AD.[209] Reports of goatpox were first made in Norway in 1879. Sheeppox and goatpox diseases are considered to have a significant impact on domesticated animals. Geographically, they currently cause disease in Southwest Asia, on the Indian subcontinent, and in central and northern Africa. There is increasing concern for the agricultural, and economic, impact of this emerging infectious disease.[10]

Transmission of lumpy skin disease is mechanical through arthropod bites; virus has been detected in two species of biting flies, and one of these, the stable fly (*Stomoxys calcitrans*), has been shown capable of transmitting disease.[175] The reservoir host is postulated to be the African Cape buffalo. Experimentally infected young buffalo and wildebeest failed to show disease or a rise in antibody titers after infection.[272] However, LSDV seroprevalence in wild-caught buffalo has been low.[55] Within susceptible species, *Bos taurus* and *Bos indicus* mortality is usually 1% to 2%. Transmission of sheeppox and goatpox within domestic flocks is considered to be airborne[209]; additional evidence supports mechanical arthropod transmission by *S. calcitrans*. Scabs contain infectious material for months permitting fomite transmission. Sheeppox and goatpox are notifiable diseases in many countries. The spread of disease within a flock can infect up to 75% of the animals. Morbidity and mortality are highest in young animals and in lactating females, and overall mortality rates of 10% to 58% are reported.

Lumpy skin disease primarily affects species *Bos taurus* and *Bos indicus* and presents with a febrile prodrome followed, 10 days later, by cutaneous manifestations and lymphadenopathy. The skin lesions initially appear as raised nodules in the dermis and epidermis, which subsequently ulcerate and can become superinfected. In the oropharynx and mucosal surfaces, the nodules appear yellow-grey. Edema of the extremities and lymphadenitis are associated features. Recovery is slow, lasting up to 1 month.

Generally, sheeppox and goatpox are host (sheep and goat, respectively) specific, although clinical disease symptoms have been reported in both species during some outbreaks. An asymptomatic incubation period of 1 to 2 weeks is followed by febrile prodrome (up to 108°F) of mucosal swelling of the eyelids and mucosal discharge from the nose. Decreased appetite and occasionally arched back stance is noted. One to two days following prodromal symptoms, generalized appearance of approximately 1-cm lesions over the corpus develop (Fig. 17.13A and B), which progress through macular, popular, vesicular, and pustular stages; these are most obvious on areas with the least amount of hair. The lesions persist for 3 to 4 weeks and eventually scab over. Generalization of rash is more pronounced in young animals ages 4 to 5 months than it is in adult animals. Oral lesions ulcerate, and, in some animals, lesions in the lower respiratory tract are seen.

Diagnosis of capripoxvirus infections is often made on a clinical basis; differential diagnosis of lumpy skin disease includes consideration of bovine herpesvirus 2. Control strategies have largely used vaccination. Sheeppox and goatpox viruses can be grown in primary culture from ovine bovine or caprine sources. Cytoplasmic inclusion bodies are characteristic. Additional laboratory diagnostics, including ELISA and PCR-based techniques, are available and have been reviewed.[209]

Prevention and control of capripoxvirus disease involve vaccination strategies. For lumpy skin diseases, strategies have included the use of sheeppox or goatpox, attenuated by tissue culture passage, or an attenuated strain of lumpy skin disease virus (strain Neethling). A review of the epidemiology and vaccination control issues is available.[110] Control of sheeppox and goatpox disease has been attempted with live attenuated and inactivated viral vaccines. However, inactivated vaccines provide only short-term protection, and the safety of live attenuated vaccines is questionable; they can cause generalized disease and death in some animals.

Suipoxvirus

An episodic viral disease of pigs with worldwide distribution, the swinepox genome, has been sequenced. The virus is currently the sole member of the *Suipoxvirus* genus and is phylogenetically most similar to species of the *Capripoxvirus* genus. Clinical disease can be heralded by low-grade fever, followed by papules, which over the course of 1 to 2 days per stage of development, progress to vesicles and pustules with umbilication (Fig. 17.13C). Crusting and scabbing of lesions ensues over the following 7 days. The duration of clinical disease can be 3 weeks. Mechanical transmission of disease between pigs occurs via the pig louse (*Haematopinus suis*). Disease control is provided by appropriate hygienic animal husbandry practices and control of the louse population.

Leporipoxvirus

The leporipoxvirus virions are brick shaped, with a size of 300 × 250 × 200 nm. Genome size is approximately 160 kbp and is 40% G+C in content. The viruses can infect multiple tissue culture cell lines. Myxoma virus is an obligate rabbit pathogen that demonstrates features that typify a general understanding of the distinction between reservoir host species and non–reservoir-susceptible species. Viral infection results in a localized “fibroma” infection in its reservoir species (Fig. 17.13D), the South American rabbit (*Sylvilagus brasiliensis*), causes a systemic, lethal disease in nonreservoir European rabbits (*Oryctolagus cuniculus*); and has coevolved with this new host. After intentional introduction of myxoma to control feral rabbit populations in Europe and Australia (the susceptible nonreservoir hosts), initial success of the program resulted in 99% mortality; however, milder virus variants emerged, and the surviving rabbits became more resistant to the effects of infection.[74]

In species susceptible to generalized disease, the illness proceeds along an aggressive course. Early clinical signs of illness are blepharoconjunctivitis and swelling of the muzzle and anogenital regions; symptoms are fever and listlessness. Within 48 hours of development of clinical signs and symptoms, animals can die; if they survive past this time point, the classic

myxomas, subcutaneous swellings, develop (Fig. 17.13E). The disease is mechanically transmitted by arthropod vector bites or experimentally by intradermal injection; it can also be transmitted by droplets.

The pathogenesis in nonreservoir species follows deposition of virus into the dermis. Virus replicates in MHC-II dendritic-like cells, moves, within cells, to the draining lymph node within 24 hours to replicate in the lymph node,[27] then disseminates to the epidermis of the skin, lung, testis, and spleen. Virus from the primary lesion also moves to epidermis. A number of myxoma genes have been characterized to affect virulence and disease pathogenesis, usually via inflammatory and immune response modulation, and have been reviewed.[13,14,278] Proteins that modulate TNF, γ-IFN, and chemokines; bind CC chemokines; and inhibit apoptosis are expressed.

The fibroma viruses cause small, localized tumors—the fibroma. The host range (Table 17.1) is restricted. To date, rabbit fibroma, squirrel fibroma, and hare fibroma diseases are described, caused by rabbit fibroma (also called Shope fibroma), squirrel fibroma, and hare fibroma viruses, respectively. These have been reviewed.[14]

Control and prevention of disease is facilitated through immunization. Vaccination and protection of rabbits from myxomatosis can be provided using a related species, fibroma virus, or through the use of attenuated myxoma viruses.

Avipoxvirus

The virions of the *Avipoxvirus* genus are brick shaped, with dimensions of 330 × 280 × 200 nm. The genome size is one of the largest, about 300 kbp in size. There are a large number of avipoxviruses, mostly described by the avian species where infection has been evident to cause illness. The viruses do not cause illness or true replicative infection in mammalian hosts or mammalian cell lines but are able to present antigen to the immune system. For this reason, some have become important research vaccine vehicles. Currently, the ICTV classifies a number of avipoxvirus species: fowlpox virus, canarypox virus, juncopox virus, mynahpox virus, psittacinepox virus, quailpox virus, sparrowpox virus, starlingpox virus, turkeypox virus, and pigeonpox virus. Unclassified members are penguinpox virus, peacockpox virus, and crowpox virus.

The disease fowlpox has been best characterized. Two forms of disease manifest, and it is likely that the different manifestations are due to different routes of exposure. The first to be described manifests with largely cutaneous manifestations on the comb, wattles, and around the beak; other lesions can be evident on the limbs and cloacae. Most likely, disease results via the mechanical transmission of virus from a biting arthropod to the fowl. The lesions that develop are nodular and yellowish, and can coalesce and present a nidus for secondary bacterial infection. Lesions usually resolve in 3 weeks. Avian species with large combs are more susceptible to this form of disease than those with small combs. The other form of fowlpox has also been referred to as “diphtheric” disease. Transmission is likely via respiratory droplets between members of a flock in close proximity. The infectious lesions present in the mucosal surfaces of the airway and can coalesce to create a pseudomembrane and cause death by asphyxiation. Mortality is usually low in healthy flocks, but in flocks under stress, such as those that are egg laying, mortality can range to 50%.[30]

Novel Unclassified Poxviruses

In recent years, several novel poxviruses and new viral strains have been identified and genome sequenced. Bats are known to be a reservoir for multitude of different virus families, poxviruses are no exception, isolated from different geographic locations (Africa, Australia, Europe, and North America).[11,37,65,102,154,174,192] The viral genomes varies from 133 to 176 kb, are phylogenetically divergent, and exhibit diverse and unique clinical symptoms (progressive tenosynovitis and osteoarthritis). These bat poxviruses are tentatively classified into new genus, pteropoxvirus.[255] While poxvirus infections from marsupials were identified previously, only recently viruses were isolated and sequenced from kangaroos from different regions of Australia.[25,173,231] The genome of these viruses are around 170 kb and encode the majority of the conserved genes encoded by chordopoxviruses and are grouped under a putative new genus termed thylacopoxvirus (*thylakos*—sac or pouch). New poxvirus strains from cetaceans were identified recently, expanding the number of phylogenetically distinct strains that could tentatively be classified into genus cetacean poxvirus.[12,48] First reports of poxviruses from mustelid sp. (sea otters) were published a few years back followed with complete genome sequence of sea otterpox virus.[119,256] The genome of sea otterpox virus is the smallest known poxviral genome (127, 879 bp; 62 bp shorter than the previously determined seal parapoxvirus).[119] Salmon gill poxvirus isolated from Atlantic salmon now represent one of the most divergent and distinctive chordopoxviruses sequenced. The 241 kb genome codes for more than half the genes not previously observed in other poxviruses and lacks several of the conserved genes including the proteins required for membrane formation and morphogenesis.[83] These unclassified chordopoxviruses demonstrates greater genetic variability observed in poxviruses and the need to characterize further to understand different mechanisms adapted by poxviruses to exploit various hosts. While majority of these viruses are isolated from clinical cases, next-generation methods like pathogen discovery using metagenomics could lead to more discoveries in future.[11]

CHAPTER 18

Hepadnaviridae

Christoph Seeger • Fabien Zoulim • William S. Mason

History
Classification of viruses within the hepadnavirus family
Virion structure
Genome structure and organization
Stages of replication
- Attachment to hepatocytes
- Entry, intracellular trafficking, and uncoating
- Transcription
- Viral proteins
- Replication of genomic nucleic acid
- Virus assembly and release

Pathogenesis and pathology
- Infection of the liver
- Cell and tissue tropism
- Immune response
- HBV reactivation
- Cirrhosis and hepatocellular carcinoma

Epidemiology
- Global prevalence
- Main routes of transmission
- HBV genotypes

Clinical features
- Clinical manifestations
- Variants and HBeAg-negative chronic hepatitis B
- HBeAg seroconversion
- Occult HBV infections

Diagnosis
- Differential
- Laboratory

Prevention and control
- Treatment
- Vaccines

Perspective
Acknowledgments

HISTORY

Highly transmissible liver disease has been known for several thousand years. A major cause is hepatitis A virus (HAV), a picornavirus that infects the liver and is shed in feces. Evidence for a distinct form of hepatitis, transmitted from blood and body fluids, began appearing in the 19th and early 20th centuries. This 2nd form was finally accepted following outbreaks of hepatitis after vaccination for measles, mumps, and yellow fever in the 1930s and 1940s. These vaccines all contained convalescent serum or plasma, or human serum added as a "stabilizer," which inadvertently contained an infectious agent. Plasma, blood transfusions, and repeated use of nonsterile needles were also identified as causes of hepatitis outbreaks, and the disease was shown to have a viral etiology (reviewed in Refs.[18,195,590]). Originally identified as hepatitis B or serum hepatitis, in distinction to the disease caused by hepatitis A virus, this newly recognized disease was later discovered to be two separate diseases. Once tests were available for hepatitis B virus (HBV), a unique DNA virus discovered during the 1960s, it became clear that there was a second form of serum hepatitis, thereafter called nonA nonB hepatitis. A virus with structural similarities to flaviviruses was identified in the late 1980s as the major cause of nonA nonB hepatitis, and named hepatitis C virus (HCV).[40,90]

The discovery of HBV came during attempts to track genetic differences in human populations. Blumberg and colleagues were using sera from multiply transfused individuals as sources of antibody to human serum proteins. The idea was that these sera would contain antibodies that bound to proteins differing in sequence from those of the transfusion recipients. During the course of these studies, a new antigen, named "Australia antigen," was identified in serum from an Australian Aborigine.[31] Because this antigen was found to be common in leukemia patients and in Down syndrome patients, who have a high risk of leukemia, it was hypothesized that the antigen predicted leukemia risk. However, a Down syndrome patient initially negative for Australia antigen was observed to seroconvert and seroconversion was correlated with a mild case of hepatitis. At about the same time, a member of Blumberg's laboratory experienced a mild case of hepatitis following contact with contaminated material, again with the appearance of Australia antigen in the blood.[32,33]

The Australia antigen was quickly associated with serum hepatitis in a wider group, including a significant fraction of posttransfusion hepatitis cases. At the time, posttransfusion hepatitis occurred in at least 10% to 30% of multiply transfused individuals. Screening blood banks for contaminated blood (Australia antigen-positive) resulted in an approximately twofold decline in the incidence of posttransfusion hepatitis. The remaining cases were mostly due to HCV. For the discovery of HBV, Blumberg received the Nobel Prize in Medicine.[34]

The ability to carry out retrospective studies with assays for Australia antigen confirmed a long held suspicion that HBV was responsible for a chronic hepatitis leading to cirrhosis and liver cancer in many parts of the world. The Australia antigen, purified from the serum of infected individuals, also proved to be an effective vaccine, with greater than 90% efficacy in inducing an antibody response in adults. However, universal vaccination still remains a goal rather than accomplished fact.[241] The WHO estimates that there are approximately 257 million people worldwide who are chronically infected with HBV, of whom approximately 1 million are estimated to die annually of chronic liver disease or hepatocellular carcinoma

(https://www.who.int/news-room/fact-sheets/detail/hepatitis-b).

EM studies revealed that Australia antigen is carried by subviral spherical particles, with a diameter of approximately 22 nm, and to a lesser extent, by approximately 22 nm rod-like particles (Fig. 18.1). Sera contain a much smaller amount of spherical virus with a diameter of approximately 42 nm, termed the Dane particle.[108] Australia antigen is a component not just of the 22 nm particles but also of the virus envelope.[190] Treatment with nonionic detergent releases a spherical capsid with a diameter of approximately 32 nm from the virus. Robinson and colleagues showed that the capsids contain a circular viral DNA of about 3,000 bp, as well as an endogenous DNA polymerase activity that synthesizes virus DNA when virions are treated with nonionic detergent and incubated in the presence of dNTPs.[235,426,427] Summers showed that the circular DNA is only partially double stranded, one strand being incomplete, and that the circular conformation is maintained by a short cohesive overlap between the 5′ ends of the two DNA strands. This incomplete strand is extended, and the single strand gap is at least partially filled-in by the endogenous DNA polymerase activity.[480]

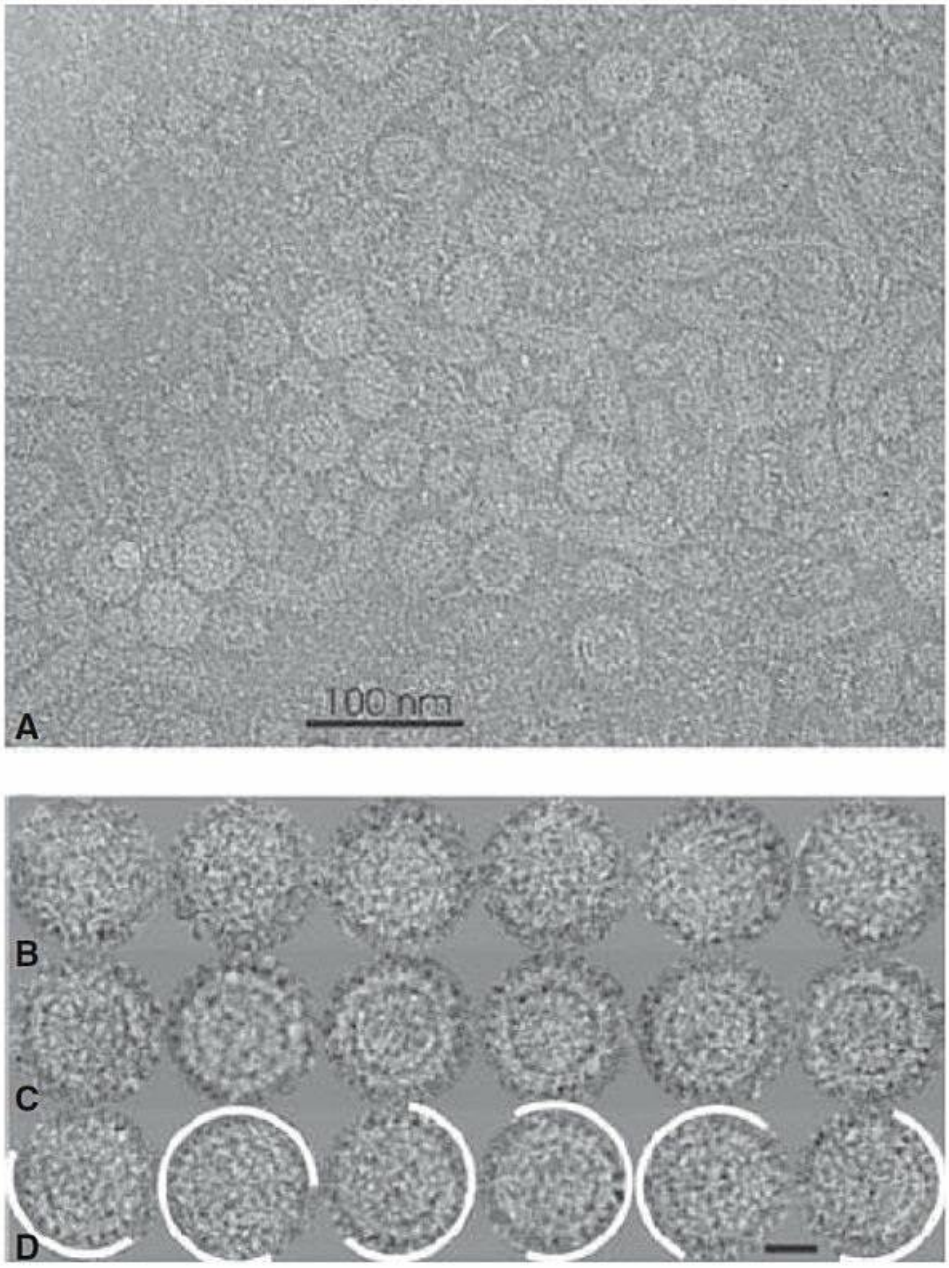

FIGURE 18.1 CryoEM of viral particles from a chronically infected patient. A: 42-nm Dane particles, and 22-nm filamentous and spherical subviral particles are seen. **B and C:** Particles with compact and gapped morphology, respectively **D:** Particles with mixed morphology. Gapped areas are delineated in *white*. (From Seitz S, Urban S, Antoni C, et al. Cryo-electron microscopy of hepatitis B virions reveals variability in envelope capsid interactions. *EMBO J* 2007;26(18):4160–4167. Copyright © 2007 European Molecular Biology Organization. Reprinted by permission of John Wiley & Sons, Inc.)

In the next few years, the endogenous DNA polymerase activity facilitated the discovery of several HBV-like viruses (Fig. 18.2) including woodchuck hepatitis virus (WHV) in eastern

woodchucks (*Marmota monax*),[481] duck hepatitis B virus (DHBV) in domestic ducks in China[533,583] and the United States,[335] and ground squirrel hepatitis virus (GSHV) in Beechey ground squirrels (*Spermophilus beecheyi*).[331] Shortly thereafter, hepatitis B–like viruses related to these original isolates were identified in Richarson's (*Spermophilus richardsonii*)[346] and arctic ground squirrels (Spermophylus parryi kennicotti),[501] ducks and geese,[74,173] cranes,[404] storks,[408] and herons.[468] More recently, HBV-like viruses have been discovered in additional mammalian and avian hosts, as well as in fish and frogs.[121,182] DNA sequence elements distantly related to HBV have also been found integrated in the genomes of a variety of species including birds, snakes, turtles, and crocodiles but so far not in mammals.[158,479]

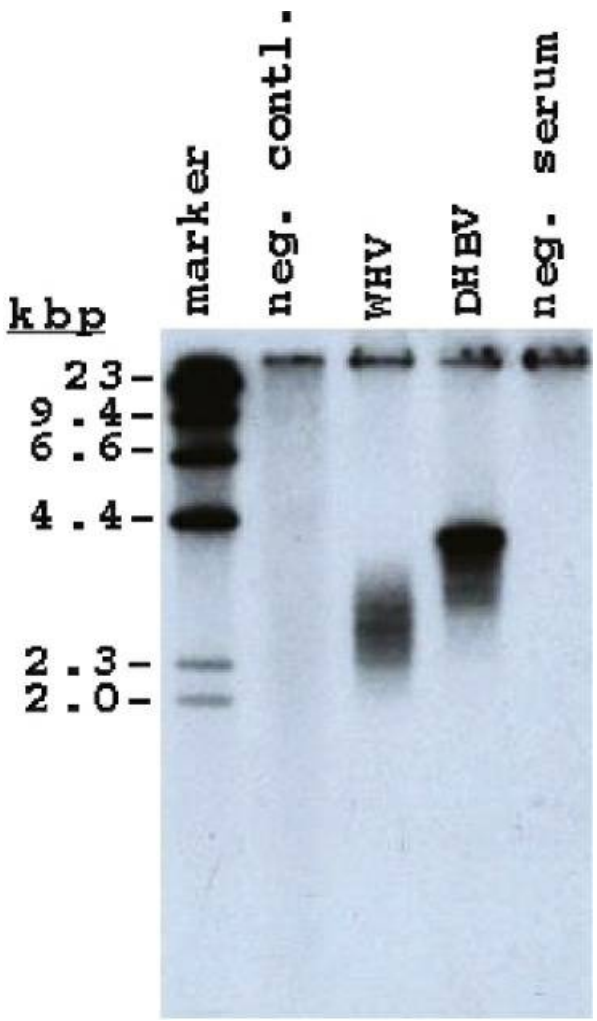

FIGURE 18.2 Detection of hepatitis B–like viruses using an endogenous DNA polymerase assay. Serum samples from a woodchuck and duck were centrifuged to pellet virus. The pellet was suspended in a DNA polymerase reaction cocktail containing radiolabeled nucleotides and incubated at 37°C. SDS-pronase was then added, and after digestion at 37°C to free DNA from protein, the products were subjected to gel electrophoresis in 1.5% agarose. Radiolabeled DNA was detected by autoradiography. The marker is bacteriophage lambda DNA digested with the

restriction endonuclease Hind III. WHV DNA migrates faster than DHBV DNA because the incomplete strand of WHV was only partially filled in by the endogenous DNA polymerase reaction.

CLASSIFICATION OF VIRUSES WITHIN THE HEPADNAVIRUS FAMILY

The hepatitis B–like viruses are assigned to the family *Hepadnaviridae* (hepatitis DNA virus), for which (human) HBV is the prototype. This family currently contains five genera, the orthohepadnaviruses, infecting mammals, the avihepadnaviruses, infecting birds, and more recently identified, the metahepadnaviruses and parahepadnaviruses, infecting fish, and the herpetohepadnaviruses, infecting reptiles and amphibians[121,182,325] (Fig. 18.3). Designation of the *Hepadnaviridae* as a new family of viruses is based on the extremely small size of the viral genomes (3 to 3.3 kbp), the novel arrangement of open reading frames, and the unique replication strategy, differing almost completely from other viruses replicating by reverse transcription. Assignment to five genera was based on the strong DNA sequence similarities within genera but not between genera. The recently discovered fish nackednaviruses,[274] unlike all other HBV-like viruses, do not encode viral envelope proteins and may belong to a distinct virus family.

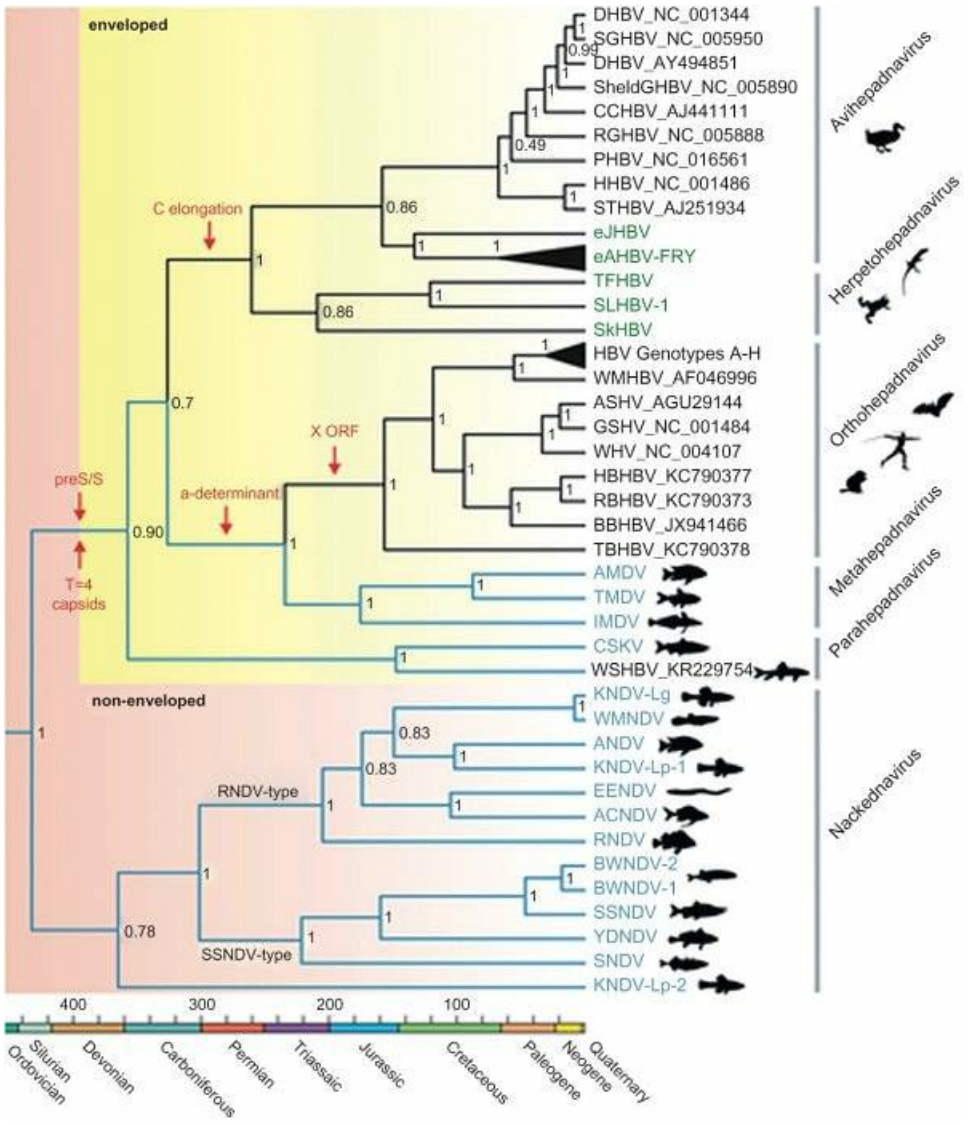

FIGURE 18.3 Phylogenetic alignment and evolution of hepadna- and nackednaviruses. The evolutionary time scale is shown in millions of years for the appearance of nackednaviruses (no envelope gene), parahepdnaviruses and metahepadnaviruses (fish), herpetohepadnaviruses (amphibians, reptiles), avihepadnaviruses (birds), and orthohepadnaviruses (mammals). The phylogenetic tree was based on protein sequence alignments of conserved regions in the terminal protein (TP), reverse transcriptase (RT), and RnaseH (RH) domains of the polymerase (P) gene. (eprinted from Lauber C, Seitz S, Mattei S, et al. Deciphering the origin and evolution of hepatitis B viruses by means of a family of non-enveloped fish viruses. *Cell Host Microbe* 2017;22(3):387–399.e6. https://creativecommons.org/licenses/by/4.0/.)

A maximum sequence divergence of about 40% is found among the orthohepadnaviruses,[151,449] compared to about 20% among avihepadnaviruses.[173] Assignment to separate species within the avihepadnavirus has been based historically upon differences in viral

sequence as well as in host range. Three species have been assigned in the avihepadnavirus group, DHBV, heron hepatitis B virus (HHBV), and parrot hepatitis B virus.[400,438] Among the orthohepadnaviruses, virus isolates very closely related to HBV are found in all apes, including chimpanzees, gorillas, orangutans, and gibbons. At present, these primate isolates are considered subtypes of HBV rather than distinct species. Primate viruses related to HBV have also been isolated, in the New World, from the woolly[270,272] and capuchin monkeys.[112] Other HBV-related viruses recently found in antelope, bats, cats, and shrews may, along with the woodchuck, ground squirrel, woolly monkey, and capuchin monkey viruses, bring the orthohepadnavirus species assignments up to 11[4,161,267,368,417] (Fig. 18.3).

Because of their potential clinical importance, numerous studies have been performed to gain information on the number and geographic distribution of HBV genotypes infecting humans. Ten HBV genotypes, A to J, have been identified, with isolates belonging to different genotypes showing pairwise differences greater than 8% and less than 17%. Distinct genotypes have also been found in great apes. Different genotypes in humans tend to have distinct geographic distributions and possibly distinct clinical manifestations.[306] These are discussed later in this chapter.

VIRION STRUCTURE

HBV is a spherical virus with an outer diameter of approximately 42 nm (Fig. 18.1). The inner shell of the virus has a diameter of approximately 32 nm and is made up of 120 dimers of the core protein. The dimers form the icosahedral capsid with a triangulation number T = 4. A small fraction of capsids consists of only 90 dimers with a triangulation number T = 3.[100,124,552] It is not known whether virions with the smaller capsids are infectious or represent dead-end products caused by an aberrant assembly process. The capsid is covered with a lipoprotein membrane made up of three forms of the viral envelope protein, large (L), middle (M), and small (S) (Fig. 18.4), acquired together with host lipids during budding into multivesicular bodies (MVB) (Fig. 18.5). The L, M, and S proteins are present in the virus envelope at a ratio of about 1:1:4.[190] A model based on the analyses of virions and capsids by electron cryomicroscopy predicts that virions with T = 4 capsids carry 120 dimers formed by core proteins.[124,453] Virions from patient sera exhibit morphological variation: they appear either as compact or as gapped particles, which differ in the distance between the capsid and membrane[453] (Fig. 18.1). Capsids contain a single copy of the partially double-stranded DNA genome, which is covalently linked to the viral reverse transcriptase (RT) at the 5′ end of the complete strand (Fig. 18.6). The RT provides the endogenous DNA polymerase activity, discussed earlier[235,480] (Fig. 18.2). There is also evidence for the presence of cellular proteins including one or more serine kinases within the virus.[5] The virus has a buoyant density of 1.24 to 1.26 g/cm^3 in CsCl and an $s_{20,w}$ of 280S. The titers of HBV can vary significantly among patients ranging up to 10^{10} per mL in blood.

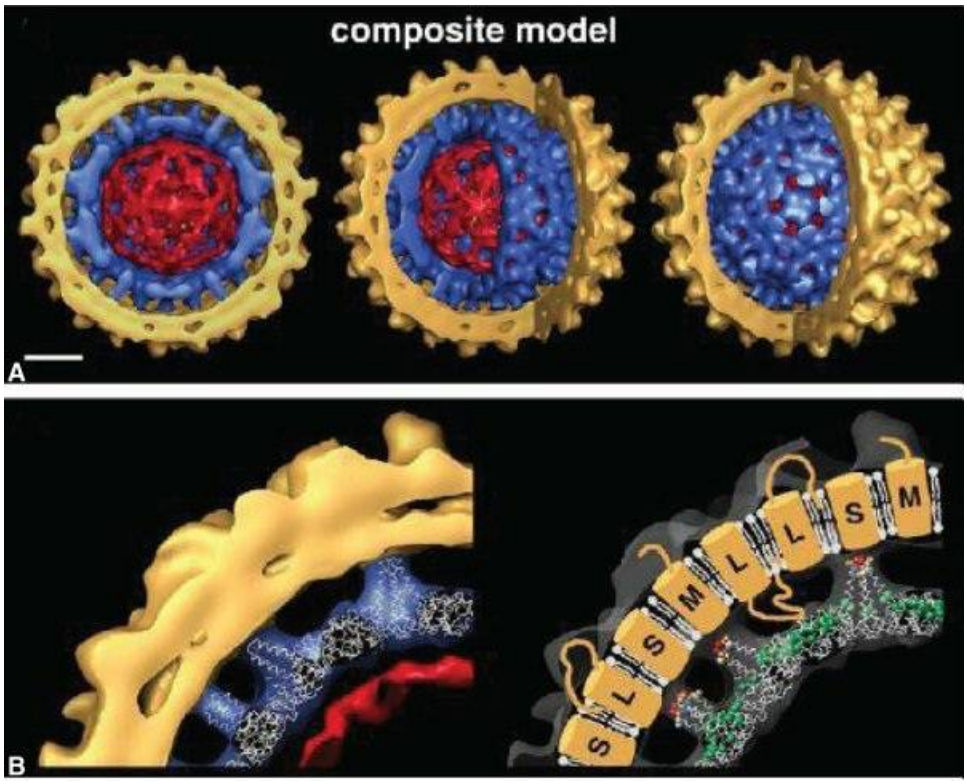

FIGURE 18.4 Model of HBV virions. **A:** HBV virion with a T = 4 icosahedral capsid (*blue*) with 120 spikes and an outer envelope with protein projections. **B:** X-ray crystal structure of a capsid docked into the cryo-EM density map of the virion capsid **(left)**. *S*, *M*, and *L* refer to the three envelope proteins described in the text. Amino acids around the base of the spikes in core proteins that are important for envelopment of core particles are shown in green.[277,385] (Reprinted from Dryden KA, Wieland SF, Whitten-Bauer C, et al. Native hepatitis B virions and capsids visualized by electron cryomicroscopy. *Mol Cell* 2006;22(6):843–850. Copyright © 2006 Elsevier. With permission.)

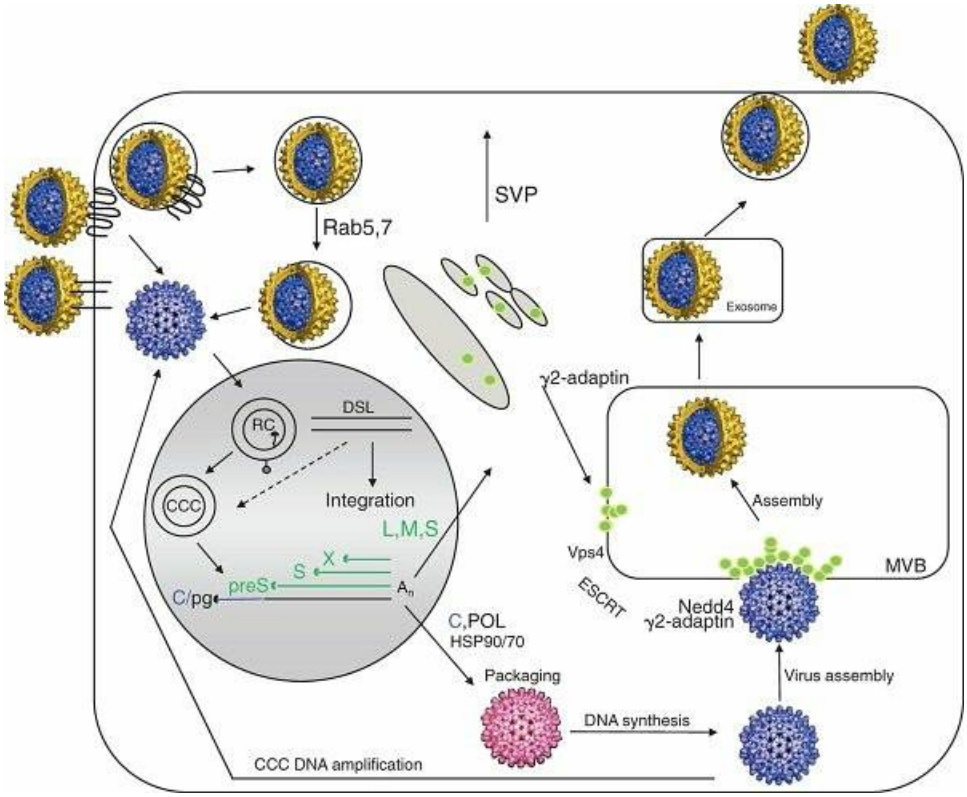

FIGURE 18.5 Hepadnavirus life cycle. Envelope proteins are shown in yellow, DNA-containing capsids in *blue* and RNA-containing capsids in *red*. Early in infection, when envelope protein concentrations are low, capsids enter the cccDNA amplification pathway. Envelope proteins enter the ER and assemble into subviral particles (*SVP*) or transfer to *MVBs* where virion assembly is believed to occur. Mature virions might exit cells through exosomes (for details and references see the text).

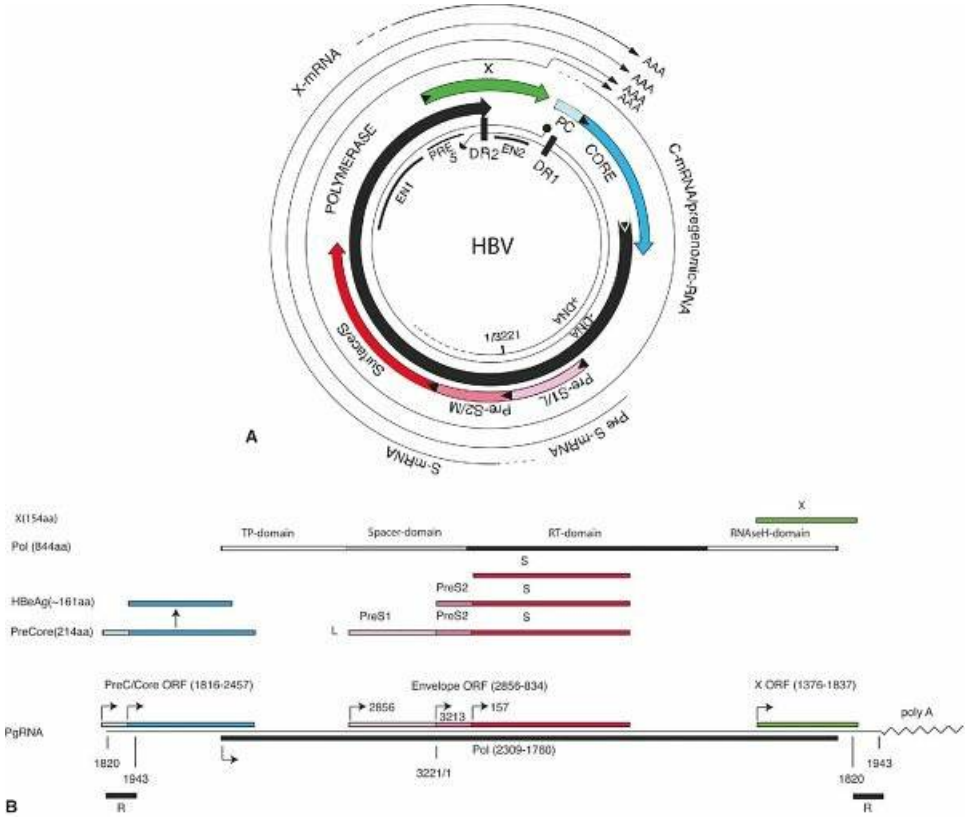

FIGURE 18.6 Genome structure and organization. The relaxed circular DNA genome of HBV with a complete minus strand and incomplete plus strand is shown in **panel A** (inner circle), along with the known mRNAs, all of which end at a common polyadenylation signal located in the core open reading frame. All open reading frames have a clockwise direction. The single-stranded gap in the plus strand is filled in by the viral RT, which is covalently attached to the 5′ end of minus strand DNA. The proteins produced from each open reading frame are illustrated in **panel B**, using pgRNA, a terminally redundant mRNA that is reverse transcribed to produce viral DNA, as a map reference. Map coordinates are from the sequence reported by Valenzuela et al.[520] (accession number X02763), with numbering from a unique EcoR1 restriction endonuclease site. R, large terminal redundancy; PgRNA, pregenomic RNA; DR, direct repeat; EN, enhancer, PRE, post transcriptional regulatory element.

As noted, HBV infections also lead to the production of noninfectious subviral particles (SVP) (Fig. 18.1). The 22 nm spheres, which represent the most abundant particles released into the blood from infected hepatocytes, have been claimed to reach titers of more than 10^{12} per mL.[370,586] Cryo-EM studies of the isometric subviral particles isolated from serum revealed that the spheres have an octahedral symmetry, different from the icosahedral structure of Dane particles.[159] The spheres are composed of 48 dimer subunits that assemble into two classes of particles that differ in size, presumably caused by the heterogeneity of the subunits. Spheres contain M and S proteins at a ratio of about 1:2 and only trace amounts of L.[191] The 22 nm rod-like particles found in the blood (tubes, filamentous particles) contain approximately equal amounts of M and L. Their surface exhibits spike-like features composed of homo and

heterodimers of L, M, and S proteins which, like virus, are in the ratio 1:1:4.[457] However, in contrast to octahedral isometric 22 nm spheres, rod-like particles isolated from patient sera do not have an ordered structure.[457]

Subviral particles contain 40% lipid and sugar by mass and have a buoyant density of 1.18 g/cm^3 in CsCl. Their exact role in the HBV life cycle is not known. One possibility is that, by adsorbing virus-neutralizing antibodies, they facilitate virus spread and maintenance in the host.

GENOME STRUCTURE AND ORGANIZATION

The structure of the HBV genome and the organization of open reading frames on viral DNA is shown in Figure 18.6. All of the ORFs are in the same direction (clockwise in this illustration), defining minus and plus strands of viral DNA. Within virions, minus strand DNA is complete and spans the entire genome, in contrast to plus strands, which extend to about two-thirds of the genome length and have variable 3′ ends.[321,480] In this regard, avihepadnaviruses differ from orthohepadnaviruses because they normally extend plus strands almost all the way to the location of the modified 5′ end.[304] The protein primer of minus strand synthesis and the RNA primer of plus strand synthesis remain attached throughout virus maturation. Minus strands are covalently linked to the viral RT, which is also their protein primer, through a phospho-tyrosine bond. Plus strands contain a short RNA oligomer primer derived from the 5′ end of pregenome (pg) RNA, the template for minus strand DNA synthesis. Minus strands exhibit a small 8 to 9 nucleotide-long terminal redundancy, termed r, which is required for the formation of relaxed circular (rc) DNA during plus strand DNA synthesis.[304,451,546] A small fraction (5% to 20%) of virus contains double-stranded linear (dsl) DNA in lieu of rcDNA, a consequence of *in situ* priming of plus strand DNA synthesis[473] (see below). Virions with DSL DNA are infectious but can lose important sequences from their ends during initiation of infection and appear, therefore, to play only a minor role in hepadnavirus replication.[562,563] However, they can integrate into chromosomes by illegitimate recombination. Integrated HBV DNA may play a role in hepatocarcinogenesis,[517] as discussed later in this chapter.

The genetic organization of HBV is complex. The genome contains four promoters, two enhancer elements, and a single polyadenylation signal to regulate transcription of viral RNAs. In addition, there are four open reading frames and several *cis* acting signals that are required for viral DNA replication (Fig. 18.6). All viral transcripts are encoded by the minus strand and are capped and polyadenylated. Transcription regulatory regions are present within open reading frames and are active following the transport of the viral genome into the cell nucleus, where it is converted into a covalently closed circular DNA form, called cccDNA.

The major transcripts that are detected by Northern blot analyses of HBV infected livers are 3.5 kb, 2.4 kb, and 2.1 kb in length and termed pre-C/C, pre-S, and S mRNAs, respectively.[69] In addition, a minor transcript, X mRNA, about 0.7 kb, has occasionally been detected by Northern blot analysis in infected tissues and more consistently, in cells transfected with subgenomic HBV DNA. Avihepadnaviruses express three major transcripts analogous in length to the three major

mRNAs of mammalian hepadnaviruses.[54] All hepadnavirus transcripts share a common 3′ end created by a polyadenylation signal located in the core gene. Fine mapping of the 3.5 kb preC/C mRNAs revealed three different 5′ ends bracketing the initiation codon of the pre-C gene, indicating that translation of the overlapping pre-C and core genes occurs from separate transcripts (Fig. 18.6).[69] The two longer RNAs, beginning upstream of the pre-C initiation codon, are referred to as pre-core (pre-C) mRNAs and the shorter, beginning downstream, is pregenome RNA. PgRNA is the template for the translation of the core and RT proteins and, as the name indicates, is also the template for viral DNA synthesis via reverse transcription.[359] In contrast, the function of the pre-C mRNAs appears to be limited to the translation of the pre-C gene. As with the large, terminally redundant mRNAs, S mRNAs also have heterogeneous 5′ ends flanking the initiation codon of preS2 and, hence permitting the translation of either the M or S protein.[68] The pre-S transcript has a unique 5′ end and supports the translation of L. In addition to the four promoters, two enhancers, EN1 and EN2, regulate transcription of the viral RNAs (Fig. 18.6). The X transcript can generally not be detected by Northern blot from infected tissue due to its low abundance and small size.

The core protein is a cytoplasmic, basic phosphoprotein with a molecular weight (MW) of 21 kd that assembles into subviral capsids. Historically, core antigenicity was recognized, and diagnostic assays to monitor ongoing or resolved infections were developed. The pre-C protein is best known by its serological name: e-antigen or HBeAg. Although the pre-C gene includes the entire core protein open reading frame and upstream coding sequences, the polypeptide is shorter than the core protein due to posttranslational processing and has a MW of only 15 kd. The mature pre-C protein exhibits distinct antigenic properties from the core protein. Pre-C is not required for viral replication but might exert a role in the regulation of the immune response against HBV, particularly against the core protein.[82,508] HBeAg is also an important diagnostic tool that can be used to determine the status of ongoing HBV infections.

The pol gene encodes the viral RT, which is the sole enzyme encoded by hepadnaviruses. It consists of three functional domains and a hinge region, known as the “spacer,” and has a MW of about 90 kd. The N-terminus encodes the terminal protein (TP) domain, which acts as the primer for minus strand DNA synthesis. The C-terminal region encodes DNA polymerase and RNAseH domains.

The Pre-S/S genes overlap the hinge region and RT domains of the pol gene, albeit in a different reading frame. They encode three integral transmembrane envelope glycoproteins with distinct N-terminal domains. The shortest, the S protein, contains the major antigenic determinants of Australia antigen, which led to the discovery of HBV and provided the reagent for the development of diagnostic tools for the detection of HBV infections and of vaccines against HBV infections.[34] A fraction of S protein is modified by asparagine (N)-linked oligosaccharides, increasing the apparent MW of the protein from 24 to 27 kd.[330] The 31 kd M protein represents a larger form of HBsAg with a 55 amino acid N-terminal, glycosylated extension, referred to as PreS2, translated from an in-frame initiation codon. It represents about 10% to 15% of total envelope proteins in infected cells. A specific function for this protein is not yet known, as it is not essential for virion assembly.[49] Recent studies suggest that the 55 amino acids that distinguish M from S may serve primarily a spacer function between S and the PreS1 domain of L.[365]

The 42 kd L protein is a myristoylated polypeptide translated from the first initiation codon

of the PresS/S open reading frame.[396] The extra amino acids at the N-terminus, relative to M, define the PreS1 domain. Although it represents only 1% to 2% of total surface proteins in infected cells, L is enriched in virions and rod-like 22 nm subviral particles, where it represents approximately 17% of the envelope proteins.[190] In contrast, spherical subviral particles are primarily composed of M and S proteins. Consistent with its distribution, L protein provides the primary ligand for the viral receptor. In contrast to the mammalian hepadnaviruses, avihepadnaviruses encode only two, nonglycosylated envelope proteins, corresponding to L and S of HBV. DHBV subviral particles are pleomorphic, roughly spherical, with diameters ranging from 35 to 60 nm,[335] as compared to the approximately 40 nm HBV virion.

The smallest viral gene, found in mammalian hepadnaviruses, encodes HBx (also called X) with a MW of 17 kd. The X gene overlaps, in a different reading frame, the C-terminal portion of the polymerase and two transcriptional control elements, EN2 and core promoter. Except for the spacer region in the polymerase, X is the least conserved hepadnavirus protein. It has a short half-life in the range of a few hours in primary human hepatocyte cultures (PHH) and accumulates primarily in the nucleus.[256] X expression is required for efficient HBV replication *in vivo*.[80,577,588] This is because HBx induces degradation of the cellular Smc5/6 complex, which otherwise directly or indirectly inhibits transcription from cccDNA.[114]

STAGES OF REPLICATION

Attachment to Hepatocytes

Critical viral and cellular factors for target cell binding and initiation of infection comprise a ca. 60 aa-long segment in S and the myristoylated N-terminal PreS1 domain of L on virions, which are required for attachment of HBV to the low affinity receptor heparan sulfate proteoglycan (HSPG) and the high-affinity receptor, sodium taurocholate cotransporting polypeptide (NTCP). Hepatocyte specificity is provided by NTCP, which is encoded by the solute carrier family 10 member 1 (SLC10A1) gene[488,556] and is expressed almost exclusively by hepatocytes. Moreover, for DHBV (but not HBV), infection may depend upon a conserved peptide translocation motif (TLM), which is located near the N-terminus of preS1.[476]

The most compelling evidence for a role of the myristoylated PreS1 domain in L in attachment to hepatocytes stems from genetic experiments with chimeric envelope proteins between closely related hepadnaviruses that exhibit different host-range specificity, such as DHBV and its close relative, HHBV, or HBV and woolly monkey hepatitis B virus (WMHBV).[91,214] These studies revealed that the specificity of these viruses for their cognate hepatocytes segregates with the N-terminal half of the PreS1 domain. Consistent with these observations, infectivity of DHBV and HBV can be neutralized by anti-PreS1 antibodies, and infection of hepatocytes can be blocked by peptides homologous to portions of the PreS1 region of the L protein.[398,519] For HBV, the most potent preS1-derived peptide spans aa 2 to 47 and carries myristic acid at the N-terminus akin to the natural L protein.[398] Using this lipopeptide as bait, Yan and coworkers identified the liver bile acid transporter NTCP as the *bona fide* high-affinity HBV receptor.[298,556] NTCP is an integral membrane glycoprotein expressed on

basolateral membranes of hepatocytes where it is required for sodium-dependent uptake of bile salts. Ectopic expression of NTCP in the HepG2 cell line, for instance, confers susceptibility to HBV infections.

A study with hepatitis delta virus (HDV, Chapter 19), a viroid-like satellite of HBV that requires HBV envelop proteins to infect hepatocytes, provided initial evidence that a second determinant required for infectivity maps to the external hydrophilic loop of the S domain in L.[218,488] Subsequently, HSPG was invoked as a low-affinity receptor for HBV that "captures" virus particles to facilitate their binding to NTCP.[284,436,448] Some controversy exists concerning the site responsible for binding to HPSG. Based on genetic data, it coincides with the "a determinant," which is found in the S domain of all HBV genotypes and contains immunodominant virus-neutralization epitopes.[226,488] However, it has also been claimed that trypsin-mediated cleavage of PreS1 from the virus surface can abolish binding of virions to heparin, suggesting that PreS1 plays a role in binding to HPSG[448] (Fig. 18.6).

Identification of NTCP as the HBV receptor provided opportunities to investigate the basis of the remarkable species specificity of hepadnaviruses, limiting HBV and HDV infections to human, great apes, and the tree shrew (*Tupaia belangeri*) hepatocytes.[366] For receptor studies, HDV has been particularly useful because its species selectivity appears to be solely dependent on the binding of PreS1 in L to NTCP. In contrast, HBV infections are also restricted at subsequent steps in viral entry. Genetic analyses identified two domains in NTCP (aa 84 to 87 and 157 to 165) that are critical for PreS1 lipoprotein binding and HBV/HDV infectivity.[556,557] Replacement of aa 84 to 87 in mouse NTCP with the human residues confers susceptibility to HDV infection in mice.[189] Cloning and expression of the woodchuck NTCP ortholog in HepG2 cells revealed an additional amino acid residue (aa 263) that is critical for infection and species specificity, explaining why chimpanzees could not be infected with WHV.[149] It should be noted that it is not yet known whether NTCP is a receptor for WHV or GSHV in their natural hosts. Finally, genetic analyses of NTCP indicated that its roles in bile acid transport and HBV/HDV infection can be genetically separated.[149]

Whether duck NTCP plays a role in infection by DHBV is unknown. Carboxypeptidase D (CPD) was proposed to act as a species specific, but not liver-specific receptor that binds DHBV particles and recombinant L protein.[258] The DHBV-CPD interaction requires the PreS1-specific domain of the envelope protein and is inhibited by PreS1-specific neutralizing antibodies.[509] Many of the characteristics of CPD are consistent with its proposed role as a viral receptor. However, experimental expression of CPD in cell lines that can support DHBV replication from transfected DNA has not, so far, made these cells susceptible to DHBV infection.

Based on current knowledge about the viral and cellular determinants required for HBV infection, a model for entry and uncoating can be envisaged (Fig. 18.5). HBV reaches hepatocytes through the space of Disse and attaches with preS1 or the "a determinant" in L to the low-affinity receptor HSPG. Subsequently, the lipomyristolated 45 amino acids at the N-terminus of PreS1 in L attach to the hepatocyte-specific receptor NTCP. In turn, NTCP binds to EGFR, which then triggers entry into hepatocytes by receptor-mediated endocytosis. This model further predicts that uncoating occurs through fusion of the HBV envelope with endosomal membranes, releasing nucleocapsids into the cytoplasm for transport to the nucleus.

Entry, Intracellular Trafficking, and Uncoating

Infection by DHBV and by HBV appears to be pH independent because it can occur in the presence of lysosomotropic agents or after pretreatment of virus at low pH.[180,422] A screen with bioactive ligands identified EGFR as an additional factor for HBV internalization into primary human hepatocytes (PHH) cultures and HepG2 cells expressing NTCP[215] (Fig. 18.6). Studies with HepaRG cells, which under certain conditions become susceptible to HBV infection, have invoked roles for caveolin-1 and in particular Rab-5 and Rab-7, known to play a role in routing cargo from the cytoplasmic membrane to early and late endosomes.[323] How HBV evades lysosomal degradation still remains unresolved. After fusion of HBV with endosomal membranes, capsids are transported to the cell nucleus.[232] Experiments with capsids produced in either hepatoma cells or *Escherichia coli* provided evidence for a model where core particles migrate along microtubules to the nuclear periphery. From there, capsids enter the nuclear basket in an Importin α/β-dependent process and bind to nucleoporin 153.[412,445] The model predicts that capsids disintegrate within the nuclear pore complex and release rcDNA into the nucleus,[411] where it is converted into cccDNA, the template for transcription of the viral RNAs[412,445] (Fig. 18.7).

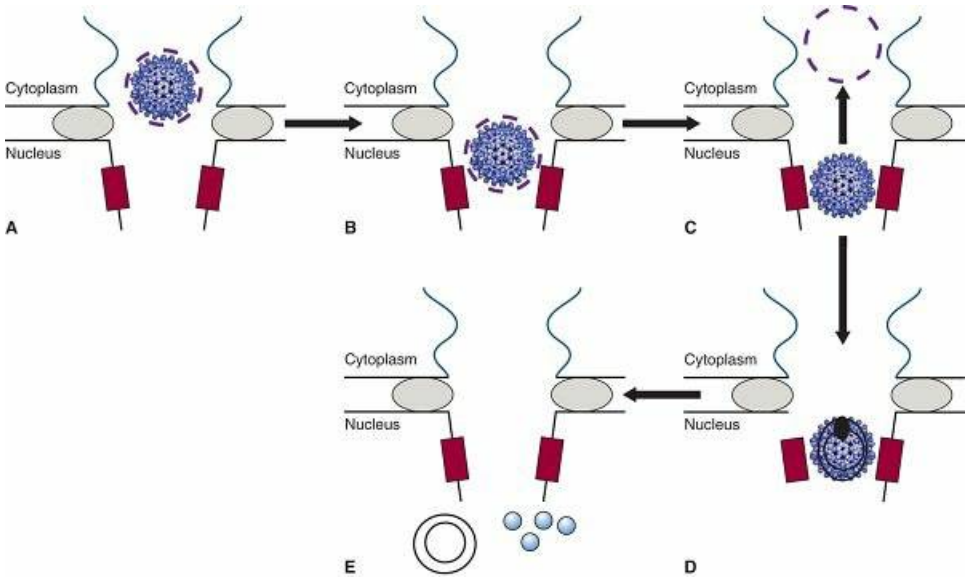

FIGURE 18.7 Transport of capsids through the nuclear core complex. A: Capsids in complex with the nuclear transport receptors Importin α and β (*purple dashed circle*) attach to the nuclear pore (*grey oval*). **B:** The complex passes the nuclear pore and becomes arrested by interaction between importin β and Nup153 (*red box*). **C:** RanGTP dissociates the nuclear transport receptors from the capsid which then interact with the nuclear transport receptors Nup153 **D:** Capsids disintegrate by a still elusive mechanism. **E:** rcDNA and capsid subunits diffuse into the nucleus. RcDNA is converted to cccDNA. (Adapted from Schmitz A, Schwarz A, Foss M, et al. Nucleoporin 153 arrests the nuclear import of hepatitis B virus capsids in the nuclear basket. *PLoS Pathog* 2010;6(1):e1000741. https://creativecommons.org/licenses/by/3.0/.)

Several questions remain concerning HBV attachment and entry into hepatocytes: for example, how do significant amounts of HBV ever reach the liver considering that HSPG are ubiquitously expressed? This point is particularly intriguing because less than 10 HBV particles can initiate an infection in chimpanzees.[11] Another unresolved issue concerns the identity of cofactors that play a role in HBV entry and delivery of rcDNA to the nucleus. Expression of human NTCP in mouse, rat, or dog hepatocytes does not confer susceptibility to HBV infections, indicating that additional factors are required for early steps of the HBV replication cycle.[287] A defect in transport of capsids to the cell nucleus or release of viral DNA into the nucleus possibly makes these cells refractory to productive HBV infections. This view is in agreement with observations made with transgenic mice that efficiently produce HBV DNA-containing capsids in the cytoplasm but do not accumulate cccDNA in the nucleus.[168] Interestingly, cultured AML12 cells derived from hepatocytes of a transgenic mouse overexpressing human transforming growth factor alpha (TGFα) support efficient cccDNA synthesis from cytoplasmic nucleocapsids produced from an integrated HBV expression vector.[102] The ability of these cells to produce cccDNA was attributed to the presence of unstable capsids, implying that uncoating of nucleocapsids is controlled by host factors. This view is supported by results demonstrating that expression of human NTCP in AML12 cells confers some permissiveness to HBV infection.[286] However, cccDNA formation following infection is several orders of magnitude lower compared to HepG2-NTCP cells indicating that additional restrictions occur on the ultimate formation of cccDNA. Hence, it is possible that binding of human NTCP to another protein required for endocytosis, for example, EGFR,[215] produces some level of species specificity. Remarkably, expression of human NTCP in macaque and pig hepatocytes confers permissiveness to HBV infections, indicating that subtle differences in the makeup of the intracellular environment can have a profound effect on capsid migration, disassembly, and delivery of viral DNA into the cell nucleus.[287] Purified orthohepadnavirus DNAs are infectious in their respective hosts, including HBV in the chimpanzee, implying that delivery of rcDNA into the nucleus is sufficient for initiation of productive infections.[450,545]

Transcription

Orthohepadnaviruses contain four promoters that control the transcription of the 3.5-kb preC and pgRNAs and the subgenomic 2.4 kb, 2.1 kb, and 0.7 kb RNAs; PreS1, S, and X, respectively (Fig. 18.8). All promoters, except for preS1, lack a TATA box and hence produce transcripts with heterogeneous 5′ ends, which in the case of the S and preC/C promoters encode distinct proteins: M and S, and pre-C and core/pol, respectively. The possibility that the PreC/C promoter actually consists of two distinct promoter elements has been suggested by genetic experiments and by analyses of naturally occurring mutants that fail to express HBeAg.[462]

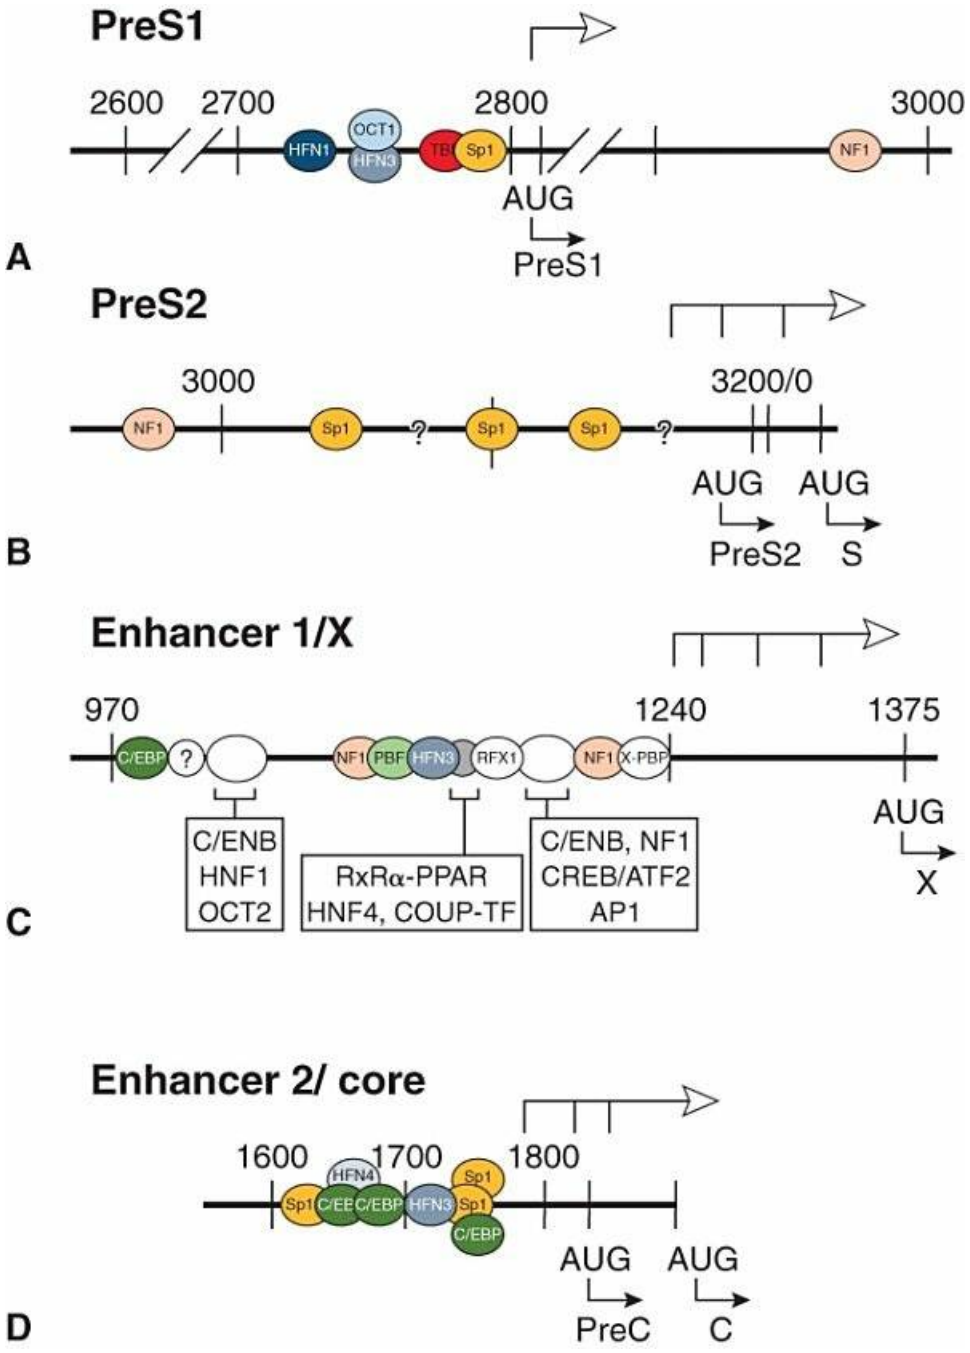

FIGURE 18.8 Transcription factor–binding sites. The figure shows the binding sites for transcription factors on the preS1 and preS2 promoters **(A and B)**, enhancer 1 and the X promoter **(C)**, and enhancer 2 and the pre-core/core promoter **(D)**. Transcription start sites are indicated with arrows (for details and references, see the text).

While the transcripts encoding preC/pgRNA, PreS1, and S were identified and characterized with RNA isolated from infected liver tissue of human patients and ground squirrels infected with HBV and GSHV, respectively,[69,133] X transcripts could first only be detected in tissue culture cells transfected with subgenomic HBV DNA constructs.[458,581] More recent global

mapping of capped 5′ ends of HBV RNAs isolated from livers of HBV-infected patients provided convincing evidence for the presence of capped HBx transcripts and unexpectedly for shorter transcripts potentially encoding a shorter HBx protein initiating at a conserved AUG codon in the body of the X open reading frame.[9]

A single polyadenylation signal located in the core gene regulates the formation of the 3′ ends of all HBV transcripts. In the case of Pre-C/C RNAs, RNA polymerase II bypasses the poly A signal once, leading to the formation of terminally redundant transcripts (Fig. 18.6). Sequences located close to the 5′ end of the transcript play a role in the suppression of premature polyadenylation during the first passage by RNA polymerase II.[433]

The two enhancers, EN1, located upstream of the X region, and EN2, overlapping the pre-C/C promoter, regulate the transcription of the four promoters. Consistent with the hepatotropic nature of hepadnaviruses, all transcriptional regulatory elements of HBV, except for the S promoter, contain binding sites for liver-enriched transcription factors (Fig. 18.8; for a more comprehensive description, see Ref.[462]) For instance, the PreS1 promoter contains binding sites for the liver-enriched factors HNF1 and HNF3.

EN1, a complex enhancer less than 300 nucleotides in length, harbors binding sites for liver-enriched factors HNF1, HNF3, and C/EBP (Fig. 18.8). In addition, the pre-C/C promoter and both enhancers contain binding sites for nuclear receptors (NRs) including HNF4-α, retinoid X receptor alpha (RXR-α), peroxisome proliferators-activated receptor alpha (PPARα), the chicken ovalbumin upstream promoter transcription factors (COUP-TF) 1 and 2, and others. It should be noted that a clear separation between the binding sites on the pre-C/C promoter and EN2 is not possible because of the overlap between the two elements. Ectopic expression of RXR-α and PPARA-α in NIH3T3 cells can induce the expression of pgRNA and the accumulation of HBV replication intermediates that otherwise are not produced in these cells, underscoring the significance of NRs in the control of viral gene expression.[205,492,570] Curiously, substantial differences in the organization of the transcriptional control elements seem to exist among mammalian hepadnaviruses. For example, WHV does not appear to bear an element corresponding to HBV enhancer EN1.[118]

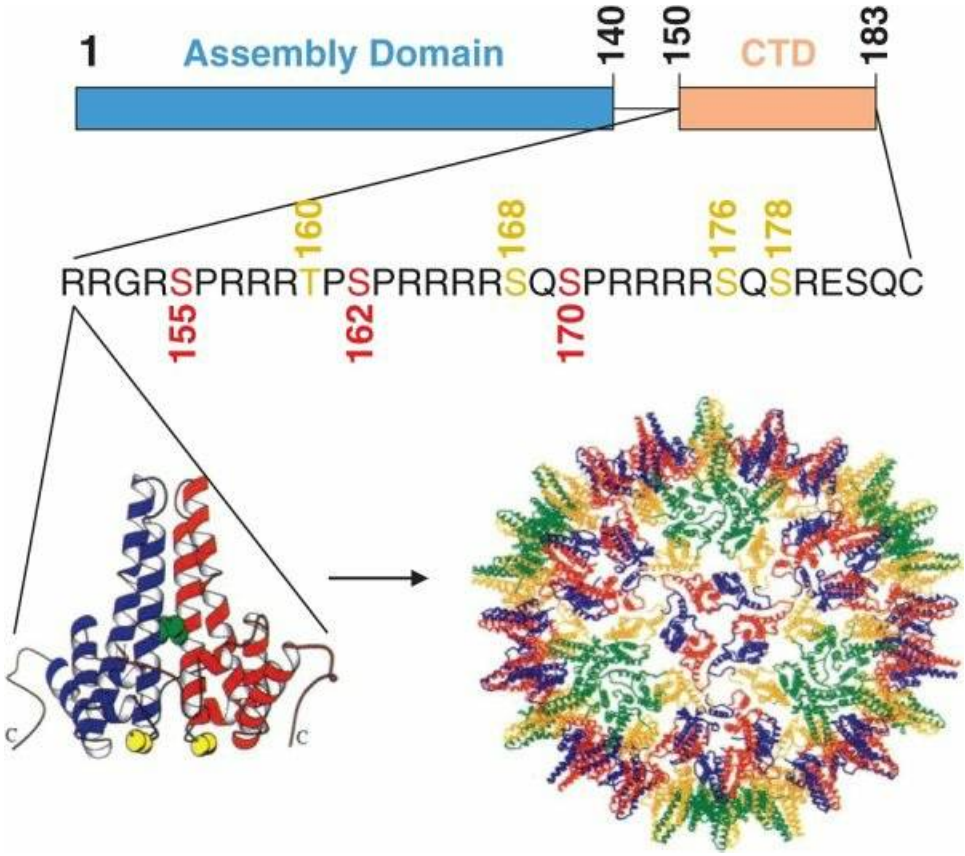

FIGURE 18.9 Structures of the HBV capsid. The assembly and C-terminal domains (*CTD*) of the HBV core protein are separated by a linker region. Major and minor phosphorylation sites in the CTD are marked in *red* and *orange*, respectively. The atomic structure of dimer subunits shows Cys-61 (*green*) forming the disulfide bridge between the monomers and amino acid sequences of arginine-rich C-terminal domains. Assembly of the dimers produces icosahedral capsids. (Adapted from Wynne SA, Crowther RA, Leslie AG. The crystal structure of the human hepatitis B virus capsid. *Mol Cell* 1999;3(6):771–780. Copyright © 1999 Elsevier. With permission. Ref.[552])

Under physiological conditions, cccDNA is associated with histones and other proteins to form a mini-chromosome.[35,36,360] Nucleosomal spacing on cccDNA is 180 and 150 nucleotides for HBV and DHBV, respectively, compared to 200 in liver chromatin. *In vitro* reconstitution experiments provided evidence for a role of the HBV core protein in altering the cccDNA chromatin structure.[36]

Genome-wide analysis of posttranslational modifications (PTM) of histones on cccDNA from HBV-infected PHH, HepG2/NTCP cells, and HBV-infected liver tissue demonstrated enrichment of PTMs normally associated with cellular transcriptional activation, including H3K4me3, H3K27ac, H3K36me3, and H3K122ac at positions overlapping the four viral promoters.[513] Transcriptionally inactive cccDNA produced by HBx deficient virus exhibits biochemical properties common to heterochromatin which, for cccDNA, can be reversed upon ectopic expression of HBx.[423] IFN-α-induced repression of cccDNA transcription is accompanied by a reduction of activating PTMs and not, as expected, by an increase in

deposition of repressive PTMs.[513] It is conceivable that prolonged treatment with IFN-α leads to the replacement of active PTMs perhaps following recruitment of histone deacetylase 1 to cccDNA.[25]

The major mammalian and avian hepadnavirus transcripts are unspliced. In HBV and WHV, transport of unspliced viral RNA from the nucleus to the cytoplasm is regulated by a posttranscriptional *cis* regulatory element (PRE) overlapping EN1 and a portion of the X gene.[122,206] A screen to identify small molecule inhibitors of HBV surface antigen expression identified a compound, RG7834, that prevents accumulation of pgRNA and surface RNAs.[349] The compound inactivates the noncanonical poly(A) polymerases TENT4A and TENT4B (also known as PAPD5 and PAPD7).[350] Genetic studies revealed that these proteins bind to a stem-loop structure termed SLα in PRE and that this binding promotes RNA polyadenylation and, in turn, accumulation of pgRNA and surface mRNAs.[582] A second host-factor, ZCCHC14, is another component of an apparently larger complex binding to PRE to stabilize pgRNA and surface mRNAs by an yet unknown mechanism.[211]

A functional PRE element has not been identified in avian hepadnaviruses. Instead, they contain positive and negative effectors of transcription (pet, net) that regulate the synthesis of pgRNA.[207] Pet spans a 60 nucleotide-long sequence near the 5′ end of pgRNA, whereas net is located downstream of the polyadenylation signal. Pet prevents net-induced termination of transcription of nascent pregenomes during the first passage of the RNA polymerase through the polyadenylation site. Like PRE, pet acts in an orientation-specific fashion, but its mode of action remains elusive. Evidence for the presence of a spliced transcript has been obtained with DHBV.[376] It contains a short sequence from the 5′ end of pgRNA fused to PreS mRNA and appears to be required for replication in primary hepatocytes and ducks. However, the exact role of this transcript for viral replication is still unclear.

Viral Proteins

Translation of HBV proteins is controlled by initiation codons located closest to the 5′ end of the relevant mRNA. An exception is the polymerase protein. It is translated from an internal AUG codon on pgRNA (Fig. 18.6). Although many other viruses (i.e., picornaviruses, hepaciviruses) control internal initiation of translation with internal ribosome entry sites (IRES), hepadnaviruses do not have an IRES. Moreover, pol is not translated by a mechanism depending on a plus one frameshift from the core to the polymerase gene, as it has been described for certain retroviruses, because stop codons or frame shift mutations placed upstream of the initiation site have no effect on translation.[72,441] Some experimental data are consistent with a model predicting leaky scanning where a small fraction of ribosomes recruited at the 5′ end of pgRNA bypass the core AUG codon and scan the transcript until they reach the initiation AUG of the pol ORF.[144,305] Other reports favored a ribosomal shunting mechanism for DHBV pol translation; however, the sequence motifs comprising the “donor” and “acceptor” sites have not yet been identified.[64]

Core

The core protein of HBV is a 183 to 185 aa-long polypeptide of MW 21 kd with an assembly domain (aa 1 to 140) followed by a linker region and an arginine-rich C-terminal domain (CTD) (aa 150 to 183) (Fig. 18.9). Avihepadnaviruses encode core proteins that are approximately 80 aa

longer than HBV core, with similar properties except for an approximately 45 aa-long insertion in the central domain of the polypeptide that forms the “spike” characteristic of viral capsids, and additional amino acids in the arginine-rich carboxy terminus.[43] Cryoelectron microscopy and X-ray crystallography helped reveal the structure of capsids produced in *E. coli*.[38,97,552] The folding of the core polypeptide chain is primarily α-helical and, unlike other viral capsid proteins, lacks β-sheets (Fig. 18.9). Two juxtaposed alpha helices (α3, α4) connected by a loop represent the central domain of the monomeric structure. Dimerization leads to the formation of a 4-helix bundle that assumes the shape of an inverted T, where the stem constitutes the dimer interface and forms the spikes on the surface of capsids. The tips of the arms form the contact points, primarily located in α5, for the polymerization of the dimers into capsids. During an infection, the majority of capsids are assembled from 120 dimer subunits into a T = 4 structure with a diameter of approximately 34 nm. Capsid formation is thought to be a slow process where capsid dimers might first assemble into trimeric structures followed by addition of dimers to complete the capsid shell.[585] Capsids used for the structural studies were composed of core proteins lacking about 30 aa from the C-terminus including serine phosphorylation sites and, as a consequence, exhibited an increased fraction of particles consisting of 90 dimers with T = 3 and a diameter of approximately 30 nm. A structural analysis of the peptide that links the shell-forming core domain with the C-terminal region was consistent with a model predicting that the C-terminal “protamine” domain provides a mobile platform for viral DNA synthesis inside capsids.[538]

The 34 amino acid long carboxy-terminal domain (CTD) contains seven conserved serine and threonine phosphorylation sites and several arginine-rich motifs harboring nuclear localization signals[130,227,233,266,293,299] (Fig. 18.9). One or several cellular enzymes must mediate the phosphorylation because none of the viral proteins exhibit kinase activity. In cellular extracts, the SR protein–specific kinases 1 and 2 (SRPK1, SRPK2) associate with cores and phosphorylate the serine residues in the three SPRRR motifs.[111] Several other kinases, including cyclin dependent kinase 2 (CDK2), protein kinase C, and a 46 kd serine kinase, can phosphorylate cores *in vitro*.[157] The potential role of CDK2 in serine phosphorylation of the CTD was further substantiated through identification of the kinase in cytoplasmic core particles and by results indicating that CDK2 inhibitors could block the capsid-associated serine protein kinase activity.[316] Hence, CDK2 might be at least one of the enzymes responsible for the kinase activity in Dane particles first described approximately 40 years ago.[5]

Experiments with DHBV revealed that DNA replication is accompanied by the gradual dephosphorylation in the core protein, which might contribute to a reorganization of the C-terminus.[19,392] The nature of the phosphatase(s) is not yet known. As suggested for DHBV, all steps of HBV DNA synthesis may be regulated by serine and threonine phosphorylation in the core protein, implying that this mechanism is shared by all members of the *Hepadnaviridae*.[266,292] Genetic studies demonstrated that the arginine clusters in the SPRRR motifs play a role in packaging of pregenomic (pg) RNA, and in DNA replication and perhaps in the recruitment of SRPK1 and SRPK2 ([292]and below). Although the exact role of the charged arginine residues in DNA replication is not known, they might play a role in regulating the spatial organization of pg RNA and minus strand DNA to facilitate viral DNA synthesis.[277] Finally, the rigidity of capsids appears to change as a consequence of DNA synthesis because mature DNA containing particles exhibit increased protease and DNase sensitivities.[101] Such maturation-dependent destabilization of HBV capsids might be required for capsid uncoating. It

can be augmented by mutations in both the NTD and linker regions of HBc and result in enhanced cccDNA amplification.[103]

The complexity of the capsid assembly process provides excellent targets for the development of novel antiviral drugs in addition to the already available nucleoside analogues (NUCs) targeting the polymerase. Heteroaryldihydropyrimidines (HAP)[117] and phenylpropanamides (PP)[245] are two classes of chemical compounds with demonstrated antiviral activity in tissue culture cells, in experimental animals, and in ongoing clinical trials.[136,261,572] PP compounds accelerate capsid assembly resulting in the formation of empty capsids lacking pg RNA, while HAP compounds lead to misassembly of capsids. Interestingly, both classes of compounds bind to the core protein dimer–dimer interface.[239,247] More recently, it was found that a third class of compounds, sulfamoylbenzamide (SBA), also target capsids, exhibiting an activity akin to HAP compounds.[59,327] A remarkable property of capsid inhibitors that sets them apart from nucleoside analogues is that they can also interfere with the process of capsid disassembly and, as a consequence, the conversion of rcDNA to cccDNA.[27,59]

As mentioned earlier in this chapter, a second product derived from the core region is precore or HBeAg protein. It is translated from pre-C mRNA with 5′ ends located a few nucleotides upstream of the first AUG in the pre-C/core open reading frame (Fig. 18.6). A signal sequence directs the translation of HBeAg to membranes of the endoplasmic reticulum (ER). As a consequence, the protein enters the secretory pathway, where it undergoes a second cleavage event that removes about 34 aa from its C-terminus, before it is secreted from infected cells as a 15 kd protein.[154,383,472] Expression of precore is not required for the establishment of productive infections in experimentally infected woodchucks and ducks.[71,79] However, a role in progression to chronic infection in humans is likely, as *de novo* infection generally selects for reemergence of wtHBV, with mutants defective in HBeAg production only becoming prevalent late in infection.[45] This supports the notion that HBeAg transiently suppresses the immune response to the virus, thereby increasing the frequency of chronic infections, which might explain the conservation of this gene. It is assumed that this function is no longer required to maintain chronicity, once established.[82,508]

Envelope

The three envelope proteins, L, M, and S, encoded by the mammalian hepadnaviruses have two principal functions: (a) they provide the protein components of the virus envelope and (b) they assemble into aggregates that are secreted as subviral particles. L and M differ from S in their N-terminal regions (Figs. 18.6 and 18.10). As a consequence of the common S region, the three proteins share several features: they contain two topogenic signals I and II that determine their orientation in lipid bilayers, a hydrophobic C-terminal region that is most likely embedded in ER membranes and a common N-glycosylation site (Asn-146) in S. Like a conventional signal sequence, signal I is located at the N-terminus of S, but is not proteolytically processed. Signal II is a hydrophobic domain acting as a stop-transfer sequence and a signal sequence. As a result, the two hydrophobic domains form a hairpin structure with a cytosolic loop.[128,129] The presence of a third hydrophobic domain invokes the theoretical possibility of two additional transmembrane passages. In addition to the common glycosylation site located downstream from signal II, the M protein harbors a second N-glycosylation site (Asn-4) near its N-terminus.[190] This site is also present in L, but not used, because of the cytoplasmic location of the preS2

domain of L. Some HBV genotypes contain o-glycans (Thr-37) in the preS2 domain of both L and M proteins.[444] L and M proteins contain modified N-termini. L carries a myristate group at Gly-2,[396] whereas M is N-terminally acetylated.[443] The role of M in HBV replication is not yet understood, because this protein is not required for the production of Dane particles and for infection of primary hepatocyte cultures with HBV or HDV.[137,365,487] In avihepadnaviruses, L-proteins are also myristoylated, but not glycosylated.[407] Instead they become phosphorylated in the preS1 domain.[165]

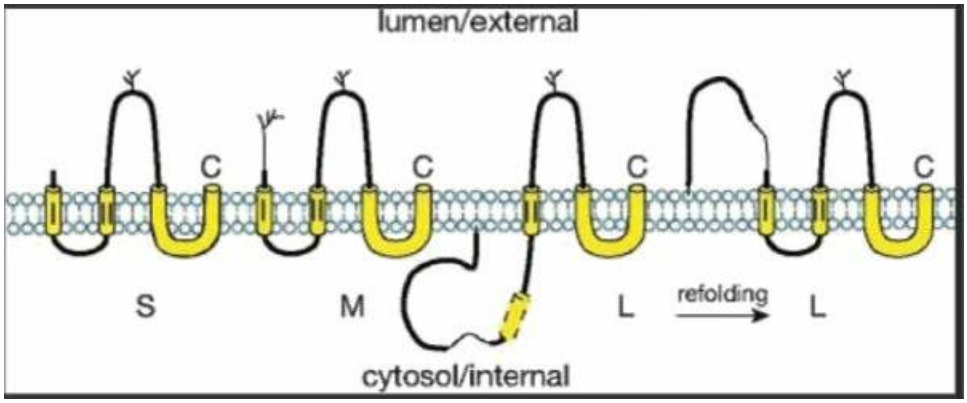

FIGURE 18.10 Proposed membrane topology of HBV envelope proteins. The orientation of the transmembrane domains (TM) is identical in S and M and the refolded L proteins. The external hydrophilic domain of S between amino acids 99 and 168 is illustrated at the left, along with the "a" determinant and the glycosylation site (branched structure) at asparagine 146. All proteins share a hydrophobic C-terminal domain that is embedded in membranes. M bears a second glycosylation site at its N-terminal extension (thin line). In contrast to the refolded product of L (e-preS), in the primary product of L (i-PreS), TM I is located in the cytosol where the N terminus is attached to membranes by the modification with myristic acid (for details see text). (Adapted from Bruss V. Envelopment of the hepatitis B virus nucleocapsid. *Virus Res* 2004;106(2):199–209. Copyright © 2004 Elsevier. With permission. Ref.[51])

A major feature of L is that it exists in two conformations that differ in the localization of the N-terminal domain (Fig. 18.10). In the first, called i-PreS, the N-terminus, including signal I, is located in the cytosol,[50,381,403] where it is required for binding to capsids and for the assembly of virions. In the second, called e-PreS, the N-terminus is exposed on the surface of viral particles where it plays a role in the infection of hepatocytes.[403] The conformational change from internal to external is facilitated by interactions of L with the molecular chaperones Hsc70/Hsp40 and BiP.[264] However, the details of the mechanism regulating this step are not yet understood. Major determinants for infectivity of HBV are located in the N-terminal domain of L containing the binding site for NTCP and possibly HPSG.[30,278,556] However, as discussed earlier, the binding site for HPSG remains controversial.[276,436,488]

Following integration into membranes, envelope proteins form intermediates that include homo- and hetero-dimers stabilized by covalent disulfide bridges between different cysteine residues in the S domain and subsequently assemble into either subviral or Dane particles[210]

(Fig. 18.5). S and M proteins contain the necessary signals for the export process because they can be secreted independently. In contrast, when synthesized in the absence of the other two envelope proteins, L is retained in intracellular membranes, suggesting that it carries a retention signal that prevents, in the absence of S and M, the export process controlled by its S domain.[84,395]

In addition to their roles as envelope proteins, L and M can activate, *in trans*, the transcription from selected promoters in transfected cells.[67,240] This function was initially described for naturally occurring mutants of these proteins with C terminal truncations. Because truncated forms of L and M were initially identified in tissues from chronically infected patients, it has been speculated that they contribute to the development of hepatocellular carcinoma (HCC). Later work showed that the complete L protein could also transactivate selected promoters.[142,192,193] This may be indirectly related to the fact that accumulation of L protein in the ER can lead to ER stress and, in consequence, increase expression of M and S.[209,554] This presumably facilitates L secretion and relieves ER stress. Mutations in the M domain have also been claimed to cause defects in host DNA repair.[198] Thus, the HBV envelope proteins may ultimately reflect adaptations to facilitate survival of infected hepatocytes but might, in the long term, lead to oncogenic transformation of rare infected hepatocytes.[263]

Reverse Transcriptase

Hepadnaviral polymerases have an approximate MW of 90 kd and consist of three functional domains: the terminal protein (TP) required for the priming of minus strand DNA synthesis, and the reverse transcriptase (RT) and RNAseH for DNA synthesis and degradation of pgRNA. A spacer (hinge) separates the TP from the other two domains (Fig. 18.11). The spacer region appears to have no other function than to provide a flexible connection between the TP and RT domains.[14,73] As will be discussed later in this chapter, the reverse transcriptase is the target for all currently FDA approved antiviral therapies with the exception of IFN-α.

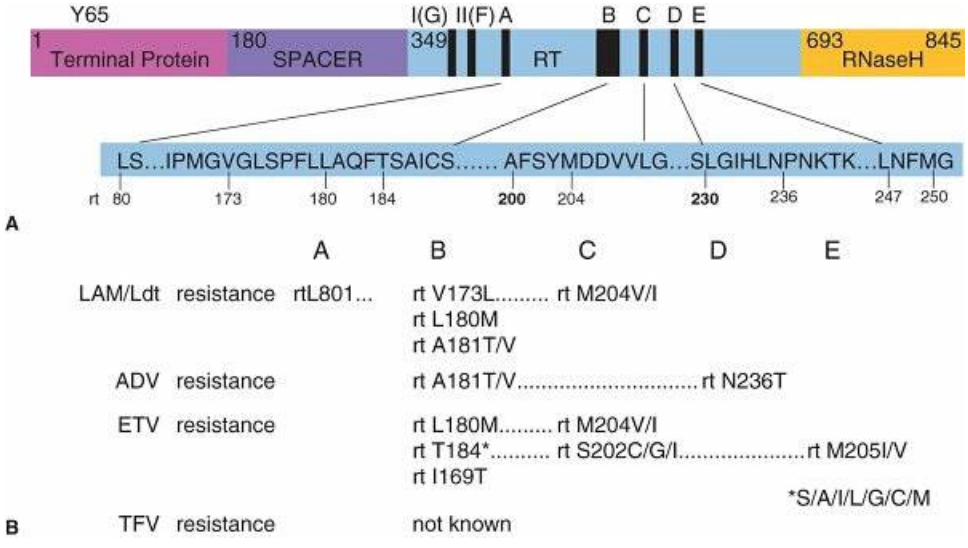

FIGURE 18.11 Physical organization of the HBV polymerase and resistance to nucleoside analogs. A: Domains of the pol protein. The polymerase contains three

main functional domains, the terminal protein domain (TP), the reverse transcriptase domain (RT), and the RNaseH domain (A). Functional domains within the RT have been assigned based on structural modeling using the crystal structure of the HIV RT as a guide.[110] By this analogy, domains A, C, and D would appear to be involved in deoxynucleotide binding and polymerization. The B domain is thought to participate in template binding and the E domain in binding of the primer strand. **B:** Resistance mutations. The figure shows the location of amino acid mutations that confer resistance to lamivudine (LAM) and telbivudine (LdT), adefovir (ADV), and entecavir (ETC). (Adapted from Zoulim F, Locarnini S. Hepatitis B virus resistance to nucleos(t)ide analogues. *Gastroenterlogy* 2009;137(5):1593–1608. Copyright © 2009 AGA Institute. With permission.)

Hepadnaviral polymerases are strictly template specific, which is a direct consequence of the mechanism for the activation of the enzyme. It requires binding of the polypeptide to a packaging signal, termed epsilon, located at the 5′ end of pgRNA (a second copy of epsilon is located near the 3′ end but does not play a role in replication, Fig. 18.12B). As is discussed later in this chapter, binding of the polymerase to epsilon leads to the priming of reverse transcription from a tyrosine residue (Y65) in the TP domain.[269,528,539] This results in the formation of a covalent link between the polymerase and the nascent viral minus strand. *In vitro* enzymatically active polymerase was first produced with the DHBV enzyme translated in rabbit reticulocyte lysates and led to the discovery that the interaction between the polymerase and epsilon RNA is dependent on chaperones including heat shock proteins 90 (Hsp90), Hsp70, and p23.[201,202,470] Consistent with these observations, both DHBV and HBV replication are sensitive to geldanamycin and its derivatives, which bind to the N-terminal ATP-binding domain of Hsp90.[202,204] Similarly, novobiocin, which binds to the C-terminus of Hsp90, inhibits HBV replication.[204] Moreover, Hsp90, p23 and three additional chaperones, Hsp70, Hsp40, and Hop can activate DHBV and HBV polymerases to bind to epsilon RNA *in vitro* and, in the case of the DHBV polymerase, restore the protein-priming activity.[203,204] With HBV, the protein-priming activity has been demonstrated in insect cells[268] and following isolation from cells as a ribonucleoprotein (RNP) complex.[225] With DHBV, enzymatically active polymerase can also be expressed in yeast.[494]

The function of the chaperones is not completely understood, because structural information about the polymerases of hepadnaviruses is lacking. It is possible that they stabilize an energetically unfavorable conformation of the polymerase and, in this way, facilitate the binding of polymerase with epsilon RNA[63,469] (Fig. 18.12A). Consistent with such a model is the observation that DHBV polymerases with deletions of the RNAseH domain can exhibit protein-priming activities in the absence of cellular factors.[534] Thus, these domains might hold the polymerase in a “closed” conformation that, in the absence of chaperones, prevents the interaction with the packaging signal.

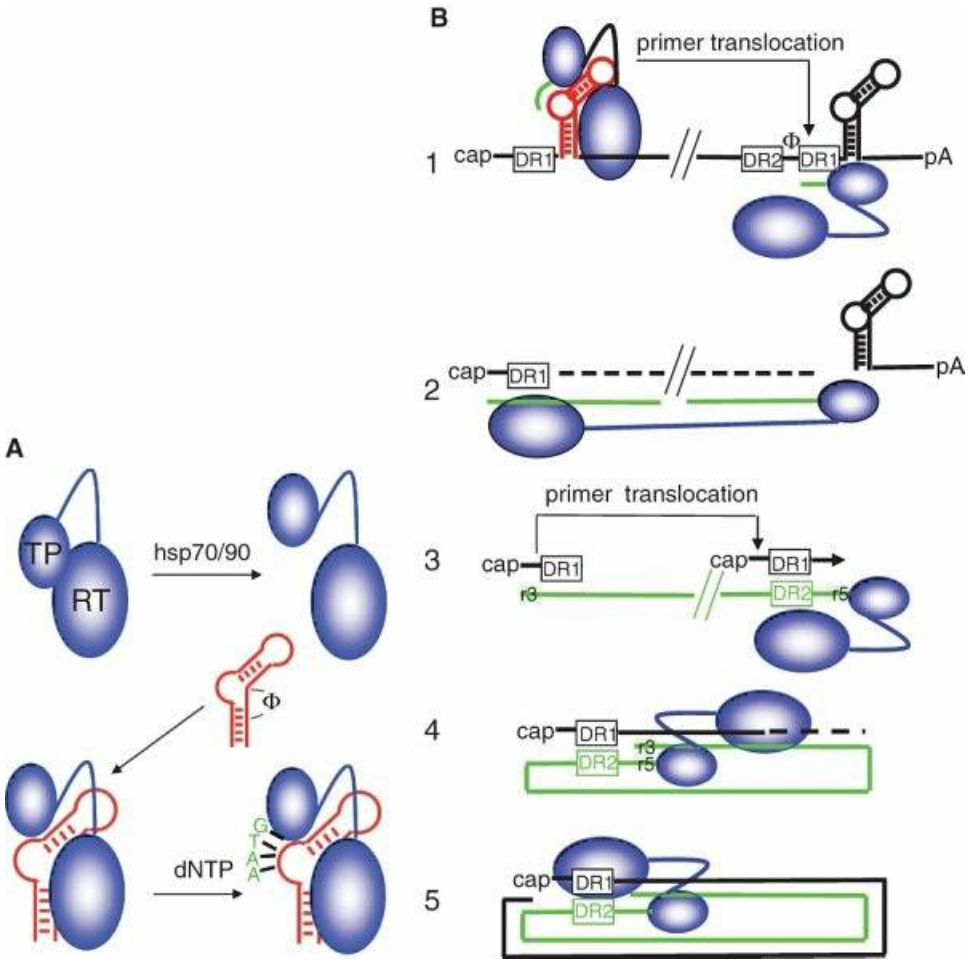

FIGURE 18.12 Genome replication. A: Binding of epsilon RNA to the TP and RT domains of the polymerase facilitated by chaperones (hsp70/90) and initiation of reverse transcription at the bulge of epsilon RNA as described in the text. Phi (F) depicts the RNA sequence on epsilon proposed to be required for circularization of pgRNA (see part B). **B:** The figure depicts five important steps in viral DNA synthesis: (*1*) Transfer of the DNA primer from epsilon to DR1 near the 3′ end of pgRNA; (*2*) Elongation of minus strand DNA and digestion of pgRNA by RNaseH of the polymerase; (*3*) Transfer of the capped RNA primer from DR1 to DR2 and synthesis of plus strand DNA to the 5′ end of minus strand DNA; (*4*) Template switch of the nascent plus strand with the help of the small terminal redundancies, r5 and r3, resulting in circularization of the genome; (*5*) Completion of plus strand DNA as described in the text. The figure was not drawn to scale. For steps *1* to *3*, pgRNA and minus strand DNA are depicted in a linear confirmation.

It is likely that a single polymerase polypeptide catalyzes one complete round of DNA replication because assembly of the polymerase into capsids depends on its interaction with epsilon sequences on pgRNA, which would indicate that polymerase and RNA templates are present at equimolar amounts in subviral particles.[16,578] Consistent with such a model, experiments meant to quantify polymerase levels in HBV capsids revealed a molar ratio of

approximately 0.7 polymerase molecules per virion DNA.[16]

HBx

WHV X is required for efficient infection and replication of WHV in woodchucks and by inference X is required in all hosts permissive for infection by orthohepadnaviruses.[80,415,577,588] Moreover, the requirement for HBx in establishing viremia has been reproduced with the immune-deficient chimeric mouse model demonstrating that X is required for the HBV life cycle even in the absence of a functional immune system.[515] Expression of this polypeptide has been assessed in the livers and primary hepatocyte cultures from WHV-infected woodchucks where it can accumulate to 40,000 to 80,000 molecules per cell in the cytoplasm.[106] In PHHs, HBx accumulates primarily in the cell nucleus and has a short half live of approximately 3 hours.[256] For a long time, the exact role of X for the HBV life cycle has been difficult to elucidate because the protein interacts with many cellular factors including the proteasome and its activity varies depending on the cell lines used for a study (reviewed in[462]). However, the discovery that HBx was required for transcription of cccDNA in PHH and HepaRG cells demonstrated the significance of HBx in the life cycle of HBV and provided an explanation for its essential role in infectivity *in vivo* noted earlier.[314]

Several groups reported that expression of X proteins from both HBV and WHV inhibits nucleotide excision repair (NER) through binding to DNA damage–binding protein 1 (DDB1).[23,221,281,460] Subsequent studies provided evidence for an HBx-DDB1 complex binding to cullin4A-RING (CUL4A) ubiquitin ligase. This association is mediated by DDB1 acting as an adaptor protein.[399] Structural data have revealed an α-helical motif at position 88 to 100 in HBx that binds to the BPA-BPC domains of DDB1,[296] and validated the HBx-CUL4A interaction,[297] suggesting that HBx might act as a bridge linking the CUL4A-DDB1 complex to a substrate that is then ubiquitinated by the CUL4A-RING ubiquitin ligase (Fig. 18.13). Consistent with such a model, the structural maintenance of chromosomes 5/6 (Smc5/6) complex normally required for DNA repair and chromosome stability was identified as a substrate for the CUL4A-DDB1-HBx complex.[114,353] Besides Smc5 and Smc6, the complex contains the four kleisins Nse1-4. Consistent with a direct role of the complex in silencing HBV cccDNA, depletion of Smc5 or Smc6 rescued transcription of HBx-deficient virus.[114,353] So far, structural data about the binding of HBx to any of the Smc5/6 complex components remains elusive.

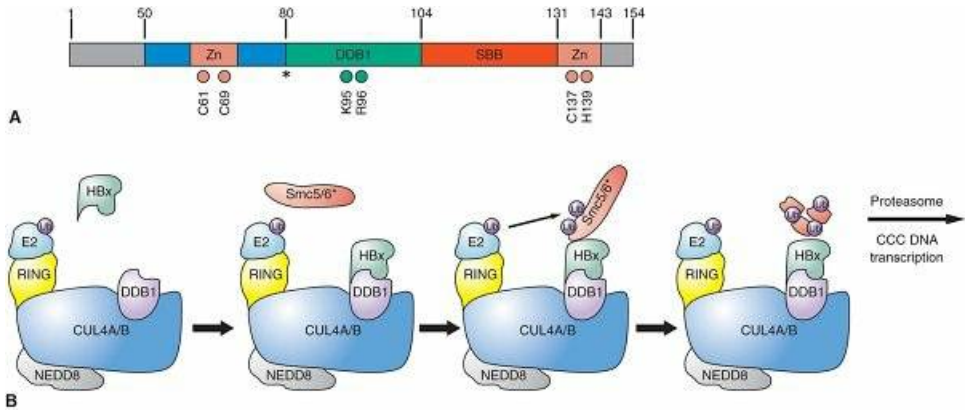

FIGURE 18.13 Formation of the HBx-Smc5/6 complex. A: Schematic representation of HBx based on ref.[415] depicting the two domains forming the Zn-binding motif (Zn), the DDB1-binding motif,[297] and a hypothetical smc–binding box (SBB). The N- and C-terminal domains spanning aa 1 to 50 and 143 to 154, respectively, are not required for HBx function. **B:** The model for HBx function stipulates that HBx binds to the CUL4A-DDB1 complex with the DDB1 domain and recruits the smc5/6 complex, which is subsequently ubiquinated and degraded by the proteasome.[114,297] *Asterisk* denotes conserved methionine (aa 79) that could lead to the expression of a truncated HBx protein.[9] Panels A and B are not to scale.

Smc5/6 restriction of HBV transcription requires colocalization of the complex with nuclear PML bodies (nuclear domain 10 (ND10)) where the Smc5/6 complex is believed to bind directly or indirectly to cccDNA.[114,373] Genetic analysis of HBx function identified a region spanning aa 45 to 140 essential for Smc5/6 ubiquination and degradation. This domain comprises a conserved CCCH motif defined by a cluster of three cysteine residues at positions 61, 69, and 137 and a histidine at position 139 proposed to form a zinc-binding motif.[415]

It is still difficult to assess whether Smc5/6 ubiquination and degradation is the only function of HBx for the HBV life cycle or whether any of the many other reported activities are relevant for HBV infections. For example, what is the role of the relatively weak transactivator activity for promoters with NF-κB, AP-1, AP-2, c/EBP, ATF/CREB, or NFAT binding sites that has been observed in tissue culture cells[463,466]? Because Smc5/6 is required for DNA repair and genome stability, it is conceivable that at least some of the effects attributed to HBx in the past were derived indirectly as a consequence of HBx-mediated inactivation of the Smc5/6 complex, triggering stress responses and even cell death in established cell limes. An important unresolved issue is whether a small form of HBx expressed from one of the conserved internal AUGs is expressed and whether it has an activity in transcriptional regulation in infected hepatocytes as observed earlier in transfected tissue culture cells (Fig. 18.13).[260]

Replication of Genomic Nucleic Acid

Formation of cccDNA

The first step in the hepadnavirus replication cycle is the conversion of genomic rcDNA into cccDNA (Fig. 18.5). Although knowledge concerning the mechanisms responsible for this step is still incomplete, a comparison of the two DNA forms can be used to establish a model for cccDNA formation. It predicts that the polymerase and one of the terminally redundant segments on the minus strand, termed r, are removed prior to the ligation of the two minus strand ends. Similarly, a capped RNA oligomer present at the 5′ end of plus strand DNA must be removed and the incomplete plus strands extended before the ends can be joined. Cellular DNA polymerases most likely elongate the 3′ end of plus strands because RT inhibitors do not block cccDNA formation from rcDNA.[147,348] Reverse genetic experiments with DHBV suggested that an endonuclease removes the 5′ end of minus strand DNA leading to the formation of a protein-free rcDNA, which can be detected in HNF1α null HBV transgenic mice and in tissue culture cells.[153,174,416,465] Identification of rcDNA species harboring covalently closed minus strand

DNA suggests that plus strand DNA repair occurs after ligation of the ends of minus strand DNA.[318] So far, investigations aimed at identifying cellular DNA repair enzymes responsible for the conversion of rc- to cccDNA revealed possible roles for the Y-DNA polymerase kappa (polK), DNA ligases I and III, and the Flap endonuclease 1.[246,313,409] More recently, DNA polymerase alpha (pol α) has been shown to be required for cccDNA synthesis when rcDNA in cytoplasmic core particles enter a retrograde pathway leading to cccDNA amplification, as described below.[493] Curiously, pol α does not appear to play a role in the production of cccDNA from rcDNA following *de novo* infection, indicating that distinct pathways might lead to cccDNA formation depending on the origin of the rcDNA-containing core particle. Tyrosyl-DNA-phosphatase 2 (Tdp2) can cleave the tyrosine-DNA linking the RT to the 5′ end of minus strand DNA *in vitro* and based on RNAi experiments was invoked to act as a host factor involved in HBV cccDNA formation.[252] However, HepG2-NTCP cells deficient in Tdp2 expression are permissive for HBV replication.[104] Whether the conversion of rc- to cccDNA in hepatocytes *in vivo* relies on the same enzymes as identified in hepatoma cells is not yet known.

Packaging of pgRNA

pgRNA has dual functions in viral replication. It acts both as the mRNA for the translation of the core and polymerase polypeptides and as the template for genome replication. The transition from the first to the second function is triggered by the binding of the polymerase to the packaging signal, epsilon, at the 5′ end of the mRNA (Fig. 18.14A). In turn, this reaction creates a signal for the assembly of this ribonucleoprotein complex (RNP) into capsids. Polymerases preferentially bind to their own mRNA, possibly while translation is still ongoing, which increases the chance for packaging and replication of biologically intact pgRNA.[17,194] The interaction between the polymerase and epsilon RNA requires cellular chaperones as described earlier. While structurally intact polymerase is required for RNA packaging, DNA polymerization activity *per se* is not required for this process, indicating that the RNP can induce assembly without a requirement for DNA synthesis.[15,73,194] A more recent study revealed that N6-methyladenosine modification within the packaging signal epsilon on pg RNA might increase reverse transcription of pgRNAs.[213] Packaging of pg RNA is inhibited by IFN-α by mechanisms that are not yet known.[542]

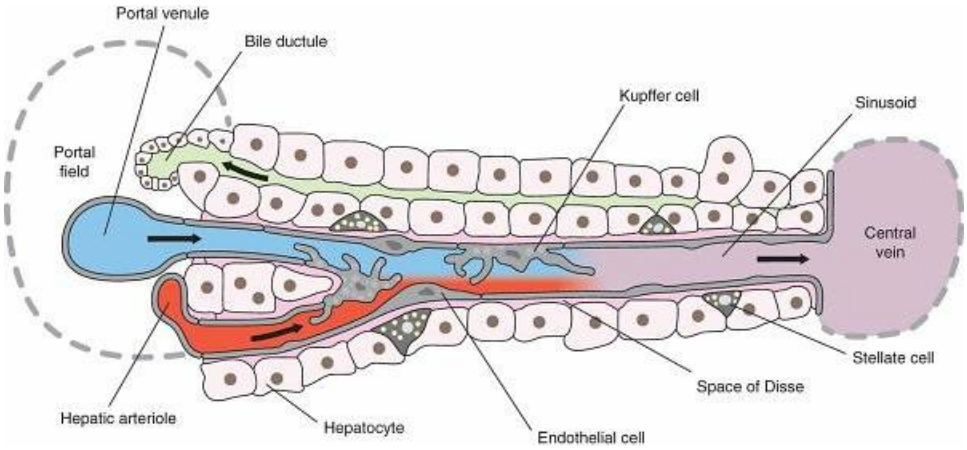

FIGURE 18.14 Structure of the liver lobule. Two dimensional representation of a

small portion of a liver lobule with various cell types present (hepatic stellate cells, localized between sinusoidal endothelial cells and hepatocytes, within the space of Disse, are not shown). Blood enters the lobule from the hepatic artery and portal vein and flows through the sinusoids bounded by plates of hepatocytes, exiting at the central vein. Hepatocytes produce bile, which is released into bile canaliculi, small channels formed where the apical surfaces of hepatocytes make contact, flows to the Canals of Hering and then to bile ductules. From there, it flows to larger ducts and exits the liver. The origin of hepatic progenitor cells, which normally only appear during certain conditions of acute and chronic liver injury, is also illustrated. The exact location of progenitor cells in the healthy liver is uncertain, with different lines of evidence pointing to either bile duct epithelium or cells in the Canals of Hering. In the actual lobule, many plates of hepatocytes connect the portal triad to the central vein, though only two are shown here. (Adapted from Frevert U, Engelmann S, Zougbédé S, et al. Intravital observation of Plasmodium berghei sporozoite infection of the liver. *PLoS Biol* 2005;3(6):e192. https://creativecommons.org/licenses/by/2.0/.)

Based on secondary structure predictions, epsilon contains two inverted repeats that can fold into an RNA hairpin with a basal and an apical stem that are separated by a bulge (Fig. 18.12). The upper stem is capped by a loop.[228] RNA footprint analysis of free and bound epsilon RNA suggested that binding of the polymerase could induce a single-stranded conformation in the upper stem.[22] Again, it should be noted that due to a terminal redundancy (R), epsilon RNA is present at both ends of pgRNA. However, genetic experiments showed that only the 5′ copy provides a binding site for the polymerase and is required for packaging. Consistent with these results, evidence has been obtained that the nearby cap structure on pgRNA may play a role in RNA packaging. These results also evoked the possibility that the polymerase might interact with translation factors to induce a transition from translation to replication.[220] In support of this idea, evidence has been obtained that translation of pre-C RNA, with passage of 80S ribosomes through epsilon, prevents its packaging[359]; the AUG for core is downstream of epsilon.

In contrast to the mammalian hepadnaviruses, packaging in the avian viruses requires, in addition to epsilon, a second pregenome sequence, termed region II, located about 900 nucleotides downstream of epsilon and spanning approximately 300 nucleotides.[60,382] The role of this downstream sequence in RNA packaging is not yet understood.

In addition to the chaperones required for RNA packaging described previously, the human cytidine deaminase APOBEC3G can be incorporated into viral particles through binding to the viral reverse transcriptase at least when APOBEC3G is expressed at high levels.[362,363] Ectopic expression of several members of the APOBEC family of proteins inhibits HBV replication.[431] Notably, unlike the inhibition by APOBEC of retrovirus and retroposon replication,[430] inhibition of HBV is not dependent upon the catalytic activity of the deaminase. Instead it appears that the protein inhibits virus replication during an early step of minus strand DNA synthesis, perhaps by binding to viral RNA or the polymerase.[362]

Minus Strand DNA Synthesis

The first step in minus strand DNA synthesis is the priming reaction that leads to the formation

of a covalent link between a tyrosine residue in the TP domain of the polymerase and dGMP (Fig. 18.12A).[271,528,539,587] The template for this protein-priming reaction is a C residue located in the bulge of epsilon. Although *in vitro* priming can occur immediately following the binding of the RT to epsilon in the absence of core protein, the exact sequence of events in infected cells is not known. Thus, priming could occur prior to, during, or after the assembly of capsids. To complete the priming reaction, the polymerase copies the next two or three nucleotides from the bulge of epsilon. As a consequence of this mechanism, the polymerase remains covalently linked to the 5′ end of minus strand DNA during all subsequent steps of viral DNA synthesis, virus assembly, and release.[156,347]

To continue DNA synthesis, the 3 to 4 nt DNA oligomer is transferred to the 3′ end of pgRNA, where it anneals with a complementary sequence motif located in a 10 to 12 nucleotide-long region known as DR1 (Fig. 18.12B, step 1).[529] However, the 3- to 4-nucleotide acceptor site by itself is too short to specify the transfer to DR1. Additional sequences on pgRNA are necessary to control the translocation of the DNA primer to DR1. The selection of the natural site is most likely facilitated by the structural arrangement of pgRNA in the capsid. The acceptor site and epsilon RNA presumably must be held in close physical proximity to facilitate the transfer of the 3- to 4-nt oligomer across the pregenome. Indeed, a short cis-acting element, termed phi, located upstream of the acceptor site at DR1 is required for accurate minus strand DNA synthesis from DR1 in HBV, but not DHBV.[1,328] Phi can basepair with the 5′ region of epsilon RNA, thereby stabilizing the predicted structural conformation of pgRNA required for the transfer of the short minus strand. Following the translocation reaction, minus strand DNA synthesis continues all the way to the 5′ end of the RNA template (step 2). During this reaction, pgRNA is degraded by the RNaseH activity present near the C-terminus of the polymerase.[451] Due to the location of DR1 within the terminal redundancy on the pregenome, the completed minus strand DNA bears the short terminal redundancy, r. As described below, r plays a role in the circularization of the viral genome.[304,451,546]

Plus Strand DNA Synthesis

Plus strand DNA is primed by an 18-nucleotide-long, capped RNA oligomer derived from the 5′ end of pgRNA. The oligomer contains a complete copy of DR1 and represents a product of the RNAseH activity of the polymerase (Fig. **18.12**B, step 3).[303,311] As a consequence of this priming mechanism, plus strand DNA synthesis can only begin after minus strand DNA synthesis is complete. To prime plus strand DNA synthesis, the RNA oligomer must first translocate to and anneal with DR2, located near the 5′ end of the minus strand DNA and identical in sequence to DR1.[303,451,546] As expected, mutations that disrupt the homology between DR1 and DR2 block the formation of rcDNA and instead favor an *in situ* DNA priming reaction from the non–translocated primer, leading to the formation of double stranded linear (dsl) DNA.[95,473,561] DSL DNA is produced even under natural conditions, albeit with a low frequency of about 5% to 20% of rcDNA (Fig. **18.5**).

The mechanism responsible for the transfer of the RNA primer to DR2 is not completely understood. The most likely scenario is that the regions encompassing DR1 and DR2 on minus strand DNA are juxtaposed to facilitate the transfer of the primer from DR1 to DR2. Studies with DHBV and HBV revealed the presence of three sequence motifs on the minus strands, which have the potential to form short duplexes that might stabilize a secondary structure required for

plus-strand primer translocation.[177,291,309] Mutations that would be expected to disrupt the formation of these duplexes inhibited rcDNA, but not dsl DNA synthesis. In addition, capsid proteins might impose certain structural constraints on minus strands and thereby play a role in primer transfer.

Following the priming reaction at DR2, plus strand DNA synthesis ensues until it reaches the 5′ end of minus strand DNA. At this point, a template switch (i.e., circularization) is required for the continuation of DNA synthesis (Fig. 18.12B, step 4). The template switch is facilitated by the aforementioned terminally redundant sequences, r, in minus strand DNA. The structural requirements for this reaction must be complicated, because the polymerase attached to the 5′ end of the minus strand accommodates both ends of the minus strand DNA in close proximity. In spite of the expected steric constraints, the polymerase can copy the entire r5 region, including the dGMP residue that is covalently linked to the RT and then induce the necessary template switch to r3.[310] As with priming at DR2, this event also depends on the formation of small duplexes on distant sites in minus strand DNA, indicating that the two critical steps in plus strand DNA synthesis might be controlled by the same mechanism.[187,351]

In mammalian hepadnaviruses plus strand DNA synthesis is incomplete and reaches approximately half the genome length prior to virion formation.[426,480] The cause and significance of the premature termination of plus strand synthesis remains obscure. Perhaps the arrest in DNA synthesis is caused by steric factors imposed by the capsid and by the polymerase itself. For instance, DHBV capsids assembled with core proteins with truncated C-termini are defective in plus-strand elongation,[568] demonstrating that capsid structure can influence elongation of plus strand DNA. In addition, the coating of capsids with envelope proteins probably leads to the depletion of the dNTP pool prior to the completion of DNA synthesis. This latter possibility is supported by the fact that plus strand DNA can be extended in an *in vitro* reaction in the presence of precursor dNTPs and nonionic detergents that disrupt the viral envelope[235,480] (Fig. 18.2). In contrast to orthohepadnaviruses, plus strand DNA synthesis in wild-type avihepadnaviruses is virtually complete,[304] except that the polymerase does not displace the RNA primer from DR2, so DR2 has to be copied prior to cccDNA formation.

Amplification and Stability of cccDNA

The fate of newly made DNA-containing capsids in the cytoplasm of infected cells is twofold: The particles either enter a retrograde pathway for delivery to the cell nucleus and release of rcDNA or assemble with envelope proteins into virions and enter the secretory pathway (Fig. 18.5). The first pathway amplifies the copy number of cccDNA.[518,551] Using DHBV, cccDNA amplification in cultures of nondividing hepatocytes was shown to occur early in an infection when the cytoplasmic concentration of viral envelope proteins is still low.[483,484] The final, average cccDNA copy number per nucleus, *in vivo*, has an estimated range between 1 and 20 copies per hepatocyte[224,230,344] but exhibits large variation among individual hepatocytes.[576] Transport of newly made capsids from the cytoplasm to the nucleus does not require envelope proteins because cccDNA amplification still occurs when hepatocytes are infected with viral mutants that are unable to synthesize these proteins.[483,484] Instead, signals generated on capsids during their maturation might play a role in the retrograde transport. In fact, in the complete absence of envelope proteins, the retrograde transport leads to nonphysiological overamplification of cccDNA than can be toxic to hepatocytes.[289,290] It remains unclear if

envelope proteins regulate HBV cccDNA amplification.

Critical issues with important implications for antiviral therapies with inhibitors of viral DNA replication are whether cccDNA has a half-life in resting hepatocytes and hence, whether ongoing cccDNA synthesis is required to maintain a steady-state within a nondividing cell and whether cccDNA can survive mitosis of hepatocytes. In cultured primary woodchuck and human hepatocytes, differentiated HepaRG cells and DMSO-treated nondividing HepG2-NTCP cells cccDNA appears to be very stable with long half-lives comparable to that of infected hepatocytes.[107,249,315,348] The view that cccDNA stability is high is also supported by studies of competition in infected liver between strains of DHBV with different replication rates and during Antiviral Therapy in infected woodchucks. Competition between the DHBV strains essentially stops in the fully infected adult liver, where cell turnover is low, suggesting that cccDNA has a low turnover rate in infected cells.[575] A kinetic analysis of WHV cccDNA in experimentally infected woodchucks treated with the RT inhibitor L-FMAU ([1-(2-fluoro-5-methyl-beta-L-arabinofuranosyl) uracil] suggested a half-live for cccDNA of 33 to 50 days, which corresponded to the expected loss of hepatocytes during that period.[584] Similarly, long half-lives of cccDNA ranging from 38 to 68 days were reported from experiments with ducks infected with DHBV and treated with a combination of the RT inhibitors lamivudine and dideoxyguanosine.[2,319]

A caveat with interpretation of results obtained with animals treated with RT inhibitors lies in the uncertainty about the completeness of inhibition of viral replication in infected livers.[418] Sporadic reduction in therapeutically effective concentrations in a fraction of hepatocytes could permit low-level viral replication and as a consequence replenishment of the cccDNA load. Thus, whether cccDNA is lost or partitioned to daughter cells during cell division is still not resolved. HBV does not appear to encode a protein that could tether cccDNA to chromosomes as it has been reported for human papilloma and other DNA viruses.[26,123] Hence, it would be expected that cccDNA were lost during division of hepatocytes, which probably occurs during recovery from infections as discussed later in this chapter. A recent study with HBV-infected hepatocytes that were serially transplanted into human hepatocyte chimeric uPA mice indicated that cccDNA is diluted and lost during hepatocyte proliferation.[6] However, even in the presence of the entry inhibitor Myrcludex-B or the RT inhibitor lamivudine, cccDNA persists in a small fraction of hepatocytes. Also, an earlier report revealed significant cccDNA loss during proliferation of tupaia hepatocytes infected with WMHBV in uPa chimeric mice in the absence of an antiviral.[320] On the other hand, a study with HBV-infected patients undergoing antiviral therapies with nucleoside analogs that inhibit viral DNA synthesis suggested that cccDNA may be stable in the chronically infected liver and survive through mitosis.[540] Experiments with tissue culture cells generally favor a model where cccDNA can survive mitosis and partition to daughter cells.[176,295] cccDNA also appeared to survive mitosis in primary woodchuck hepatocyte cultures derived from a chronically infected woodchuck that were treated with the nucleoside analogue adefovir dipivoxil and EGF, to block viral DNA synthesis and induce cell proliferation.[107] Again, a caveat exists with studies involving antiviral therapies due to the possibility of break-through DNA synthesis and replenishment of the cccDNA pool obscuring the detection of a more significant cccDNA loss.

Virus Assembly and Release

Assembly of Dane particles occurs in at least two distinct steps: The formation of capsids that

contain pgRNA and reverse transcriptase and the formation of enveloped virus particles that contain the viral DNA genome. During the completion of viral DNA synthesis, capsids gain the ability to interact with envelope proteins[210,390] (Fig. 18.5). Interestingly, empty capsids, but not RNA or minus strand containing capsids, interact efficiently with envelope proteins.[370] This interaction must occur independently of the phosphorylation state of capsids, because secreted empty particles are hyperphosphorylated, whereas rcDNA containing particles are hypophosphorylated.[371] As explained earlier, genetic evidence pointed to a mechanism where DNA synthesis is accompanied with successive dephosphorylation of capsids.[392] A more recent study revealed that RNA containing capsids are hypophosphorylated suggesting that partial dephosphorylation of the carboxy terminal domain might occur concomitantly with RNA packaging rather than DNA synthesis.[317,580]

DNA containing core particles assemble with envelope proteins at membranes of the late endosomal multivesicular bodies (MVPs) resulting in the formation and release of infectious virus (Dane) particles.[265,535] The N-terminal domain of L plays an important role in this step, because M and S proteins alone cannot support translocation of capsids across membranes.[288] Based on biochemical and structural studies, PreS1 binds to gamma2-adaptin (γ2).[186,229] In turn, γ2 might bind through its ubiquitin recognition motif to ubiquinated Nedd4, an alleged binding partner of capsids.[432] Such a preassembly complex appears to provide a substrate for the endosomal sorting complex required for the transport (ESCRT) complex at the MVB[535].[265] Moreover, Vps4 ATPase and AIP1/ALIX, known MVB-associated proteins, are required for HBV budding.[242,265,535] Following budding into MVBs, virions must enter the exosome pathway to exit the cell.

Besides DNA-containing particles, hepatocytes also secrete empty enveloped virion-like particles. Empty particles were first recognized in plasma of HBV infected patients as a population of Dane particles with lower density in CsCl and devoid of the nucleic acid and endogenous polymerase activity associated with the population with virions of higher density.[155,236,434] Notably, empty virions were more abundant than DNA-containing virions suggesting that they might represent defective interfering particles. The significance of these early observations was obscured by the prevailing notion that viral DNA synthesis provided signals necessary for the interaction between capsids and envelope proteins and hence for the formation and secretion of Dane particles.[482] However, experiments with viral DNA synthesis inhibitors and mutants defective in polymerase activity validated the original observations.[370] A revised model for Dane particle formation stipulates that capsids containing RNA or minus strand DNA exhibit a blocking signal preventing their interaction with envelope proteins.[370] Hence, the elusive signal proposed to trigger envelopment of core particles might be represented by a negative signal on RNA and minus strand containing capsids, a hypothesis awaiting further investigation. A more recent study indicated that secretion of rcDNA-containing virions and genome-free particles employ both common and distinct interaction determinants on capsid and envelope proteins.[372] Also, it is not known if empty particles have a role in HBV biology. It should be noted that none of these restrictions is absolute; for example, a small fraction of secreted virus particles contain pgRNA or minus strand DNA.[326]

In contrast to virions, formation and secretion of 22 nm SVPs occurs through the ER-Golgi compartment independently of the MVB.[389] Consistent with this view, dominant-negative mutants of Vps4 and AIP1 do not prevent SVP release from cells.[265,535] EM studies indicated

that disulfide-linked S dimers accumulate as filaments in the perinuclear space of the ER from where they must be transferred by unknown mechanisms to the ER-Golgi intermediate compartment (ERGIC).[389] Subsequently, filaments reorganize into spheres that enter the constitutive secretory pathway. It is also possible that SVPs use different exit strategies depending on the ratio of L:M:S.

PATHOGENESIS AND PATHOLOGY

Infection of the Liver

The main cellular target of HBV is the hepatocyte, the parenchymal cell of the liver, and the only liver cell that expresses NTCP, an HBV receptor. In humans, hepatocytes are the only cell type convincingly shown to replicate the virus. Structurally, the liver is composed of microscopic lobules into which blood enters from the hepatic artery and portal vein, which are situated in a region known as the portal triad, and exits via the hepatic vein (Fig. 18.14). Hepatocytes comprise 60% to 70% of liver cell mass. Other cells include bile ductular epithelial cells, sinusoidal endothelial cells, hepatic stellate cells (Ito cells), and Kupffer cells, the resident liver macrophages. Nonparenchymal cells of the liver do not appear to have a direct role in infection of hepatocytes, although an indirect role in virus transport to hepatocytes has been suggested based on experiments with DHBV.[42]

Hepatocytes are long-lived and self-renewing, with a half-life exceeding 6 months under normal conditions, and in adults a correspondingly low proliferation rate.[166,257,322,454,525,547] As a consequence, following *de novo* infection of adults, HBV primarily infects hepatocytes arrested in G0, though cycling hepatocytes are presumably infected in neonates. Infection occurs at the basolateral membrane consistent with the site of expression of NTCP, which is required for uptake of conjugated bile acids.[7]

Though hepatocytes are considered a self-renewing population in the normal liver, under conditions of severe injury, or where hepatocyte proliferation is blocked, for instance by a toxic chemical, facultative progenitor cells, considered to be located in the Canal of Hering, were considered to give rise to oval cells that proliferated and ultimately differentiated into hepatocytes.[507] Possible progenitor cells were also found in the bone marrow,[361] though their quantitative contribution to hepatocyte replacement and their relationship to progenitor cells attributed to the Canals of Hering were unclear. It has also been suggested that self-renewal in the normal liver is due to division of hepatocytes surrounding the central vein.[527] However, the prevailing concept is that most or all mature hepatocytes participate in renewal in the healthy liver. In addition, data suggest that mature hepatocytes may dedifferentiate under conditions of stress, proliferate, and then redifferentiate to mature hepatocytes, again questioning the role of stem cells in hepatocyte maintenance.[167] In this scenario, the mature hepatocyte population in adults is a closed population that can evolve to compensate for hepatotoxic conditions. Consistent with this notion, clonal outgrowth of hepatocyte lineages has been observed in genetic diseases impacting hepatocytes[334] and during the progression of chronic hepatitis B.[338,516]

Hepatocyte replacement in response to killing of infected hepatocytes by antiviral cytotoxic

T cells (CTL) during transient (acute self-limiting) hepadnavirus infections also appears to be primarily through division of other hepatocytes.[224,230,485] Possible replacement from undifferentiated progenitors has been suggested to occur during late stages of chronic infections, by which time the liver may be highly damaged,[150,197,429] but mature hepatocyte proliferation also occurs, and current information would suggest that the undifferentiated cells represent dedifferentiated hepatocytes.[167] The fate of HBV during hepatocyte proliferation is difficult to assess because proliferation occurs under varying local conditions produced by the level of liver inflammation and cytokine production, factors that are believed to affect the stability of cytoplasmic capsids, nuclear cccDNA, and viral RNAs, as well as RNA packaging. Even less is known about whether a fraction of proliferating hepatocytes becomes refractory to reinfection. In any case, immune clearance of virus from most of the hepatocyte population does not appear to depend on coproduction of virus-neutralizing antibodies.

Cell and Tissue Tropism

Early immunohistochemical studies of human tissues other than the liver suggested that exocrine and endocrine cells of the pancreas can be infected, though this was not shown to reflect productive infection. However, evidence for HBV DNA replication intermediates in the spleen was also described for humans and chimpanzees. Evidence for infection, gene transcription, and viral replication in peripheral blood mononuclear cells (PBMCs) has also been reported. Data in support of infection in bone marrow, as evidenced by the presence of HBsAg and 3 kbp rcDNA, but not DNA replication intermediates, has also been presented. The idea that any of these observations reflect actual infection of blood cells has, however, been challenged by a study that failed to detect cccDNA in these cells, suggesting instead that viral DNA and antigen signals, and by inference, virus replication reported in these studies arose from observations of passively adsorbed virus.[250] At present, the question of whether PBMCs, or any other site outside the liver of HBV carriers, are productively infected, or just accumulate HBV that was produced in the liver remains elusive.

The issue of extrahepatic replication has also been addressed in woodchucks infected with WHV. The most convincing evidence of extrahepatic infection was obtained from a study with PBLs. Although PBLs did not replicate WHV *in vivo*, they produced typical viral DNA replication intermediates and released virus when stimulated with lipopolysaccharide *in vitro* and thus appear to be latently infected *in vivo*.[253,254]

The best evidence for active *in vivo* replication in cells other than hepatocytes comes from studies of ducks infected with DHBV, where replication intermediates were found in subsets of cells in the spleen, kidney, and pancreas, as well as bile duct epithelial cells of the liver,[148,183,196,223,279,367,490] and of the yolk sac during embryonic development.[491] Viral DNA also accumulates in the spleen, due to passive accumulation of virus by follicular dendritic cells[223]; evidence for DNA replication intermediates[490] and cccDNA[173] in the spleen has also been reported, though DNA replication intermediates were not observed in the latter study.

Immune Response

A remarkable aspect of the hepadnavirus life cycle is that virus infection and spread can occur in the absence of a measurable innate immune response, which only becomes evident after the

appearance of the adaptive immune response, which may appear after several weeks of infection. Transcriptome analysis of liver tissue obtained from three HBV-infected chimpanzees demonstrated that genes known to be expressed upon activation of pattern recognition receptors or interferons remained at basal levels.[544] Subsequent studies using single-cell analyses of HBV-infected HepG2-NTCP, HepaRG cells and PHH confirmed the observations made in the chimpanzee model and also demonstrated that the observed lack of an innate immune response was not due to an inhibitory viral activity.[85,356,373] These observations are not entirely surprising because HBV does not produce known ligands for intracellular pattern recognition sensors such as uncapped RNA, or DNA exposed to the cytoplasm.

Indeed, a number of studies suggest that the liver can regulate or at least protect itself against the host immune response.[421] First, in some species including rats, pigs, and mice, liver transplantation between allogeneic animals induces tolerance to grafts of other tissues from the same donor that would normally be rejected, suggesting that the liver has immunoregulatory properties, possibly attributable to hepatic dendritic cells.[504,505] Second, a number of different cell types in the liver appear to have the ability to present antigen in a suboptimal context, in some cases leading to immune tolerance or a weak immune response.[99,248,506] Third, the adaptive immune response to a number of human viruses that are thought to infect, predominately hepatocytes, including HAV, HBV, HCV, and hepatitis E virus (HEV), only becomes robust enough to induce high levels of cell death and virus clearance 4 to 8 weeks after infection. During this time, the entire hepatocyte population may become infected by HBV.[543] A similar pattern has been seen following DHBV infection of ducks and WHV infection of woodchucks.[224,230] These observations suggest that scanning of hepatocytes by the immune system is low and has been attributed to low expression of major histocompatibility class I (MHC I) genes and limited access of circulating lymphocytes to hepatocytes, despite the occurrence of fenestrations in the liver endothelial cells.[171] The possibility that liver cells other than hepatocytes may induce at least partial tolerance to viral antigens could also contribute to the prolonged course of transient and chronic infections.

HBV infection, replication, and virus shedding are not cytopathic to hepatocytes. This may be another reason the immune response to infected cells is slow to evolve, often not appearing until weeks after essentially every hepatocyte is infected,[248,503,541] which may take weeks to months depending upon the infecting viral dose. The result of this massive infection is that a strong immune reaction, with killing of large numbers of hepatocytes, is typically seen during the clearance phase of such an infection.[485] About 95% of immunocompetent adults are able to mount such a response, resolving the infection within a few weeks once clearance begins. Unfortunately, about 5% of adults and most children under the age of 1 year are unable to resolve the infection (Fig. 18.15, see Fig. 18.17). Instead, chronic hepatitis B with ongoing liver injury may occur, mediated by a T-cell immune response targeting hepatocytes that express viral antigens.[28,88,152] Chronic infections, with persistence of readily detectable levels of serum virus and surface antigen particles, are generally lifelong. Antiviral T cells are rare in these patients compared to patients that have previously recovered from a transient HBV infection.[420] In addition, in chronically infected patients, a certain degree of T-cell function defect is reported which may contribute to viral persistence. It is suggested to result from T-cell exhaustion by high antigen concentrations that promote HBV-specific T-cell dysfunction by affecting phenotype and function of peripheral and intrahepatic T cells.[109,141]

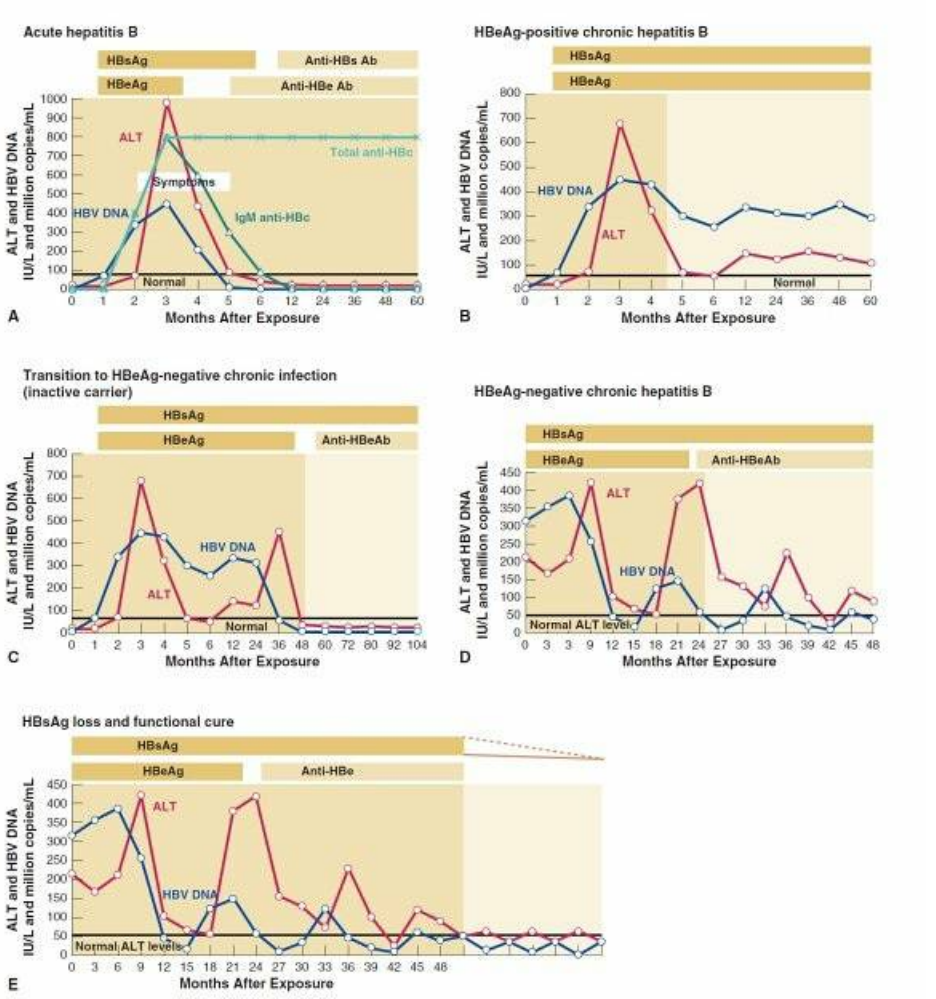

FIGURE 18.15 Serological profiles of HBV infections. A: Laboratory diagnosis of acute hepatitis B. Acute hepatitis is diagnosed in patients with jaundice or fatigue and high ALT levels. Evidence of transient HBV infection is obtained by the detection of HBsAg and anti-HBc IgM antibody. Viral replication is authenticated by the detection of serum HBeAg and HBV DNA. Resolution of infection is accompanied by the decline in viral load, seroconversion to anti-HBe, and normalization of ALT levels. Subsequently, HBs seroconversion is observed and represents a serological marker of the cure of the infection. **B:** Laboratory diagnosis of chronic hepatitis B associated with wild-type virus infection. Chronic HBV infection is diagnosed by the persistence of serum HBsAg and markers of viral replication (i.e., serum HBeAg and HBV DNA). Depending on the phase of disease, ALT levels may be normal (i.e., HBeAg-positive chronic *infection*) or elevated (i.e., HBeAg-positive chronic *hepatitis*). **C:** Laboratory diagnosis of transition of chronic hepatitis B to the inactive carrier state (i.e., HBeAg-negative chronic *infection*). HBe seroconversion is associated with the loss of serum HBeAg, the appearance of anti-HBeAb, the decline of serum HBV DNA levels, and the normalization of ALT levels. A flare in ALT levels sometimes precedes it, suggesting that HBe seroconversion may be associated with an immune-mediated hepatocyte lysis. HBe seroconversion is associated with an improved clinical outcome, and the patients are classified inactive carriers **D:** Laboratory diagnosis of HBeAg-

negative chronic hepatitis. In some patients, pre-C mutants are selected at the time of HBe seroconversion, and the disease continues to progress with a typical fluctuation of serum HBV DNA and ALT levels. This stage of chronic hepatitis B, which was historically described in the Mediterranean basin, is usually referred to as HBeAg-negative chronic hepatitis B. **E:** After achieving spontaneous or treatment-induced remission, some patients may lose serum HBsAg; serum HBV DNA is undetectable and ALT levels are normal. HBs Ab may become positive but not always. It is expected that in the liver compartment, cccDNA persists and may be responsible for viral reactivation in case of immune depression. This phase is called "functional cure"; it is associated with a decreased risk of hepatocellular carcinoma and represents the new end point for novel therapies in clinical development.

Nonetheless, virus titers in the blood often decline during the course of a chronic infection, from as high as 10^{10} per mL to as little as a few hundred per mL. One explanation is that antiviral cytokines produced during chronic hepatitis suppress virus replication,[342] as also seems to occur during the clearance phase of transient infections.[230,485,503,541,543] Another possibility is that persistent killing of infected hepatocytes by antiviral CTLs selects for the clonal outgrowth of hepatocytes that have lost the ability to support high levels of virus replication.[336]

Results of placebo-controlled trials of antiviral agents suggest that approximately 5% of patients each year experience spontaneous decline of virus titer and HBe seroconversion and enter the remission/inactive hepatitis phase.[119,262,329,566] However, unlike clearance of a transient infection, the serum of a chronic HBV carrier undergoing spontaneous remission generally remains HBsAg positive, most likely because many hepatocytes contain both low amounts of cccDNA and integrated viral DNA with an intact S coding region.[550]

The mechanisms of clearance of transient infections have been investigated in detail in clinical studies as well as through the use of experimental models including HBV-infected chimpanzees, WHV-infected woodchucks, and DHBV-infected ducks. A key point in these studies is to explain how the liver recovers after infection of all hepatocytes and how hepatocytes in the recovered liver are derived mostly from previously infected hepatocytes.[337,485] From these studies, it is generally agreed that virus clearance requires the coordinated action of several components of the immune response[169,337,485,543,560]: (a) A cytolytic response by CD8-positive cells recognizing infected hepatocytes expressing viral antigens; (b) A noncytolytic response whereby the CD8-positive cells and other, non–antigen-specific cells recruited to the sites of inflammation, produce TH1 cytokines such as IFN-γ, TNF-α, and interleukin 12 (IL-12) that exhibit a direct antiviral effect, suppressing virus reproduction in the infected hepatocytes,[459] in part by blocking assembly of DNA replication complexes[176,384,388,425,446,447,544]; (c) hepatocyte proliferation to generate new cells to replace those killed by the antiviral response and repopulate the liver, with the idea that cccDNA may not efficiently survive through mitosis.

Another factor that has been considered is the innate immune response mediated by NK and NKT cells, possibly induced or triggered by ER-associated endogenous antigenic lipids that might be generated by HBV-induced secretory phospholipase.[125,140,574] However, as alluded to above, experimental HBV infection of chimpanzees does not induce a detectable innate response in the liver prior to the appearance of the adaptive response,[541] suggesting factors in the innate response critical to virus clearance are, in the context of *de novo* HBV infection, secondary to the

adaptive T-cell response. The role of virus-neutralizing antibodies has also been considered. At present, anti-HBsAg antibodies are considered to prevent reinfection of the recovered liver by residual virus. Evidence that B cells play a major role during the recovery phase, when virus-infected hepatocytes are being cleared from the liver, is less compelling, as HBsAg appears to have a suppressive effect on maturation of HBsAg-specific B cells.[53,435] In addition, antibodies to the viral envelope are often not detectable before virus is cleared from the liver.[138,230,401]

An issue that is least understood is how cccDNA is cleared from the liver. Although the existence of cytokine-mediated, noncytocidal, clearance has been invoked,[169,315] the evidence for this occurring *in vivo* remains problematic because of the difficulty of quantifying hepatocyte turnover. Results of a study with HBV transgenic, HNF1alpha-deficient, mice that produce cccDNA suggested that this DNA is sensitive to noncytolytic purging by antiviral cytokines,[10] but unfortunately, the contribution of hepatocyte death to this finding was unclear. Studies of acute infection of chimpanzees have also been interpreted to argue the importance of noncytolytic clearance of HBV DNA replication intermediates and cccDNA. However, interpretation of cccDNA decline is again problematic because of the difficulty of quantifying the large amount of hepatocyte destruction during virus clearance.[170,175,337,354,485,503,543] Thus, the roles of noncytopathic clearance versus clearance by hepatocyte death versus clearance due to a failure to survive mitosis remain unresolved.

HBV Reactivation

Despite the fact that many patients will undergo spontaneous HBsAg seroconversion after acute infection or HBeAg seroconversion during the course of chronic infection and will be in a state of “immune control” of the infection, HBV infection persists in the majority of these patients whose liver still harbor low amounts of cccDNA. Thus, HBV infection is a model of viral persistence where remission is the result of a fine equilibrium between antiviral immune responses and the maintenance of viral minichromosomes at low copy numbers. Several clinical situations have shown that this equilibrium (or “immune control”) may be challenged when patients undergo immune suppression or if escape variants are selected.

In patients undergoing immunosuppressive therapies (i.e., chemotherapy, biotherapies for autoimmune diseases, B-cell selective monoclonal Ab-based therapies (anti-CD19/20; e.g., Rituximab and Ofatumumab) for lymphomas or other diseases), HBV replication may reactivate from the reservoir of infected hepatocytes harboring cccDNA.[81,259] In these situations, viral reactivation may occur in inactive carriers and even in patients who previously lost HBsAg. Several studies have shown the presence of very low levels of cccDNA in the liver after HBsAg seroconversion.[341,540] For these reasons, international clinical guidelines recommend antiviral prophylaxis in patients undergoing immunosuppressive therapy as follows[127]: (a) all candidates for chemotherapy and immunosuppressive therapy should be tested for HBV markers prior to immunosuppression, (b) all HBsAg-positive patients should receive nucleos(t)ide analogue therapy as treatment or prophylaxis, (c) HBsAg-negative, anti-HBc–positive subjects should receive anti-HBV prophylaxis if they are at high risk of HBV reactivation. In patients undergoing liver transplantation with an anti-HBc positive donor, there is a potential risk for transmitting the infection to the recipient even in the absence of detectable viremia due to presence of cccDNA in the donor hepatocytes and reactivation of viral infection because of the recipient’s immunosuppressive context.[89] Antiviral prophylaxis reduces the risk from 47.8% to

12% in naive recipients and from 15.2% to 3.4% in anti-HBc–positive recipients.[89] Finally, several clinical observations showed that HBs variants may escape HBsAb neutralization and result in viral reactivation, especially in case of immune suppression.[94,437]

In the case of HBV and HCV coinfections, serum HBV DNA levels are usually low possibly due to indirect mechanisms mediated by an innate immune response induced by HCV. With the advent of efficient direct-acting antivirals (DAA) that cure almost 100% of chronic HCV carriers, several cases of HBV reactivation have been observed after elimination of HCV in both HBsAg-positive and in anti-HBc–positive patients.[526,564] Thus, international clinical guidelines recommend (a) that HBsAg-positive patients undergoing DAA therapy should be considered for concomitant nucleos(t)ide analogue prophylaxis until week 12 post DAA and (b) that HBsAg-negative, anti-HBc–positive patients undergoing DAA should be monitored and tested for HBV reactivation in case of ALT elevation.

Cirrhosis and Hepatocellular Carcinoma

Chronic Infections

About 5 years after the discovery of HBV, Sherlock and colleagues looked for a link between HBV infection and HCC.[456] In a cohort of 17 chronically infected males, 5 presented with HCC. Definitive support for the hypothesis that HBV plays a primary role in the development of HCC came from epidemiologic studies,[340,405] and particularly from a prospective study by Beasley and colleagues, who followed more than 22,000 Taiwanese men.[21] The relative lifetime risk for HBsAg–positive males was found to be about 20 compared to uninfected individuals.[135] An even stronger correlation between chronic hepadnavirus infection and HCC was found in WHV–infected woodchucks.[481] Investigations with captive woodchucks showed that WHV induced HCC in essentially 100% of neonatally infected woodchucks within 2 to 4 years and in 20% of those that resolved the infection after neonatal inoculation.[255,495,496] In contrast, the chimpanzee did not prove to be a model for hepatocellular carcinoma, as only a few cases of HCC have been reported in HBV-infected chimpanzees and only in chimpanzees coinfected with either HDV or HCV.[402]

In humans, liver cancer usually develops after several decades of infection and is often preceded by cirrhosis of the liver (Fig. 18.16). Consistent with the distribution of chronic HBV infections around the globe, HCC is one of the two or three most common malignant neoplasms in people living in China, Taiwan and southeast Asia as well as in sub-Saharan Africa. The field has been driven by two hypotheses, one positing a direct effect of the virus in cancer development, the other predicting that HCC formation is a consequence of persistent liver injury caused by the immune response against infected hepatocytes and hence, attributing an indirect role to the virus. In reality, both may contribute to HCC.

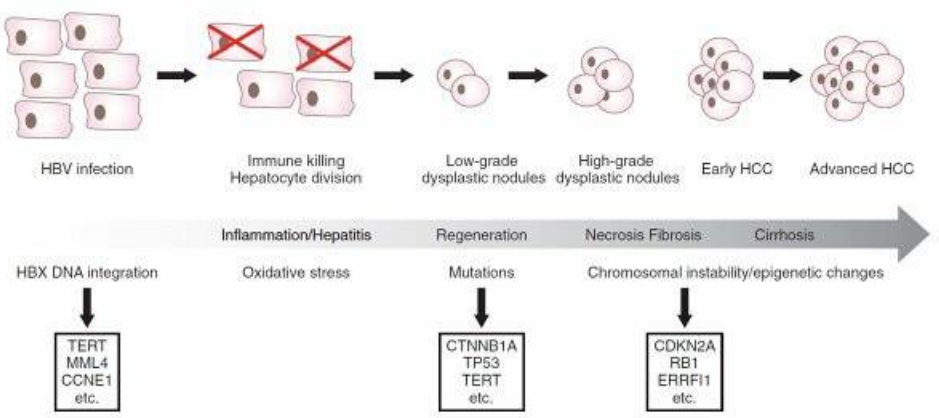

FIGURE 18.16 Model for HCC development. Schematic representation of HCC development initiated by HBV infections (see text for a detailed description and references).

The vast majority of tumors contain integrated HBV DNA and, since hepatocytes are the only liver cells clearly susceptible to HBV, it is assumed that most tumors arise by dedifferentiation of mature hepatocytes. While it cannot be excluded that some tumors arise from undifferentiated progenitor cells present in the liver, present findings are most consistent with the concept that the majority of tumors arise from HBV-infected hepatocytes.

Cellular Factors and HCC

Models explaining HCC development in HBV patients entirely via indirect mechanisms take into consideration a hallmark of HBV infections, death, and compensatory regeneration of hepatocytes. Hepatocytes, as noted above, appear to constitute a mostly self-renewing population. Progenitor cell proliferation may also be seen late in infection, especially in the tumor bearing and cirrhotic livers, but these progenitors may arise from dedifferentiated hepatocytes. While hepatocyte death and compensatory proliferation to maintain liver mass are inconsequential on a sporadic basis, persistent liver injury due to CTL killing observed in chronic hepatitis B can cause substantial fibrosis and cirrhosis of the liver. The progression to cirrhosis may be interrupted, and even reversed, if the infection is controlled by antiviral therapies.[300,386,424,428,567] Cirrhosis often precedes HCC, but whether this means that cirrhosis contributes to oncogenesis or that both cirrhosis and HCC are a consequence of infection and persistent hepatocyte destruction is unresolved. It is noteworthy that alcohol abuse, storage diseases, and chronic HCV infections have the same effects, and all are risk factors for HCC.[334] That is, independent of the cause, chronic liver disease is associated with an increased risk of HCC.

Whole-genome sequencing of HCC DNA obtained from HBV-infected patients identified the Wnt/beta-catenin and JAK/STAT pathways as potential oncogenic drivers in approximately half of the cases examined.[231] The same study revealed TP53 mutations in over one-third of HCCs. However, a direct link between those events and HBV infection does not yet appear to exist.

The importance of chronic liver injury in HCC has been documented in many studies with

mouse models. For instance, transgenic mice expressing levels of the HBV L-protein that are toxic to hepatocytes developed HCC.[87] It was suggested that a contributing factor in emergence of HCC in this model was free radicals generated by the large number of macrophages activated in response to the high rate of apoptosis, leading to extensive DNA damage in surviving hepatocytes. The idea that oxidative DNA damage was occurring was supported by the detection of deoxyguanosine adducts on DNA isolated from the livers of these mice.[181] These data support the notion that HCC is not just due to the effects of L overexpression on the hepatocytes, leading to a high level of hepatocyte death and compensatory proliferation, but also to hepatocyte DNA damage attributable to free radical formation by activated macrophages.[334]

In a perhaps more relevant model of the events occurring during chronic HBV infections, studies were carried out with transgenic mice expressing low levels of L, which did not cause any apparent liver disease. When the immune system of these mice was ablated and replaced with bone marrow cells from syngeneic nontransgenic mice, the resulting immune response led to liver cell injury and HCC.[357] Moreover, inoculation of the mice with anti-fas ligand antibodies reduced the incidence of HCC, establishing a possible correlation between the rate of hepatocyte death, compensatory proliferation, and development of HCC.[358]

Viral Factors and HCC

Evidence for a direct role of HBV in human HCC was fueled by the observation that DNA from HCC contained integrated HBV DNA and that tumors were clonal with respect to the viral integration site.[41,70,134,455] This discovery suggested a model of insertional mutagenesis, as found by retrovirologists, in which activation of proto-oncogenes was caused by nearby provirus integration.[188,391] However, initial efforts to identify proto-oncogenes adjacent to integrated HBV DNA were not met with clear candidates, save for a few isolated cases, where integration sites were found adjacent to or within coding regions of candidate proto-oncogenes including cyclin A, erb-A, or retinoic acid receptor beta.[115,116,530] Subsequent genomic analyses using Alu-PCR–based amplification of sequences adjacent to HBV integration sites revealed several cancer-related genes including human telomerase (hTERT), which was identified as a recurrent site of HBV integration[352] (Fig. 18.16). Massive parallel sequencing of DNA derived from over 100 HCC tissue samples identified approximately 20 recurrent HBV integration targets in HCCs including hTERT, the histone H3K4 methyltransferase (MLL4), and cyclin E1 (CCNE1).[61,283,486,579] However, most of the individual recurrent sites were only found in a small percentage of tumors.

HBV integration occurs preferentially within or near the DR1 and DR2 segments of the viral genome[222,486,579] Integration has been associated with increased expression of genes adjacent to integration sites, disruption of coding regions, and DNA copy number alterations.[222,486] Thus, HBV integration events are not limited to transcriptional deregulation but can also cause chromosomal instability.[222,579] It is also possible that HBV DNA alters the expression of some genes that are distant from the integration site, perhaps by altering the structure of chromosomes as observed with N-myc2 activation in woodchuck HCCs, which has been attributed to WHV integrations over 100 kb distal to the gene.[52,146]

Further evidence for a direct viral role in HCC development was obtained from studies with GSHV infections in woodchucks. HCC in GSHV-infected ground squirrels develops in about

50% of animals beyond 4 years of infection[105,332,333] (compared to 100% of WHV-infected woodchucks by 3 years). Delayed onset of HCC development is also observed in woodchucks infected with GSHV compared with the WHV-infected woodchucks, suggesting that the difference in pathogenesis between WHV and GSHV in their natural hosts might be a property of the viruses rather than the hosts.[452] Tumors from WHV-infected woodchucks revealed very different results from those reported with HBV in humans. The majority of these HCCs overexpress N-myc2, a functional pseudogene of N-myc1[145,410] that is not normally expressed in the liver.[145,184,216] C-myc and N-myc1 are more rarely overexpressed in woodchuck HCCs. N-myc1 or C-myc overexpression in woodchuck HCCs is typically associated with nearby integration of WHV DNA, while overexpression of N-myc2 may be due either to nearby integration[145,184] or to integration in the distal *b3n*[47,48] or *win*[146] loci.

The majority of ground squirrel HCCs overexpress C-myc.[184,511] However, C-myc overexpression in the ground squirrel does not correlate with nearby integration of GSHV DNA, though it sometimes correlates with copy number amplification of the C-myc locus. Interestingly, the pattern of DNA integration and myc activation, in HCCs that arise in woodchucks infected with GSHV, is more typical of that seen in ground squirrels infected with GSHV. This suggests that N-myc activation in WHV-infected woodchucks characterizes WHV infections rather than hepadnavirus infections of the woodchuck *per se*. Transcriptional activation of N-myc and C-Myc have not been reported to characterize human HCCs, suggesting that myc activation may play a more central role in rodent than primate HCCs.[511] This does not, however, preclude the possibility that genes regulated by myc play a central role in human HCC.[237]

Alternative models, consistent with a direct role of HBV in human HCC, posit that one or several viral gene products are oncogenic. Although the long latency period observed for HCC development indicates that HBV gene products cannot transform hepatocytes in a single hit event, the hypothesis gained momentum with the discovery that transgenic mice expressing HBx developed HCC.[243] The success of this model depended on the selection of the mouse strain, CD1, known to develop spontaneous hepatomas at an increased rate compared to other mouse strains and high expression levels of the transgene that are not observed during natural infections.[251] Thus, it appears that X promotes but does not necessarily initiate carcinogenesis. In agreement with this notion, an HBx transgene did not promote HCC in another genetic background but, interestingly, these mice were more susceptible to HCC induction by diethylnitrosamine (DEN) than nontransgenic controls,[461] which was subsequently attributed to increased proliferation of altered hepatocytes in the absence of elevated host gene mutation rates.[324] In addition, an HBx transgene accelerated development of HCC in C-myc transgenic mice.[497] One possibility is that these different *in vivo* activities attributed to HBx reflect its ability to degrade the cellular Smc5/6 complex, which plays a key role in chromosome maintenance and repair. Finally, it is important to note that in the past investigations on HBx expression in HCCs have been hampered by the lack of antibodies that can reliably detect expression of the protein.

The discovery of the transactivation function of truncated M envelope proteins also supported a viral oncogene hypothesis (i.e., Ref.[442]). Truncated M proteins are not produced by wild-type HBV but are produced by naturally occurring mutants. Overexpression of the truncated M protein with the help of the albumin promoter in transgenic mice activated the c-

Raf/Erk2 signal transduction pathway and, in turn, increased hepatocyte proliferation.[193] These mice developed very small liver tumors by 1 to 2 years of age. Interestingly, Su and colleagues have suggested that L/M protein mutants are responsible for development of a class of preneoplastic lesion consisting of ground glass hepatocytes[478] as well as HCC.[565]

In summary, the details of HBV-induced liver cancer remain elusive. We can infer that the combination of alterations in hepatocyte physiology caused on one side by viral gene expression and on the other by changes in the microenvironment of hepatocytes due to inflammation results in the proliferation and eventual transformation of hepatocytes. Viral mechanisms that could contribute to hepatocyte transformation include changes in host gene expression caused by HBx, truncated M (or L), and integrated HBV DNA, and inhibition of DNA repair pathways. Cellular mechanism include hepatocyte killing by CTLs, induction of DNA damage via reactive oxygen (and nitrogen) radicals produced by macrophages, and expression of cytokines that in conjunction with viral gene expression provide a proliferative stimulus to hepatocytes.

EPIDEMIOLOGY

Global Prevalence

Disease caused by HBV has a worldwide distribution. Serum HBsAg prevalence of ≥8% defines highly endemic areas, 5% to 7% defines high intermediate, 2% to 4% low intermediate, and less than 2% defines low endemic areas. In 1995, it was estimated that more than 2 billion people globally had a history of HBV infection, though a majority had recovered. In 2015, the global prevalence of chronic HBV infection in the general population was estimated at 3.5%, or about 257 million individuals, making it the most common chronic viral infection (https://www.who.int/hepatitis/publications/global-hepatitis-report2017/en/). HBsAg seroprevalence varies considerably among the WHO Regions, with the highest in Africa (6.1%) and the Western Pacific (6.2%). HBV-induced mortality (887,220 deaths/year globally; 337,454 due to HCC; 462,690 due to cirrhosis and 87,076 due to acute hepatitis) is now twice that of malaria (429,000 deaths/year (https://www.who.int/news-room/fact-sheets/detail/malaria)) and HBV represents the seventh highest cause of mortality worldwide. HBV is responsible for greater than 50% of the hepatocellular carcinomas (HCCs) worldwide and up to 10% of liver transplants.[132,160,471] HCC caused by HBV predominated over other important causes of HCC (such as HCV) in countries where the prevalence of chronic HBV infection is high.

Most of the burden of HBV-related disease results from infections acquired in infancy, through perinatal or early childhood exposure to HBV. This is because infection acquired at an early age is much more likely to become chronic than infection acquired later in life. The risk of chronic infection remains high until after 5 years of age, when the rate stabilizes at around 5%.

Coinfection with other viruses occurs most frequently in high HBV endemic areas. About 2.7 million of the 36.7 million people infected with HIV worldwide are coinfected with HBV. Approximately 10% to 15% of patients with chronic HBV infection are coinfected with HCV. HDV infection occurs exclusively in HBV-infected individuals, and approximately 5% of HBV-infected persons are infected with HDV.

WHO estimates that only 10% of the 257 million people living with HBV have been diagnosed and as few as 1% are being adequately treated worldwide. Studies performed in highly endemic areas have shown that screening and treatment programs would be cost-effective but would require national health programs with adequate resources in order to have a significant public health impact.[285] WHO recognizes the importance of hepatocellular carcinoma and other HBV-related diseases as global public health problems and reiterates its recommendation that hepatitis B vaccines should be included in national immunization programs. WHO has defined several objectives to eliminate viral hepatitis as a public health issue by 2030 (https://www.who.int/hepatitis/strategy2016-2021/ghss-hep/en/).

Main Routes of Transmission

The main routes of HBV infection involve exposure to blood or blood-derived products, such as during childbirth from an HBV-positive mother, blood transfusion, or other potential sources of percutaneous exposure, including sexual intercourse.[282] The greatest sources of infection worldwide are from infected mothers to newborns or to or among very young children. The risk of vertical transmission from mothers varies depending on geographical regions. In Asia, the rate of perinatal transmission is as high as 90%, because many of the pregnant women who are chronically infected have high titers reaching up to 10^{10} Dane particles per mL blood.[474] In North America, Western Europe and Africa, the risk of vertical transmission from chronically infected mothers is only about 10%, which correlates with reports that infected mothers in these regions usually have a low viral load. These differences in viral loads are likely a result of different natural histories of chronic infections in different parts of the world, with neonatal infections that become chronic leading to a more persistent high-level viremia than infections later in life. That is, women infected at birth would have a higher viremia as they age and would be more likely to pass the infections to the neonate than women infected later during the first few years of life. The observed high rate of chronicity in Africa appears mostly due to horizontal spread to young children from playmates and adults involved in their care, rather than directly from infected mothers during birth.[163]

The risk of HBV transmission by blood transfusion has decreased dramatically since the early 1970s because of the exclusion of paid donors and the introduction of serological screening of volunteer blood donors for serum HBsAg and anti-HBc immunoglobulins. In the United States, the risk of HBV transmission via blood products is now one out of 63,000 transfusions, down from 15% in the 1960s.[8,162] Issues remain with the failure to identify infected blood donors because of the serological window during the incubation period following infection, the presence of some rare HBsAg variants that are not detected by the serologic assay for HBsAg, particularly when concurrent testing for anti-HBc is not performed, and the problem of so-called occult HBV infections, in which neither HBsAg nor anti-HBc is detected by serologic testing. Thus, the feasibility of nucleic acid testing (NAT) of blood donations in pools of up to 96 samples for HCV, HBV, and HIV-1 has been explored. Currently, the diagnostics industry provides commercial HCV, HIV-1, and HBV NAT tests on automated platforms. These have further decreased the risk of transmission of these viruses via blood transfusion, at least in countries where these platforms are available. However, in many endemic countries, serological assays are the only assays that are affordable for screening of blood donations.[139]

In contrast to blood transfusion, percutaneous infection of young people and adults via

intravenous drug use, tattoos, acupuncture, ear piercing, razor sharing, etc., remain major modes of HBV transmission. Sexual transmission still represents 40% of the new cases of acute hepatitis B in many developed countries, while the role of intravenous drug use seems to be decreasing with time, currently representing 6% to 10% of new cases. HBV can also be transmitted by accidental needle stick in the health care setting.[8,162] Nosocomial transmission represents approximately 10% of the new cases of HBV infection, usually as the consequence of invasive treatment or diagnostic procedures. The risk of accidental transmission by the percutaneous route is estimated to be 30% from highly viremic patients. Transmission from health care worker to patients may also occur.[185] Other cases of nosocomial transmission have been reported in hemodialysis centers, and in the setting of organ transplantation, even from donors who only have anti-HBc antibodies. When found alone, anti-HBc antibodies are usually a marker of a past infection from which an individual has recovered. However, HBV infection following a liver graft, presumably by reactivation of residual virus present in the donor liver, is observed in more than 50% of cases when the donor has antibodies to HBcAg but no other serological markers of HBV infection.[113] As discussed later, this is consistent with other studies indicating that residual amounts of HBV remain for years or decades after clearance of transient infections. Finally, horizontal transmission can be observed among institutionalized persons via close bodily contact, leading to HBV infection through skin breaks and mucous membranes.[522]

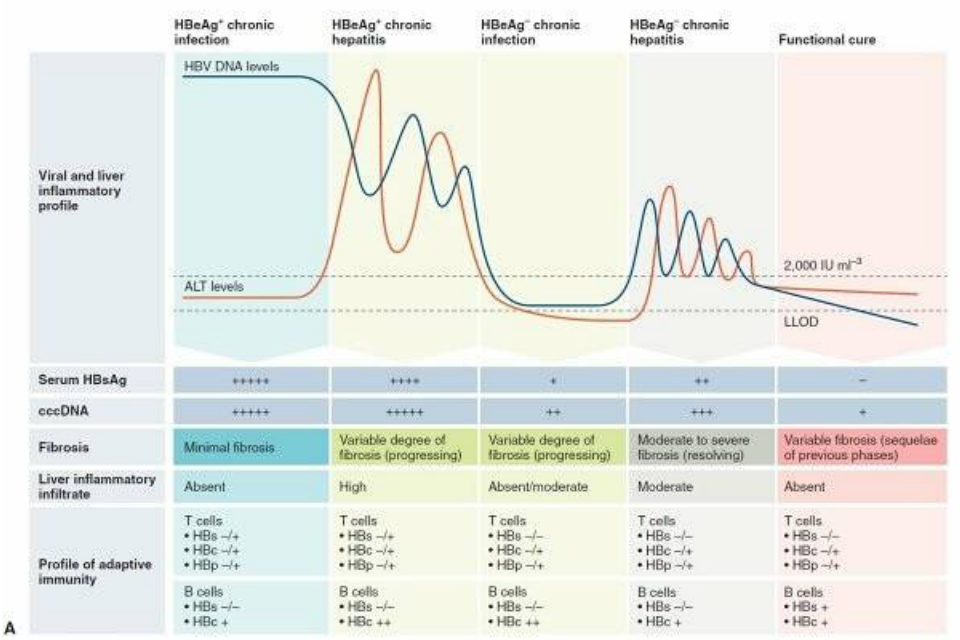
HBV Genotypes

At least 10 HBV genotypes have been recognized, named A to J, along with nearly 40 subgenotypes, named with the genotype letter followed by a digit (e.g., A1, C2).[306,414] The genomes of genotypes I and J are likely genotype C recombinants. Genotype A is found in North America, Europe, South-East Africa, and India; genotypes B and C in Asia and Oceania; genotype D, the most widespread, in North America, North Africa, Europe, the Middle-East, and Oceania; genotype E in West Africa; genotype F in South America and Polynesia; genotypes G and H in Central and South America; genotype I in Vietnam and Laos; and genotype J in Japan. Genotype G is often found as a coinfection with genotype A.[477] There is evidence that HBV genome variability and genotypes can influence clinical and virological parameters, for example, viral load, course of disease, and prognosis of treatment.

Despite being close at the genome level, HBV subgenotypes have very distinct geographical distributions, as noted above, and geographical locations appear to correlate with routes of transmission and virological features. A striking example of such differences is shown by subgenotypes A1 and A2. Subgenotype A1 is found in Africa and Southern Asia, while A2 is found in Europe and North America. A1 transmission is perinatal or in early life, while A2 is mainly acquired by adults parenterally or sexually. A1 is linked to rapid progression to chronic liver disease and HCC. Thus, the differentiation between subgenotype A1 and A2 appears to be correlated with the epidemiology and outcomes of infections.

Certain mutations associated with viral genotypes may also influence disease outcomes, development of HCC, and treatment outcomes. For instance, genotype D is observed mainly in the Mediterranean basin and is associated with a higher prevalence of pre-C mutants in chronically infected individuals (i.e., HBeAg negative patients) as well as a lower response rate to IFN therapy compared to genotype A[55,164]; other clinical studies have suggested an association of genotype C with a more severe chronic liver disease and a poorer response rate to

IFN therapy.[234,569] In a landmark Risk Evaluation of Viral Load Elevation and Associated Liver Disease/Cancer-HBV (REVEAL-HBV) study from Taiwan[559] performed in a large community cohort, male gender, high serum alanine aminotransferase (ALT), older age, positive HBeAg, higher HBV-DNA levels, and precore mutation were independently associated with a higher risk of HCC. In addition, genotype C was associated with an increased risk of HCC compared to genotype B, with an adjusted hazard ratio of 2.35 (95% CI = 1.68 to 3.30, $p < 0.001$).



In brief, these results and analysis of the literature show that the risk of HCC development is multifactorial and that many epidemiological, geographical, host and virological aspects may be intrinsically linked to viral genotypes and clinical outcomes.[414] Using predictive factors of HCC such as genotype C, nomograms and scoring systems have been developed to assess HCC risk in patients (i.e., Ref.[549]). However, validation of scoring systems for different parts of the world based on different cohorts of patients with different HBV (sub)genotypes, ethnicity, etc. remains an important goal.[414]

CLINICAL FEATURES

Clinical Manifestations

The natural history of chronic hepatitis B (CHB), particularly after infection of neonates or young children, can be schematically divided into five phases, which are not necessarily sequential (Fig. 18.17).[127] (a) The HBeAg-positive chronic infection phase, characterized by HBeAg positivity and high titers of serum HBV DNA, often up to $10^{9\text{-}10}$ IU/mL, normal levels of aminotransferases, and mild or no liver necroinflammation. During this phase, the rate of spontaneous HBeAg loss is very low. This first phase is more frequent and more prolonged in subjects infected neonatally or in the first years of life. Because of high levels of viremia, these patients are highly contagious. This phase was previously designated immune tolerant, but this designation has been revoked for many reasons including the realization that low levels of immune-mediated liver damage may be occurring. (b) HBeAg-positive chronic hepatitis, characterized by HBeAg positivity, often lower titers of serum HBV DNA (but >2,000 IU/mL), increased or fluctuating levels of aminotransferases, moderate or severe liver necroinflammation, and more rapid progression of fibrosis compared to the chronic infection phase. In this phase, the rate of spontaneous HBeAg loss is enhanced but may still occur at a late stage when fibrosis has already developed. This phase may begin after many years of the chronic infection phase. (c) HBeAg-negative chronic infection may follow seroconversion from HBeAg to anti-HBe antibody. It is characterized by very low or undetectable serum HBV DNA (virus) levels (<2,000 IU/mL) and normal aminotransferases, but still detectable levels of serum HBsAg. As a result of immunological control of the infection, this state confers a more favorable long-term outcome with a lower risk of cirrhosis or HCC. This phase was formerly called the “inactive carrier” stage. HBsAg loss and seroconversion to anti-HBs antibody may occur spontaneously, usually after several years with persistently undetectable HBV DNA. (d) HBeAg-negative chronic hepatitis may also follow seroconversion from HBeAg to anti-HBe antibody during phase 2. It is characterized by a pattern of fluctuating levels of HBV DNA and aminotransferases and active hepatitis. It is important but sometimes difficult to distinguish true inactive HBV carriers from

patients with active HBeAg-negative chronic hepatitis who, at the time of examination, are in a phase of short-term remission. (e) The HBsAg-negative phase. Low-level HBV replication may persist with detectable HBV DNA in the liver. It usually follows the HBe seroconversion phase. Generally, anti-HBc antibodies with or without anti-HBs are detectable. HBsAg loss, especially if it occurs before the age of 50, is associated with improvement of the long-term outcome with reduced risk of cirrhosis, hepatic decompensation, and HCC. This scenario is almost identical with the clearance of transient infections, since anti-HBs antibodies will help prevent virus rebound. As with clearance of transient infections, HBV DNA may still be detected in serum, though generally at very low titers (<10 IU/mL) and in the liver by the presence of low levels of cccDNA.[341,540] Also, as with transient infections, such infections may reactivate with immunosuppression. Moreover, these patients remain at elevated risk of developing HCC,[413] likely because extensive preneoplastic changes are already prevalent at the time of HBsAg loss.

	HBeAg-positive Chronic infection	HBeAg-positive Chronic hepatitis	HBeAg-negative Chronic infection	HBeAg-negative Chronic hepatitis
HBsAg	High	High/intermediate	Low	Intermediate
HBeAg	Positive	Positive	Negative	Negative
HBV DNA	>10E7 IU/mL	10E4-10E7 IU/mL	<2,000 IU/mL[**]	>2,000 IU/mL
ALT	Normal	Elevated	Normal	Elevated*
Liver disease	None/minimal	Moderate/severe	None	Moderate/severe
Old terminology	Immune tolerant	Immune reactive HBeAg positive	Inactive carrier	HBeAg negative Chronic hepatitis

B *Persistently or intermittently
**HBV-DNA levels can be between 2,000 and 20,00 IU/mL in some patients without signs of chronic hepatitis

FIGURE 18.17 Natural history of hepatitis. A: Following acute infection, approximately 95% of adults and 5% to 10% of newborns recover, while the remainder evolve toward chronic viral infection (see ref. 136). **B.** Depending on the vigor of the immune response, chronic infection can follow several phases including the HBeAg-positive chronic infection, HBeAg-positive chronic hepatitis, HBeAg-negative chronic infection, and HBeAg-negative chronic hepatitis phases (see ref. 127). These phases

may not be stable over time, and patients often evolve from one phase to the other. The major risk of chronic hepatitis is the evolution toward cirrhosis and hepatocellular carcinoma (Fig. **18.16**).

Variants and HBeAg-Negative Chronic Hepatitis B

Since HBV is under selective pressure from the immune system, HBV variants typically emerge over the course of a chronic infection.[172] These variants are assumed to facilitate immune evasion and have been detected throughout the viral genome. Because both B- and T-cell epitopes may be mutated, it is unclear if emergence of these variants occurs through virus spread or selective survival of hepatocytes infected by the mutants, or both. This issue is complicated by the fact that virus-free hepatocytes emerge even when there is abundant virus in the blood stream (such cells might still have integrated HBV DNA). In the setting of the natural history of the disease, the most studied of these mutants are those that no longer express HBeAg. These variants harbor mutations in the precore region and/or in the basal core promoter (Fig. 18.8). When these mutants become predominant, infections are characterized by the presence of HBsAg and undetectable HBeAg and may be associated either with chronic infection or, with chronic hepatitis[37,179] (Fig. 18.15D). Again, like HBeAg-positive hepatitis, HBeAg-negative chronic hepatitis B is associated with a high risk of liver fibrosis, cirrhosis, and HCC.[37,164,179]

Because of RNA folding constraints placed on the epsilon region of pgRNA (Fig. 18.12), pre-C stop codon mutations that abolish preC protein synthesis and hence, HBeAg production, would also inhibit virus replication in some HBV genotypes. This restricts their occurrence to HBV genotypes in which the mutations do not negatively impact epsilon folding and, therefore, virus replication, or by the requirement of compensatory mutations. In practice, these pre-C mutations are mainly observed in patients chronically infected with HBV genotype D.[294] Patients infected with other HBV genotypes may also present with HBeAg-negative chronic hepatitis B, in these cases mainly caused by mutations in the preC/C promoter.[378] Mutations in the preC/C promoter are not HBV genotype restricted.[164,307,387]

HBeAg Seroconversion

Seroconversion to anti-HBe antibody generally occurs during resolution of acute self-limited infections.[20,355,512] Moreover, as noted above, loss of HBeAg often occurs during the course of chronic infections, sometimes but not always with the concurrent appearance of anti-HBe antibodies. Loss of HBeAg from serum, even in the absence of anti-HBe antibodies, usually reflects a decline in the amount of virus in the liver. Thus, the loss of serum HBeAg in chronically infected individuals, either with or without the concomitant appearance of anti-HBeAg, may signal a major drop in virus titers and a reduction in disease activity as patients enter a remission phase. However, in other patients, it may be associated with an ongoing disease activity because it simply reflects immune selection for virus that has lost the capacity to produce HBeAg, or suppression of virus replication by antiviral cytokines. In either case, HBeAg seroconversion is an indication that virus production has either ceased or significantly declined.

Occult HBV Infections

Occult HBV infection (OBI) is defined as the presence of replication competent HBV DNA (i.e., HBV cccDNA) in the liver and/or HBV DNA in blood of persons testing negative for hepatitis B surface antigen (HBsAg) by currently available assays. Based on the HBV-specific antibody profiles, OBI may be categorized as: (a) Seropositive-OBI—anti-HBc and/or anti-HBs positive; (b) Seronegative-OBI—anti-HBc and anti-HBs negative.[413] Among individuals with OBI, prevalence of detectable HBV DNA in serum/plasma varies depending on the population studied, the sensitivity of the assay used, and whether blood samples at one or more time-points are tested. Many studies have found that HBV DNA is only intermittently detected, and with low concentration, usually less than 1000 virions/mL.[62,467]

In persons with seropositive-OBI, HBsAg may have become negative either following the resolution of acute hepatitis B, or after decades of HBsAg-positive chronic HBV infection with or without disease. It is unknown whether patients with chronic HBV infection/disease, who become HBsAg negative following Antiviral Therapy are immunologically comparable to patients who spontaneously clear HBsAg. Persons with seronegative-OBI, estimated to comprise between 1% and 20% of all OBI patients,[57,510] might have either progressively lost hepatitis B antibodies or have been hepatitis B antibody negative since the beginning of the infection. The latter condition has been described in the woodchuck model of occult WHV infection.[343]

A subset of individuals considered OBI are actually infected with HBV S variants carrying mutations in the S gene ("S-escape" mutations), resulting in the production of modified HBsAg that is not recognized by some commercially available HBsAg assays. Circulating HBV DNA levels in these patients may be comparable to those detected in HBsAg-positive individuals. Additional HBV variants with mutations in the S-gene promoter and splice variants have also been reported to affect HBsAg production/secretion and to be responsible for some cases of OBI.[131] There are still many unresolved issues regarding (a) the development of more sensitive, standardized, and validated assays for the detection of HBV DNA in blood and in liver and more sensitive assays for HBsAg to diagnose OBI, (b) the clinical and public health implications for the risk of transmission, liver disease progression, and development of HCC, (c) the recommendations for preventing HBV reactivation in persons with OBI.[413]

DIAGNOSIS

Differential

Diagnosis of Acute Hepatitis B

Acute hepatitis, which may occur during resolution of a transient infection, or during a hepatic flare in chronic infection, is diagnosed in patients with jaundice or fatigue and high ALT levels. Evidence of HBV involvement is obtained by the detection of HBsAg and anti-HBc IgM. Coinfection with HDV should be also checked since acute coinfection may lead to a more severe course of acute hepatitis. However, other infectious agents need to be considered as causes of a *de novo* flare of liver disease activity, including HCV, HAV, and hepatitis E virus (HEV), and rare cases of acute viral hepatitis caused by herpes simplex virus, cytomegalovirus, or parvovirus

infections. These other agents are also potential causes of a hepatic flare in HBV carriers experiencing an unexpected exacerbation of liver disease. If all factors suggest involvement of HBV alone, transient infection is indicated by disappearance of HBsAg in the weeks immediately following the flare of acute liver disease, followed by resolution of the infection (Fig. 18.15A). In contrast, a "spontaneous" acute flare of disease activity during a chronic HBV infection can be preceded by months of high titer viremia but little or no overt liver disease. These flares are typically due to changing HBV/immune system interactions, not to superinfections.

Diagnosis of Chronic Hepatitis B

Chronic HBV infections are usually asymptomatic for most of their course. The diagnosis of chronic hepatitis B is usually made by the detection of serum HBsAg for greater than 6 months and possibly by elevation in ALT levels (Fig. 18.15B-D).[126,312] Nausea, loss of appetite, and jaundice may occur during acute hepatic flares in chronic hepatitis B. However, a hepatic flare may be completely asymptomatic and diagnosed only by a close monitoring of HBV DNA and ALT levels in the serum. HBcAg is highly immunogenic and the appearance in the circulation of anti-HBc IgM is usually the first immunological sign of a transient HBV infection. Typical serological profiles of HBV infections are shown in Figures 18.15 and 18.17.

Laboratory

Assays

The most rigorous way of determining the presence of circulating HBV is to assay for viral DNA. The lower threshold for risk of active hepatitis and liver damage is considered to be around 10^4 viral genome equivalent per mL of serum, equivalent to approximately 2,000 IU/mL.[58,92,126,308] Figure 18.17 shows the evolution of viral load during the natural history of infection and underlines the necessity of highly sensitive and quantitative assays to monitor viral load in the different phases of the disease. In patients who have lost HBsAg from serum and may have an occult infection, virus titers are usually very low and therefore can escape detection even by PCR-based assays.[413]

The development of quantitative assays for HBsAg detection revealed that chronically infected patients as well as those at the peak of a transient infection can have HBsAg titers of greater than 10^{12} particles per mL, or greater than 500 μg of protein per mL.[370,586] Clinical assays can detect as little as 0.2 ng (or 0.05 IU/mL) of HBsAg per mL of serum, providing a highly sensitive assay for HBV infection. HBsAg levels in serum were found to correlate with HBV DNA levels during transient infections, but this correlation breaks down during the course of a chronic infection.[219,364] This may be due in part to expression of HBsAg from integrated HBV DNA, especially in patients with longer duration of infection in the HBeAg-negative phase (Fig. 18.15D). In fact, RNAseq analysis of liver tissue from HBV-infected chimpanzee showed that in contrast to HBeAg-positive animals, in HBeAg-negative chimpanzees, most viral transcripts were truncated at their 3′ end because of HBV DNA integration. This suggests that in the HBeAg-negative chronic infection phase, HBsAg is mainly expressed from integrated DNA, rather than from cccDNA.[550]

A number of secondary assays for HBV infection are available. IgG reactive to HBcAg is a marker of past or ongoing infection and is therefore found in both resolved infections and in chronically infected individuals. Anti-HBc IgM is typically found during transient infections and may be detected, at low levels, during acute exacerbation of chronic infections[178,394,586] (see Fig. 18.15). HBeAg is found in the blood of transiently infected individuals as well as in chronically infected individuals with high virus titers (that is, HBeAg-positive chronic infection and HBeAg-positive chronic hepatitis phases.[127]

Finally, sensitive real-time PCR assays for quantification of viral DNA in serum are available with a cut off as low as approximately 30 to 50 viral genome copies per mL, or approximately 10 IU/mL.[86,502] The combination of serological markers including quantification of HBsAg and HBV DNA in serum has improved the diagnosis of inactive carriers, which usually have a low viral load (HBsAg < 1,000 IU/mL and HBV DNA < 2,000 IU/mL).[46] In patients who have lost HBsAg in serum after resolution of a transient infection or during the course of chronic HBV infection (i.e., who are HBsAg (−) and anti-HBc Ab (+), either with or without anti-HBs Ab), detection of serum HBV DNA by sensitive PCR assays may reflect the persistence of infected hepatocytes after the clinical resolution of the disease[413] (Fig. 18.17).

As noted above, significant amounts of HBsAg may be produced from both integrated HBV DNA and cccDNA during chronic infection. Thus, HBsAg measurements do not provide a useful measure of the amount of transcriptionally active cccDNA in the liver.[550] In particular, assays are required to predict functional cure characterized by the loss of HBsAg and/or cccDNA and/or transcriptional inactivation of cccDNA (Fig. 18.15E).[77,499] This has prompted the development of new assays and biomarkers to better quantify transcriptionally active cccDNA and/or the number of infected hepatocytes harboring transcriptionally active cccDNA. To date, the most advanced biomarkers are hepatitis B virus core-related antigen (HBcrAg) and viral RNAs circulating in the blood stream.

HBcrAg

HBcrAg is a composite biomarker that comprises HBcAg, HBeAg, and a 22 kDa truncated core-related protein (p22cr). p22cr is an aberrantly processed PreCore protein containing the entire PreC region including the intact signal peptide but lacking the C-terminal arginine-rich domain described earlier in this chapter (Fig. 18.6).[244] The three proteins share a common sequence of 149 amino acids forming a linear epitope that can be recognized by a monoclonal antibody after denaturation. A pretreatment is required to release all core-related antigens from immune complexes or enveloped particles because the assay can detect all capsid-containing particles (HBcAg), either virions or free capsids, p22cr-related particles and secreted HBeAg. Unlike HBsAg, HBcrAg quantification should not be influenced by translation from integrated viral sequences, which generally lack the upstream core promoter, and hence could be a more accurate surrogate marker to quantify transcriptional cccDNA. In some patients, a correlation could be established between HBcrAg levels and intrahepatic amount of cccDNA, cccDNA transcriptional activity, fibrosis, and necroinflammatory activity scores.[500] However, improvement of the sensitivity of this test will be required prior to its use in evaluating novel antiviral compounds under clinical development.[500] For this and other reasons, the HBcrAg assay is not yet approved by the FDA and has not received CE-certification, although it has been available as a fully automated quantitative assay in Japan since 2014 and as a research tool on other parts of the

world.

Serum Viral RNA

HBV RNAs can be detected in the serum of patients at levels ranging between 0.1% to 1% of HBV DNA levels in the absence of antiviral treatment.[56,521,531] Circulating HBV RNA was initially observed in a form of HBV DNA-RNA hybrid molecules.[345] Circulating polyadenylated HBV RNAs in sera of HBV-infected patients could be detected with rapid amplification of complementary DNA (cDNA)-ends (RACE).[250] The current (unproven) view is that serum viral RNAs mainly circulate as viral particles containing pgRNAs, and thus, they may represent a biomarker of the pool of transcriptionally active cccDNA.[77] Assays to quantify pgRNA in serum are being developed by diagnostics companies.

PREVENTION AND CONTROL

Treatment

General Considerations

Historically, clinical guidelines recommend against antiviral treatment during the HBeAg-positive chronic infection phase because patients have only minimal liver disease (inflammation and/or fibrosis) detectable by histologic examination of liver biopsies.[126,312] Also, the results of therapeutic trials with IFN-α, or with early nucleos(t)ide analogue (NUC) inhibitors of the viral DNA polymerase, showed that patients with high HBV DNA load and normal ALT levels have almost no chance of HBe seroconversion or sustained virologic response as a result of treatment[126,312]; that is, the infection rebounds when treatment is withdrawn. Whether inapparent liver injury that occurs in the HBeAg-positive chronic infection phase contributes to disease progression and, in particular HCC is not known.[241,338] Thus, new clinical guidelines have expanded treatment indications in these patients to those who have a clinically detectable higher risk of disease progression, that is, family history of HCC or cirrhosis, or if they have extrahepatic manifestations.[127,498] It is expected that treatment guidelines will continue to evolve as more data become available about HBeAg-positive chronic infection, and new antiviral drugs with better efficacy are evaluated in clinical studies.

So far, Antiviral Therapy is recommended primarily for patients with active liver disease who have a significant risk of liver disease progression in the short term, and not for patients that do not have elevated ALTs and/or histologic evidence of inflammatory liver disease.[126,312] These included (a) patients with ALTs above the upper limit of normal, virus titers greater than 2,000 IU/mL and moderate necroinflammation and fibrosis, (b) patients with virus titers greater than 20,000 IU/mL and ALTs greater than two times the upper limit for normal, irrespective of histologic assessment, and (c) patients with cirrhosis (but with NUCs, not interferon, which may cause liver failure in patients with diminished liver reserve due to the cirrhosis). Newer guidelines also include considering treatment for all patients older than 30.[127] To a certain extent,

the earlier decision not to treat asymptomatic patients was due the fact that antiviral resistance developed rapidly to NUCs such as lamivudine, which has not been a major problem with the newer NUCs such as entecavir and tenofovir (Fig. 18.11). For this reason, entecavir and tenofovir are now the only NUCs that are recommended as a first-line therapy. In patients with previous exposure to lamivudine, tenofovir is recommended while entecavir is not because of cross-resistance between lamivudine and entecavir. Entecavir at higher dosage could be used in case of previous lamivudine failure but is not the preferred option in that situation.

Irrespective of the possible benefits of starting Antiviral Therapy earlier, there are major reasons for not delaying therapy once active liver disease is diagnosed: if HBV replication and elevation of ALT levels are ongoing, there is a proven risk of progression to cirrhosis and hepatocellular carcinoma (Fig. 18.16).[300,419,558,571] Antiviral Therapy, particularly with NUCs, decrease viral load, normalize ALT levels, induce a remission of the disease,[589] and reduce the progression of cirrhosis and HCC.[78,212,300] A possible reason for starting antiviral treatment earlier is that treatment according to current guidelines reduces but does not eliminate the HCC risk; whether or not earlier treatment would reduce the HCC risk further is not yet known.

With the use of the current generation of antiviral drugs within the treatment guidelines, Antiviral Therapy may lead to HBeAg-seroconversion, long-term viral suppression/control, and off-treatment control by the immune system, especially in patients in the HBeAg-positive chronic hepatitis phase (e.g., ~20% to 30% vs. a spontaneous rate of ~5%[92,566]). A decrease in virus load is usually associated with the appearance of anti-HBe antibodies. HBsAg usually remains at high levels in the serum. Liver histology usually reveals remission of liver disease activity, and arrest or reversal of fibrosis/cirrhosis progression as long as viral load remains low and ALT levels remain normal[76,120] (Fig. 18.15E).

IFN-α or NUC therapy-induced HBV DNA reduction below 2,000 IU/mL is associated with disease remission. Sustained virus suppression increases the chance of HBe seroconversion in HBeAg-positive patients and the additional possibility of HBsAg loss in both HBeAg-positive and HBeAg-negative patients.[127] The most reliable indication that therapy can be terminated is a confirmed loss of HBsAg,[98] while the development of anti-HBsAb does not seem to be required to achieve a sustained HBsAg loss, also called “functional cure” (Fig. 18.15E).

Interferon (IFN) Therapy

The principle immunological treatment for hepatitis B is IFN-α, which has been used since the 1980s. Although IFN-α has a direct antiviral effect, suppressing HBV replication, its major effect is considered immunologic, inducing, and/or abetting a hepatic flare that resolves the infection and establishes immunologic control that prevents virus rebound. This treatment only has lasting effects in patients with immunologically active liver disease, augmenting an already active host response against the virus.

In HBeAg-positive chronic hepatitis B, treatment with standard IFN-α or its pegylated form can lead to HBeAg seroconversion, loss of viral DNA, and clinical remission in approximately 20% to 30% of patients.[217,273,369,548] Clinical benefit appears to be long term in these responding patients, including a decreased risk of progression to cirrhosis and hepatocellular carcinoma. HBsAg loss may occur several years after treatment cessation. However, IFN-α treatment is not particularly well tolerated, provoking a “flu-like” syndrome in many individuals. In addition, IFN-α needs to be injected subcutaneously every week for the pegylated form for 12 months and

thus causes additional discomfort to the patient. It is however the only medication which can be administered with a finite duration. Attempts to combine IFN-α and NUCs with different schedules of administration (combination, sequential administration) did not show any significant clinical advantage compared to monotherapies in most clinical trials. Such combinations are thus not recommended by current practice guidelines.[3,127,498]

In patients with end-stage cirrhosis and little liver reserve, IFN-α treatment is not recommended because it increases the risk of liver failure due to immune killing of the remaining functional hepatocytes and because of the increased risk of bacterial infections. In contrast, NUC therapy can benefit these patients, with control of viral replication, accompanied by significant improved liver functions.[301,302]

One group reported a direct effect of high doses of IFN-α or activation of the lymphotoxin β receptor, with a super-agonistic antibody, in reducing the stability of cccDNA in HepaRG cells and primary human hepatocyte cultures by a mechanism involving APOBEC3A and 3B-mediated cytidine deamination.[315,553] However, other laboratories could not validate the original observation (i.e., Refs.[356,513]). In contrast, identification of G to A transitions in viral DNA isolated from sera of chronically infected HBV patients provided strong evidence for deamination of cytosine residues in particular in the region of the genome that is single stranded, consistent with the known substrate preference of APOBEC enzymes.[489] However, the frequency of hypermutated genomes is generally low and most likely insignificant for HBV persistence in infected patients.[24] The highest frequencies have been reported from patients with advanced cirrhosis in the presence of high cytokine levels.[524] IFN-a was also shown to modify cccDNA-associated chromatin and to induce repressive epigenetic marks leading to decreased transcriptional activity both in cultured hepatocytes and liver humanized mouse models.[25]

Nucleoside Analogue (NUC) Therapy

To date, FDA-approved NUCs belong to one of three structural groups: L-nucleosides (lamivudine and telbivudine), alkyl phosphonates (adefovir dipivoxil and tenofovir disoproxil fumarate, and the prodrugs of tenofovir, tenofovir alafenamide), and D-cyclopentanes (entecavir).[3,127,498] NUC therapy represents the primary choice for treatment of chronic HBV. The effect of treatment with inhibitors of viral DNA synthesis is to stop viral DNA replication within hepatocytes and prevent release of infectious particles into the bloodstream. The half-life of circulating virus particles is relatively short, around 24 hours, and the decline in virus titers predictable.[375] The half-life of DNA replication intermediates has not been studied in great detail but is probably a few days. However, the rate of loss of cccDNA that maintains the hepatocyte infections is much slower, with a half-life in the liver of a few days to several months according to the strength of the host immune response. Therefore, NUC therapies necessitate long-term treatment.[375,514,540] cccDNA loss is believed to reflect, primarily, the death of infected hepatocytes rather than intracellular instability, at least in the context of chronic infections.[584] Hence, NUCs that inhibit HBV DNA synthesis inhibit the replacement of cccDNA as some infected hepatocytes die and others proliferate to maintain liver cell number.[584] A key question is if cccDNA survives when hepatocytes divide, or if it is lost at mitosis. This question remains unresolved, with evidence for[584] and against[6] survival *in vivo*. One possible explanation of the claim of survival during NUC therapy, as yet unresolved, is that cccDNA is lost at mitosis but is replaced by cytoplasmic DNA replication intermediates that are produced at low levels during

NUC therapy, particularly during S-phase.[418] Results of mathematical modeling based on cccDNA monitoring of NUC suppressed patients suggest that new rounds of infection may occur during NUC therapy despite clinically efficient viral suppression.[39]

In liver transplant recipients with HBV recurrence in the liver graft, IFN-a is contra-indicated because of the risk of inducing liver graft rejection. Both tenofovir and entecavir have shown a clinical benefit that seems to be superior to that obtained with earlier NUCs.[93,393,439] The prevention of HBV recurrence after transplantation relies nowadays on pretransplantation Antiviral Therapy with NUCs to decrease viral load, and post-transplant hepatitis B immune globulin (HBIG) and NUC administration to prevent HBV recurrence. With such prophylactic protocols, the risk of HBV recurrence defined by HBsAg positivity after transplantation has decreased from 20% to 30% to below 5%.

The optimal NUCs are tenofovir and entecavir, to which resistance rarely if ever develops in treatment naive patients[75,464] (that is, patients that have not developed resistance to early NUCs, which can increase the risk of developing resistance to subsequent NUC therapies). Treatment with these drugs with a high barrier of resistance in patients over 30, as with early NUCs, prevents or reduces significantly the development of fibrosis and cirrhosis but does not eliminate the risk of HCC. Because of the limited systematic studies in patients less than 30, it is unclear if additional benefits would accrue if treatment was started much earlier, particularly in patients still in the HBeAg-positive chronic infection phase.[241] Overall, the rate of HBsAg loss that would allow treatment cessation is very low, that is, approximately 10% of patients in selected cohorts.[98]

Drugs in Clinical Development

With a better knowledge of the viral life cycle and the improvement of experimental study models, it has been possible to characterize viral and immune targets to develop new drugs with the aim of achieving higher rates of functional cure with finite duration treatments. A number of drugs are being evaluated in preclinical models or early phases of clinical development (Phase 1b and Phase 2 clinical trials). The main targets and drug classes are posted on https://www.hepb.org/treatment-and-management/drug-watch/.

Direct-acting antivirals include viral entry inhibitors, strategies targeting cccDNA (by either elimination or transcriptional silencing), agents targeting viral RNAs (siRNAs, antisense oligonucleotides, and locked nucleic acids), core allosteric modulators (CAM), and inhibitors of HBsAg release, namely nucleic acid polymers. Immune-based strategies under evaluation include (a) boosters of innate immunity: TLR-7, TLR-8, and RIG-I agonists, (b) check-point inhibitors: PD1 and PDL1 blockers, and (c) specific immune stimulation by therapeutic vaccines. All these strategies are being evaluated in combination with NUCs in Phase 1b and Phase 2a studies.

Currently, it is believed that a combination of strategies blocking viral replication in addition to decreasing HBsAg expression will be needed for efficient therapeutic vaccination. It is not yet known what will be the position of innate immunity boosters and checkpoint inhibitors in these strategies. Several trials are evaluating triple combinations of NUCs with capsid inhibitors and TLR7 agonists, or NUCs with capsid inhibitors and siRNA.

With respect to chronic HBV/HDV infections for which only peg-IFN is recommended by

international societies, several drugs are in clinical evaluation and entering phase 3 clinical trials: (a) myrcludex-B, an entry inhibitor, that works on both HBV and HDV; it showed significant drop in serum HDV RNA and ALT improvement either in monotherapy or in combination with peg-IFN, the latter showing faster and deeper declines in HDV titers; (b) lonafarnib, a prenylation inhibitor preventing the assembly and release of HDV, which is being developed in combination with peg-IFN, with the need for ritonavir to boost its metabolism and decrease side effects; and (c) nucleic acid polymers to inhibit HBsAg release, also in combination with peg-IFN.

Vaccines

Based on the difficulties in treating chronic HBV infection, including high cost, the emergence of drug-resistant mutants, and the risk of development of HCC, the efficacy of vaccine prevention is a strong incentive for mass vaccination programs worldwide.[339] At the end of 2018, hepatitis B vaccine for infants had been introduced nationwide in 189 countries. Global coverage with 3 doses of hepatitis B vaccine is estimated at 84% and is as high as 90% in the Western Pacific. In addition, 109 countries introduced one dose of hepatitis B vaccine to newborns within the first 24 hours of life, and the global coverage is 42% (http://www.who.int/mediacentre/factsheets/fs378/en/). This will contribute to a reduction in HBV incidence but more effective neonatal vaccination will be required for HBV elimination. The UN 2030 Agenda for Sustainable Development includes "combat hepatitis" within one of its goals. In May 2016, the Global Health Sector Strategy on Viral Hepatitis set targets for 2020 and 2030: to reduce new cases of chronic HBV infection by 30% by 2020, which is equivalent to HBsAg prevalence of 1% among children aged 5 years, and to achieve 0.1% prevalence of HBV infection in children aged 5 years by 2030 (https://www.who.int/immunization/sage/Guidelines_development_recommendations.pdf?ua=1).

Similar goals have been formulated by the WHO (https://www.who.int/hepatitis/topics/hepatitis-b/en/).

Vaccines containing S alone have been produced historically by processing of HBsAg purified from plasma of HBV carriers. It is now produced from the yeast *Saccharomyces cerevisiae* expressing S from recombinant DNA. The vaccine contains the immunodominant "a" determinant of HBsAg in S. New formulations of vaccines are now available in hexavalent form to protect from multiple pathogens. A recent variant of the HBV vaccine includes a Toll-like receptor 9 agonist.[440] Vaccines are administered in the deltoid muscle and are highly immunogenic, inducing a protective anti-HBs antibody titer (>10 IU/mL) in more than 95% of children or young adults usually with a three-dose schedule.[8,275,523] About 5% of those vaccinated fail to respond with development of antibodies to the vaccine. Several factors seem responsible, including genetically determined nonresponsiveness, age over 40 years, high body mass index, and immunosuppression.[8,275,523] In immune suppressed patients, a schedule with 4 administrations is recommended (Day 0, months 1 and 2, and booster at month 12). Vaccination is associated with rare side effects, most commonly pain or soreness at the injection site. Neurological disorders such as multiple sclerosis, Guillain-Barré syndrome, and transverse myelitis have not been causally linked to the HBV vaccine.[12,96] A new recombinant hepatitis B vaccine with a CpG DNA adjuvant acting as a TLR9 agonist (Heplisav-B) has been recently approved by the FDA and EMA with a two-dose schedule increasing the rate of seroprotection.

Vaccine escape mutants have been reported in follow-up studies of individuals receiving HBsAg vaccines composed of the S protein. Vaccinated individuals typically mount a very strong antibody response to the immunodominant “a” determinant (Fig. 18.10) located in the exposed hydrophilic domain of S between amino acids 99 and 168.[129,397,475] The “a” determinant itself has been mapped from amino acids 124 to 147,[13,29,44,406,536] though some authors have extended the domain a few amino acids upstream and/or downstream. Two loops bounded by disulfide bridges are inferred by some authors to exist between cys124 and cys137, and cys139 and cys147, but other pairings have also been suggested.[83] The “a” determinant is highly conserved and is found in all genotypes of HBV.[374] Vaccine escape represents a distinct phenomenon, in which a vaccinated individual develops chronic HBV infection and is seropositive for HBsAg despite the presence of antibodies to the group-specific “a” determinant of HBsAg that were induced by the vaccine. This is possible because HBsAg present in the serum of these patients lacks the group-specific “a” determinant, generally as a result of missense mutations in the region of S that encodes amino acids 124 to 147 (Fig. 18.11).

Most studies of vaccine escape have involved at-risk children and infants who were either vaccinated or received vaccine plus HBIG, which is strongly reactive to the “a” determinant of HBsAg. For instance, in the 1980s, a follow-up study of childhood vaccination in Italy revealed vaccinees who became HBsAg positive despite the presence of a strong antibody response to HBsAg. The incidence was rare, involving about 2% of the children of HBsAg-positive mothers, or with HBsAg-positive family contacts.[65,573] More detailed analysis of virus from one patient revealed a point mutation encoding a gly145arg substitution at amino acid 145 of the S protein.[65] Analysis with monoclonal antibodies to the “a” determinant of wild-type HBV revealed a loss of binding to the mutant HBsAg.[65,537] Subsequent studies in other populations with high HBV endemicity confirmed the rare occurrence of vaccine escape mutants in children, including the glyc145arg substitution in “a,” other substitutions or insertions in “a,” and mutations within the external hydrophilic domain, but outside of “a”.[66,143,199,208,238,280,377,379,380,555] Vaccine escape variants have also been detected in unvaccinated children and adults with circulating virus as well as anti-HBs,[199,555] possibly reflecting past or concurrent infection with wild-type and mutant virus. One concern was that these mutant viruses may become an increasing fraction of the pool of HBV carriers and an increasing risk for vaccinated individuals,[199] but recent studies and clinical field experience suggest that this scenario may not be correct.[200] However, a systematic molecular survey performed in China observed that newly selected mutations outside the major hydrophilic region but associated with changing antigenicity, such as lys21ser and lys98val, circulated among younger Chinese patients that had received neonatal HBV vaccination,[532] thus arguing for a continuous monitoring of HBV vaccine escape mutants in highly endemic areas where widescale vaccination is ongoing.

PERSPECTIVE

HBV biology is multifaceted and touches upon many areas in the basic and clinical sciences. Among them are liver biology, immunology, virology, and Antiviral Therapy. During the past three decades, we have witnessed major progress in all areas. Investigations on viral DNA

replication have uncovered the mechanism for HBV persistence in the infected liver, which is based on continuous rounds of cccDNA amplification. Studies in animal models have provided insights into the course of natural infections and into the process of viral clearance. The revelations that clearance depends on a strong cytotoxic T-cell response that can eliminate infected hepatocyte and that hepatocytes may comprise a closed cell population may explain why current nucleoside-based antiviral therapies can attenuate, but not cure chronic HBV infections.

In spite of the great progress, many gaps in knowledge remain to be filled. The mechanisms for the disassembly of viral capsids, delivery of the genome into the cell nucleus, and formations of cccDNA need to be clarified in much greater detail. Although the role of X protein in maintaining transcriptionally active cccDNA is now known, we still do not know how or if X directly impacts other aspects of hepatocyte biology, including oncogenic transformation. Indeed the role of HBV in HCC emergence is still mostly a matter of speculation. While antiviral therapies can attenuate virus replication and disease progression, the development of a cure may require a much better understanding of the immune response against HBV and the ability to therapeutically augment that response to permanently suppress HBV replication. Moreover, the role of cytokines in the resolution of acute and progression of chronic infections needs to be better understood. These and other questions will have to be addressed to complete the picture of HBV biology that has come only partially into focus over the past forty years.

HISTORY

The first evidence of hepatitis delta virus (HDV) in humans was reported in 1977 by Mario Rizzetto, a resolute gastroenterologist at the University of Turin, Italy, who was caring for patients suffering from chronic hepatitis related to hepatitis B virus (HBV) infection.[146] Using simple techniques of immunohistochemistry for examination of liver biopsies, Rizzetto and colleagues observed that a serum positive for antibodies directed to the HBV core antigen (HBcAg) reacted with liver specimens positive for HBV surface antigen (HBsAg), which had been previously documented as negative for HBcAg. It was initially thought to be a new HBV antigen but was subsequently proven distinct from the known HBsAg, HBcAg, or HBV e antigen (HBeAg), and given the name of delta antigen, now referred to as hepatitis delta antigen (HDAg). The new antigen was present only in liver cell nuclei of HBsAg carriers, but its staining and that of HBcAg in liver biopsy specimens were mutually exclusive. HDAg was detected neither in HBsAg-negative patients suffering from chronic hepatitis nor in patients with self-limited acute hepatitis B or asymptomatic HBV carriers. Soon thereafter, the HDAg-bearing protein was found associated with a small RNA as internal elements of a virus-like particle coated with the HBV envelope proteins.[148] The viral particle was proven transmissible in the chimpanzee model but only in the presence of HBV coinfection.[147] In 1986, the cloning and sequencing of the HDAg-associated RNA, now known as HDV RNA, unveiled the uniqueness of this entity among animal virus genomes known at the time,[181] but it also revealed structural features typical of some plant subviral agents called viroids, suggesting an evolutionary relationship.[54] The circular single-stranded HDV RNA was the smallest among known mammalian viral genomes, and its sequence presented no homology with that of the helper HBV. Overall, the characteristics of the delta agent did not fulfill the criteria for the definition of a virus, but it was nonetheless referred to as HDV.

As early as 1980, an assay was developed for serological detection of anti-HDAg antibodies,[151] which revealed a high prevalence of HDV infection among polytransfused HBsAg carriers and intravenous drug addicts.[150] HDV infection was first documented as highly endemic in the south part of Italy and then in several South American countries.[144] HDV infection was often associated with the most severe form of acute and chronic hepatitis, in particular among indigenous populations in Ecuador and Venezuela.[26,117,164] To date, chronic hepatitis D (CHD) is not only one the most severe liver diseases in humans, but one of the most difficult to treat. There is no curative therapy for HDV infection and no HDV-specific vaccine available, but HDV infection can be prevented upon HBV vaccination of individuals who are not already HBV infected.

CLASSIFICATION

According to the Baltimore classification system, the HDV RNA genome is a single-stranded RNA (ssRNA) of negative polarity. However, unlike other RNA viruses, the genome does not encode an RNA polymerase. HDV is currently assigned to the *Deltavirus* genus.[116] The origin of HDV RNA has been subject to different evolutionary theories. As an obligate satellite of HBV, it was initially speculated to have evolved—or coevolved with HBV—in humans. One hypothesis was that ribozyme originated from introns in the human cytoplasmic polyadenylation element–

binding protein 3 gene, and the HDAg coding sequence from that of a cell protein ancestor.[21,158] Another hypothesis proposed that HDV RNA derived from host circular RNAs or from plant viroids, or virusoids.[175]

These speculations should now be reconsidered in light of the recent discovery of several HDV-like RNAs in species very distant to humans. A first HDV-like RNA has been identified in ducks, which shares with its human counterpart many features such as circular conformation, self-complementarity, the presence of putative ribozymes, and a coding capacity for a protein whose sequence displays 32% similarity to that of the HDAg protein.[186] Another HDV-like RNA was identified in two specimens of the *Boa constrictor* species that were affected with central nervous system disorder.[73] It was detected in two offspring and in a water python (*Liasis mackloti savuensis*) of the same snake colony, suggesting transmission. More HDV-like RNAs have since been described in the newt, toad, fish, and termite.[30] For none of the above did the corresponding transcriptomes contain HBV-like sequences. Although identifiable avian viral sequences were identified in the duck transcriptome, there is currently no proof that the HDV-like RNAs are genomes of virus satellites. Now that HDV-like agents have been discovered in species very distant to humans, it is likely that a common ancestor with HDV arose early in the history of the Metazoa, therefore long before the appearance of HDV in humans.[30,79]

VIRION STRUCTURE

Upon electron microscopy examination of negatively stained preparations, the HDV virion appears (Fig. 19.1) as a spherical particle with an average diameter of 36 nm.[17,64,70] By ultracentrifugation in CsCl gradient, its buoyant density is at 1.24 to 1.25 g/cm^3.[148,169] The virion displays a chimeric architecture consisting of an outer coat of HBV envelope proteins, and an inner ribonucleoprotein (RNP) made of HDV-specific elements, that is, the genomic HDV RNA and multiple copies of HDAg proteins.[17,70,148] The viral envelope is identical to that of HBV subviral particles (SVPs) in including cell-derived lipids associated with HBV envelope proteins,[170] but there is no indication that lipids are organized as a bilayer. Assuming a surface density identical to that of SVPs, an HDV virion would bear approximately 100 copies of envelope proteins.[95] Electron microscopy images of the RNP revealed a spherical, core-like structure of approximately 20 nm in diameter, but no evidence of icosahedral symmetry. The three types of HBV envelope proteins that are typically produced in huge amounts by HBV-infected cells, and exported for the most part as SVPs, are present in the HDV envelope. All three bear the HBsAg and are designated small (S-HBsAg), middle (M-HBsAg), and large (L-HBsAg) proteins.[22] It was initially reported that S-, M-, and L-HBsAg were present at a ratio of 95:5:1, respectively, at the surface of HDV, as opposed to a 4:1:1 in the envelope of HBV virion.[16] Yet, considering that HDV particles can be assembled *in vitro* with S-HBsAg only,[180] it is likely that this ratio be very heterogeneous. In addition to providing HDV with an export system, the HBV envelope proteins confer an efficient protection of the RNP and stability of the virion in the extracellular space since HDV can survive after 30 hours at 60°C.[91] Obviously, there is a need for more detailed information on the 3D structure of the HDV virion, in particular with regard to the inner RNP.

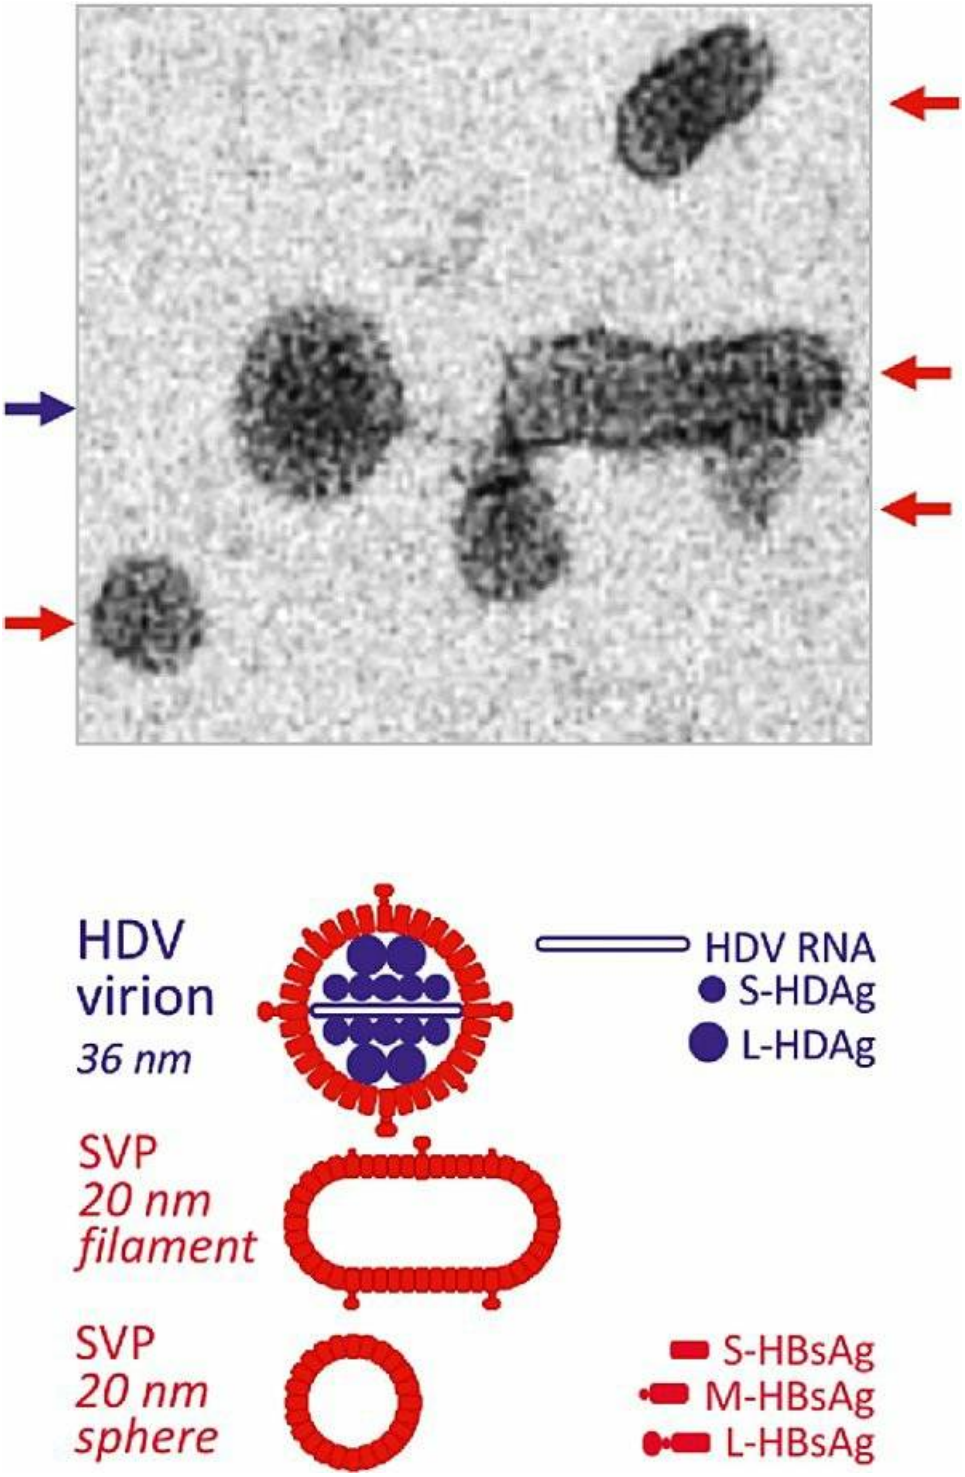

FIGURE 19.1 The HDV virion. Top panel: View of HDV virion by electron microscopy. (Modified with permission from Gudima S, He Y, Meier A, et al. Assembly of hepatitis delta virus: particle characterization, including the ability to infect primary human hepatocytes. *J Virol* 2007;81(7):3608-3617.) *Blue arrow* indicates HDV virion; *red arrows* indicate HBV subviral particles (SVPs). **Bottom panel:** Schematic representation of the HDV virion and HBV SVPs. The HDV virion

consists of two types of components: (a) the viral envelope of HBV origin (in *red*), including the HBV envelope proteins S-HBsAg, M-HBsAg, and L-HBsAg and (b) the ribonucleoprotein (RNP) (in *blue*) that consists of the circular genomic HDV RNA associated to multiple copies of the HDV-encoded S- and L-HDAg proteins.

GENOME STRUCTURE AND ORGANIZATION

The HDV genome is a circular, ssRNA of approximately 1,700 nucleotides in size (Fig. 19.2) and the smallest among the known mammalian viral genomes.[181] It is present in abundance in cell nuclei, along with its replication intermediate, and exact complementary, the antigenomic RNA. Both RNA strands adopt a quasi-double-stranded conformation, also referred to as rod-like structure, by self-annealing with 74% of their nucleotides; 60% of which are G or C. The unbranched rod includes interspersed double-stranded helical segments and internal loops and bulges. Genome and antigenome contain an 85-nucleotide in length ribozyme structure for self-cleavage activity. Circular conformation, self-annealing capacity, and the presence of ribozymes are characteristics of plant viroids and essential to replication.[174]

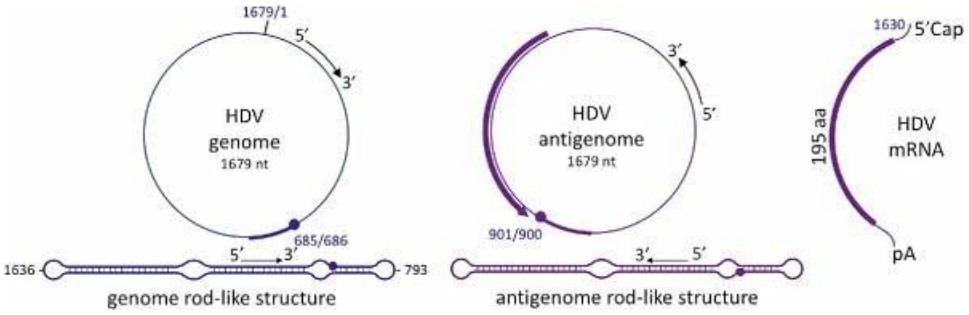

FIGURE 19.2 Representation of HDV RNA species in HDV-infected cells. Genome and antigenome are circular single-stranded RNA. Both can fold into unbranched rod-like structures. Each HDV RNA strand contains a ribozyme sequence for self-cleavage (closed *circle*) at position 685/686 in the genomic strand and 901/900 in antigenomic strand. *Arrows* on the RNA strands indicate the 5′ to 3′ direction. The mRNA, of antigenomic polarity, contains the open reading frame for HDAg protein (*thick purple line*).

The genetic organization of the HDV genome includes several open reading frames (ORFs), but only one, present in the antigenomic strand, is known to be translated into a protein, (HDAg). HDV is thus a negative sense RNA virus. The HDAg protein is produced as two isoforms referred to as small-HDAg protein (S-HDAg) of 195 amino acids in length, and large-HDAg (L-HDAg) that differs from S-HDAg by 19 or 20 additional amino acid residues at the carboxyl terminus.

The rod-like structure of HDV RNA can be schematically divided in two distinct domains: a "ribozyme domain" with a high degree of sequence conservation between genotypes and a larger "coding domain" that includes the HDAg ORF sequence and its complementary strand in the rod-like conformation.

REPLICATION

In Vitro Experimental Models

The study of HBV and HDV has long been impeded in the absence of an efficient tissue culture system able to sustain chronic infection. This is due, in part, to the very narrow tropism of these viruses for the human liver and to the difficulties in recapitulating human hepatocyte differentiation *in vitro*. The first *in vitro* models for HBV and HDV were based on human hepatoma cell lines, such as HepG2 and Huh-7, that are fully permissive to replication and production of infectious particles but not susceptible to infection for lack of entry factors expression. Until 2002, the early steps of HBV infection could only be observed *in vitro* using primary cultures of chimpanzee or human hepatocytes.[60,168] Then, Gripon and colleagues isolated a HBV-susceptible cell line—HepaRG—that was amenable to direct infection with HBV[61] and HDV.[83] This technical breakthrough opened the way to the exploration of the viral entry mechanism and to the screening of antivirals directed to the early steps of infection. Nonetheless, for a yet unexplained reason, the HepaRG cells do not sustain chronic infection, that is, simultaneous susceptibility and permissivity. As a result, in standard laboratory practices, permissive Huh-7 or HepG2 cell lines have been used for analysis of replication and virus assembly, and HepaRG cells for the study of HBV/HDV entry.[170] Then in 2012, the landmark discovery by Yan and colleagues[195] that the human sodium taurocholate cotransporting polypeptide (hNTCP), a bile acid transporter expressed at the basolateral membrane of hepatocytes, acted as a liver-specific receptor for HBV and HDV was a long-awaited information for the HBV/HDV research field. From that point on, hNTCP-expressing cell lines could be created that were amenable to high-throughput screening approaches aimed at identifying novel host factors involved in viral entry or new antiviral drugs.[82,163,179] As a result, the entire replication cycle of HDV could be recapitulated by generating cell lines that constitutively express HBV envelope proteins, the hNTCP receptor, and antigenomic RNAs from an integrated copy of HDV cDNA.[100,128]

Mechanism of Attachment

For both HBV and HDV, hepatotropism is, for the most part, governed by the HBV envelope proteins activity at viral entry, and, as a result, the two viruses engage identical cellular entry factors at the initial step of attachment and subsequent binding to high-affinity receptor(s). This assumption has been confirmed by numerous experiments, and the HDV *in vitro* infection model has been utilized extensively to study the HBV envelope proteins function at viral entry.[14,159,171] As a matter of fact, the HDV model was critical to the identification of hNTCP as a high-affinity receptor for HBV/HDV.[195]

The first step in the HDV entry process is mediated by an interaction between the viral envelope proteins and heparan sulfate proteoglycans (HSPGs), such as Glypican-5, at the surface of human hepatocytes (Fig. 19.3).[93,161,171,178] An HSPG-binding domain is present in the surface-exposed antigenic loop (AGL) of the HBV envelope proteins, which also bears the conserved immunodominant antigenic a-determinant of HBsAg.[2,159] The a-determinant elicits the most neutralizing antibodies (anti-HBs antibodies) in case of self-resolving infection, or in response to HB vaccination. It was the first identified HBV marker,[15] but its relevance to a function in the HBV life cycle had never been unveiled until the demonstration of its contribution to infectivity.[83] The HSPG-binding domain, and overlapping a-determinant, are both dependent upon a specific conformation of the AGL polypeptide stabilized by intra- and interchain disulfide bonds.[159,171] The AGL also bears an N-linked glycosylation site at N146, which is never fully functional, leading to a near-to 1:1 ratio of nonglycosylated/glycosylated isoforms for each type of envelope protein. An explanation to this peculiar pattern is that nonglycosylated N146 is essential for infectivity, while the glycosylated form is instrumental in shielding the a-determinant from neutralizing antibodies.[85]

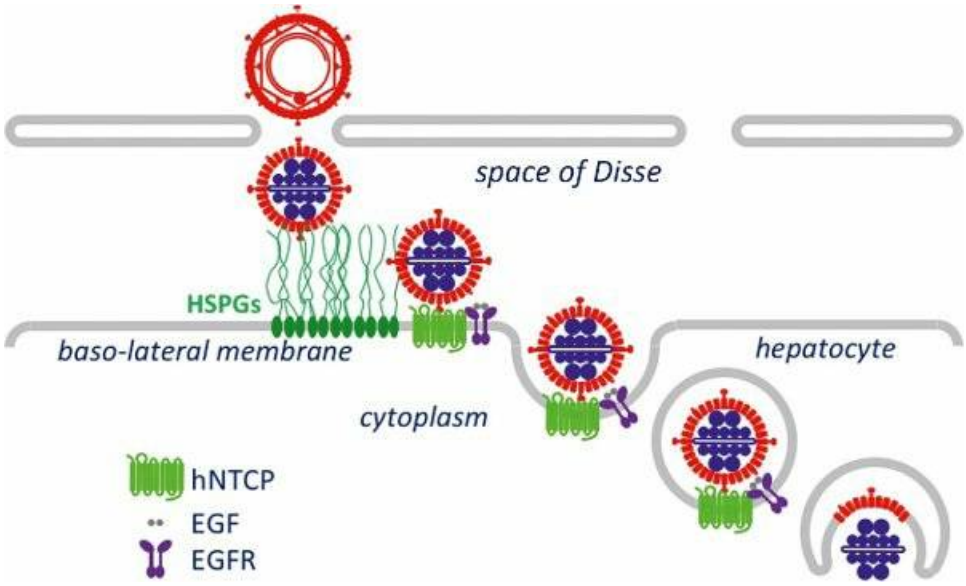

FIGURE 19.3 HDV entry into human hepatocytes. HDV and HBV virions reach the space of Disse through fenestrations of the sinusoidal endothelium. Virions first attached to heparan sulfate proteoglycans (HSPGs) at the basolateral membrane of hepatocytes then bind to hNTCP and are recruited to the NTCP–EGFR before translocation from the cell surface to the intramembrane vesicles upon stimulation with EGF.

Mechanism of Entry

After low-affinity attachment to HSPGs at the basolateral membrane of hepatocytes, the pre-S1 domain of L-HBsAg binds with high affinity to the HBV-specific receptor, hNTCP (Fig. 19.3).[127,195] The critical role of pre-S1 at viral entry was first demonstrated using the HDV

model when HDV virions lacking L-HBsAg in the viral envelope were found noninfectious.[167] Adding back a small number of L-HBsAg proteins, estimated at approximately 3 to 4 per virion, was sufficient to restore infectivity.[95] The hNTCP-binding site consists of amino acids (aas) 9 to 15 in the pre-S1 domain (position in HBV genotype D ayw3), but binding requires the integrity of the N-terminal 75 amino acids sequence of pre-S1 and its acylation with myristic acid.[14,59] Interestingly enough, a synthetic myristoylated pre-S1 peptide can block HDV/HBV infection *in vitro* at subnanomolar concentrations.[59] It is actually proposed as a potent entry inhibitor under evaluation in clinical trials in HDV chronic carriers.[108]

Internalization

After its binding to hNTCP, HBV/HDV is internalized through the EGFR endocytosis pathway as a consequence of hNTCP interacting with EGFR, irrespective of the presence of the virus (Fig. 19.3).[82] Upon stimulation with EGF, the virus–hNTCP–EGFR complex is translocated, with EGFR, from the plasma membrane to endocytic vesicles, possibly using a clathrin-mediated pathway.[77] Whether a subsequent membrane fusion occurs upon acidification in intracellular vesicles for release of the RNP into the cytoplasm is presently unknown. Trafficking of the RNP into the cytoplasm is also poorly documented, but entry into the nucleus is directed by the presence of a nuclear localization signal (NLS) in the HDAg proteins.[27]

mRNA Synthesis

Postentry, the HDV genome is delivered to the nucleus and serves as a template for initiation of antigenomic RNA synthesis by cellular RNA pol II (Fig. 19.4). The nascent antigenomic RNA can proceed through two distinct pathways: (a) synthesis of an mRNA for translation into HDAg proteins or (b) synthesis of full-length antigenomic RNA that serves as replication intermediate. However, there is no switch from an early synthesis of mRNA to a late production of antigenomic RNA, the two phenomena being independent of each other and likely carried out by different machineries in different nuclear compartments.[68,107,121] Yet, whether the antigenome is synthesized by a polymerase other than pol II is a point of contention. The HDAg mRNA is 800 nt in size and is processed in response to a polyadenylation signal AAUAAA.[65,75] Its 5′ end is capped and maps to nucleotide 1,630—or 1,631—corresponding to the left tip of the genomic rod-like structure suggesting the presence of a promoter upstream of this position.[63,121] HDAg mRNA accumulates at up to 1,000 copies per cell, a level approximately 1 and 2 log10 below that of antigenomic and genomic RNAs, respectively.[129]

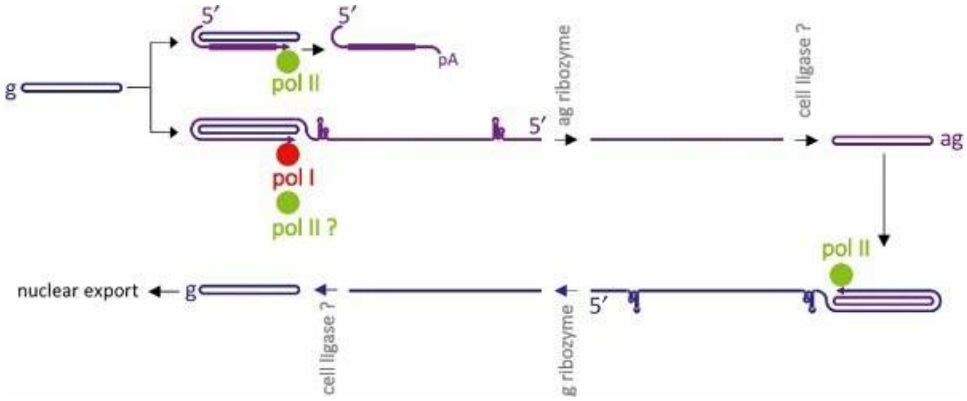

FIGURE 19.4 Rolling-circle mechanism of HDV RNA replication. Incoming genome (g) serves as template for synthesis of HDV mRNA by cellular polymerase II (pol II) and for synthesis of antigenomic RNA (ag) by pol I or pol II through a rolling-circle mechanism of replication. Neosynthesized linear antigenomic RNA is cleaved by the embedded ag ribozymes to linear unit-length molecule that is then circularized upon intramolecular ligation (cell ligase?). In turn, circular ag RNA serves as template for synthesis of genomic RNA through a second mechanism of rolling-circle amplification by pol II. HDV genomic polarity is indicated in *blue*, and antigenomic in *purple*.

Translation

Even though full-length antigenomic RNA bears the HDAg ORF, translation of HDAg proteins occurs exclusively from HDAg mRNAs.[107] In fact, two distinct mRNAs are produced during replication that differ from each other by only one nucleotide. At the early phase of replication, the mRNA codes for the 195 amino acids long S-HDAg protein, whereas at a later phase, the amber UAG codon for S-HDAg is changed to UGG for tryptophan leading to a longer ORF for L-HDAg with 19 additional codons at the 3′ end. The sequence modification occurs upon editing of UAG, not on the HDAg mRNA itself, but on the full-length antigenomic RNA.[111] It is carried out by the adenosine deaminase acting on RNA 1 (ADAR1) that converts adenosine of the UAG termination codon for S-HDAg to inosine, which is in turn recognized as guanosine by the RNA polymerase (Fig. 19.5). S-HDAg is active in promoting HDV RNA replication early in infection, whereas L-HDAg acts at a later stage to down-regulate replication and promote HDV virion assembly.[31]

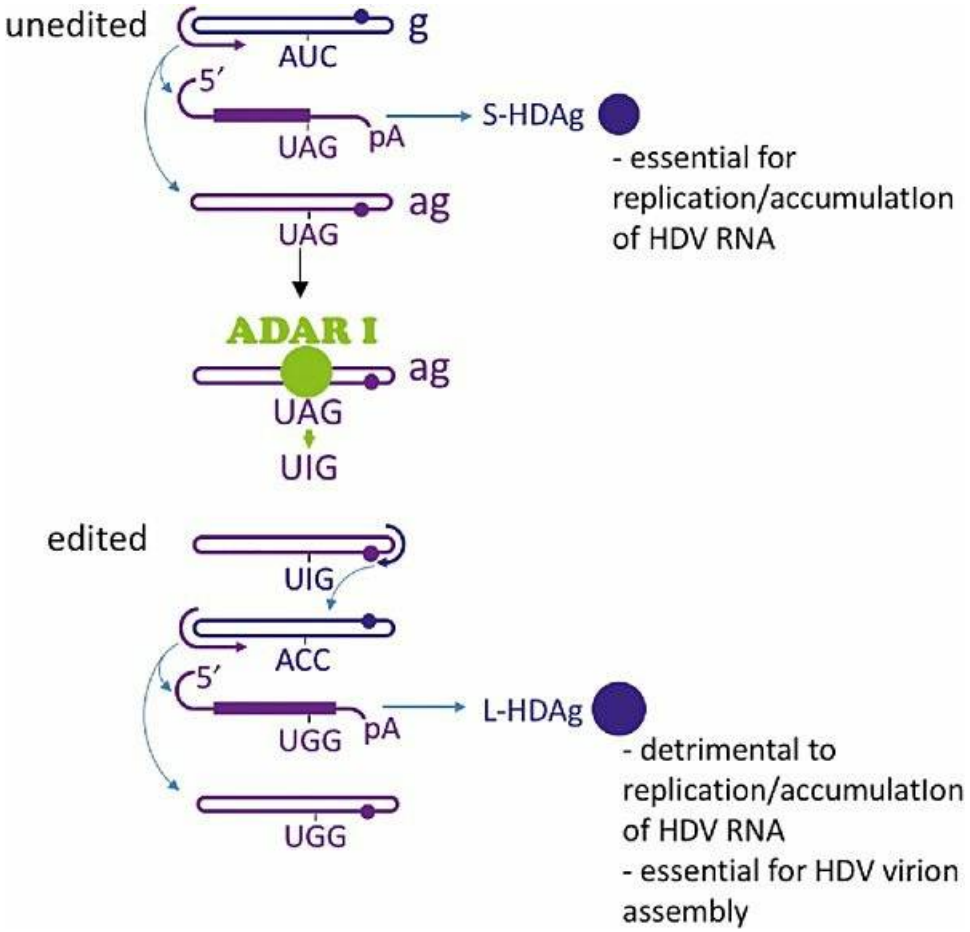

FIGURE 19.5 HDV RNA editing. Host adenosine deaminase acting on RNA 1 (ADAR1) converts adenosine in UAG termination codon for S-HDAg to inosine on the antigenome (ag). Inosine is recognized as guanosine by the RNA pol II, leading to cytidine incorporation in the complementary genome and ultimately changing the UAG amber codon in the L-HDAg mRNA to UGG for tryptophan. ADAR1 controls the switch between early phase of HDV RNA amplification and late phase of virion assembly.

The N-terminus of both S- and L-HDAg proteins is involved in the formation of dimers by establishing an inter-molecular antiparallel coiled-coil interaction (Fig. 19.6).[200] Both proteins also contain an NLS[5,27,192] and two arginine-rich motifs (ARMs) with RNA-binding properties.[99] However, the major determinant for direct binding to the rod-like form of HDV RNA resides within the N-terminal 78 amino acids of HDAg proteins.[36]

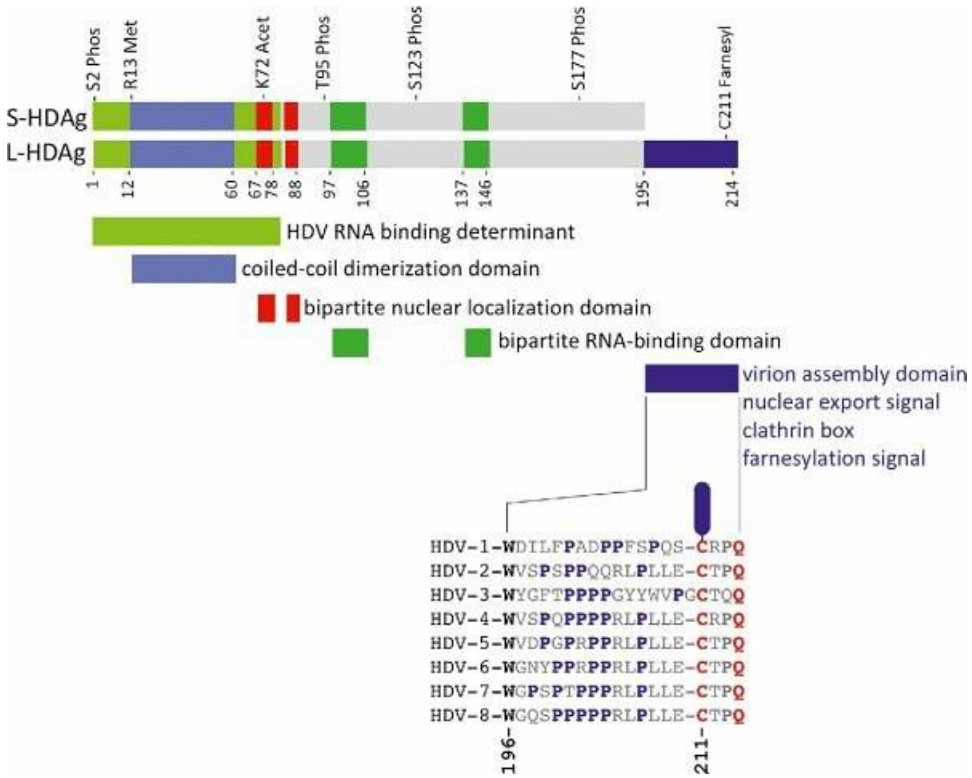

FIGURE 19.6 Functional domains of the HDAg proteins. Both S- and L-HDAg proteins contain a coiled-coil dimerization domain and a nuclear localization domain (NLS). The C-terminus of L-HDAg includes a nuclear export domain (NES), a farnesylation signal, and assembly domain. The farnesyl group covalently linked to cysteine-211 is represented (*thick blue line*). The C-terminus of L-HDAg is not well conserved among HDV genotypes, except for the presence of at least four proline residues, and the CXXQ farnesylation signal. Posttranslational modifications on S-HDAg are indicated: phosphorylation (Phos); methylation (Met); and acetylation (Acet). S-HDAg is also sumoylated at multiple lysine residues.

The C-terminal 19 amino acids sequence unique to L-HDAg contains a CXXQ farnesylation signal that is crucial to virion assembly in allowing the farnesylated L-HDAg to interact with the HBV envelope proteins at the endoplasmic reticulum (ER) membrane.[89] In addition, the proline-rich, C-terminal sequence of L-HDAg contains a nuclear export signal (NES) and a clathrin-binding motif, both reported as instrumental in virion assembly.[98,134] Surprisingly, beside the C-terminal CXXQ farnesylation signal sequence and the presence of least four diversely scattered proline residues, the 19-amino acid C-terminus of L-HDAg is not well conserved among the different HDV genotypes.[142]

S-HDAg is subjected to several posttranslational modifications that orchestrate genome replication within the nucleus.[78,176] Methylation at Arg-13,[102] acetylation at Lys-72,[123] phosphorylation at Ser-177,[74] and sumoylation at multiple lysine residues[176] directly participate to the complex trafficking of the different forms of HDV RNA within the nucleus and between nucleus and cytoplasm.[9,78] Genomic RNA and mRNA synthesis require a S-HDAg protein that is acetylated, methylated, and phosphorylated. By contrast, antigenome synthesis does not

require S-HDAg modifications.[176]

Replication of HDV RNA

HDV RNA replication takes place in the cell nucleus, and it is likely the function of the S-HDAg NLS to target the incoming RNP to the nucleus (Fig. 19.7). Since the HDAg protein is not an RNA-dependent polymerase (RdRp), the host RNA polymerase II (pol II)—a normally DNA-dependent enzyme—is first recruited for synthesis of a complementary antigenomic RNA in the nucleoplasm.[29,122] Polymerization can lead either to synthesis of the HDAg mRNA when the polyadenylation signal on the genome template is recognized by pol II, or to the production of longer-than-unit antigenomic RNA when it is ignored.[129] There is a consensus for mRNA synthesis being carried out by pol II in the nucleoplasm, but it is still uncertain whether pol II or pol I/III performs the rolling circle mechanism of antigenomic RNA synthesis, and whether the latter takes place in the nucleolus, an organelle in which pol I normally transcribes DNA into ribosomal RNA (Fig. 19.8).[177]

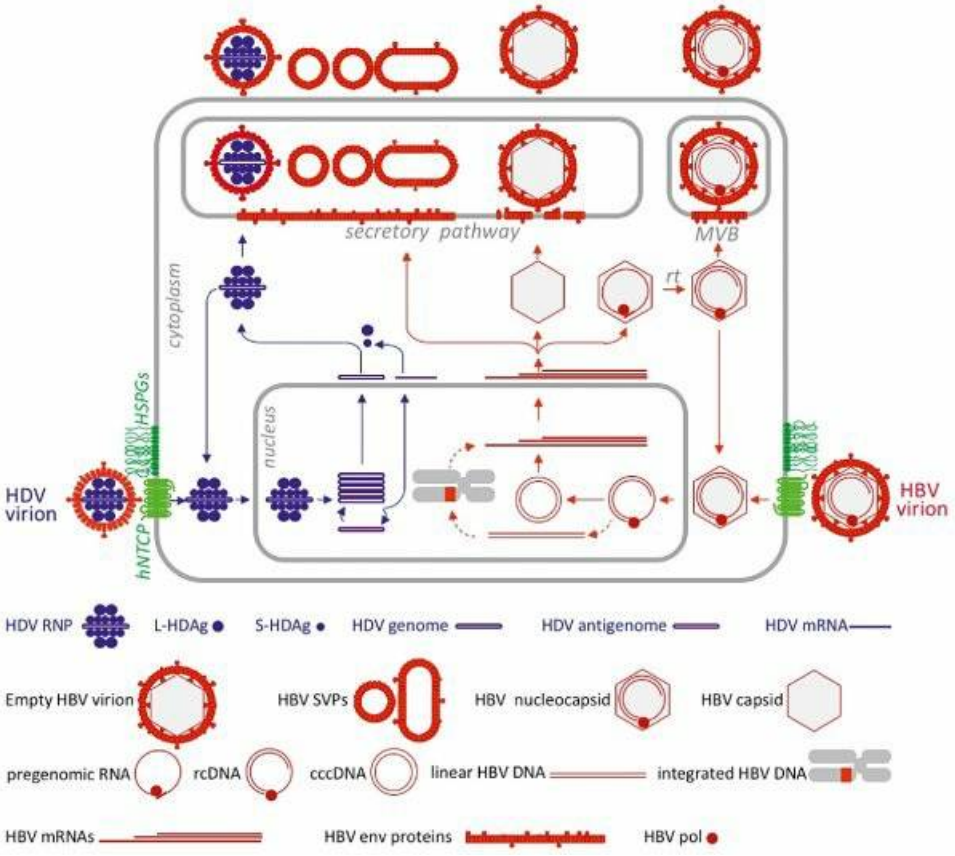

FIGURE 19.7 Schematic representation of the HDV/HBV replication cycle. Upon infection, the HDV RNP is directed to the nucleus for replication. The intrinsic HDV replication pathway is indicated in *blue* and the HBV-specific pathway in *red*. SVP, subviral particles; HSPGs, heparan sulfate proteoglycans; hNTCP, human sodium taurocholate cotransporting polypeptide; L-HDAg, large HDAg protein; S-HDAg, small HDAg protein; MVB, multivesicular body pathway; rt, reverse transcription.

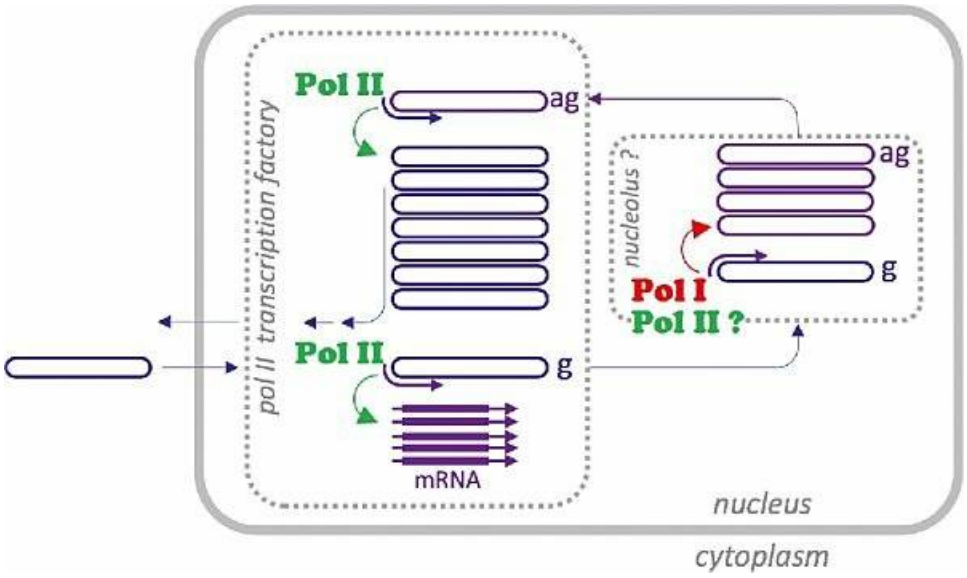

FIGURE 19.8 Intranuclear replication of HDV RNA. Genomic HDV RNA (g) and messenger RNA (mRNA) are synthesized by cellular RNA polymerase II (Pol-II) in pol II transcription factories of the nucleoplasm. Antigenomic (ag) RNA is synthesized by Pol-II—possibly Pol-I—in the nucleolus. HDV mRNAs are exported to the cytoplasm for synthesis of HDAg proteins. Genomic HDV RNA is exported through a Crm1-independent pathway.

The neosynthesized, and greater-than-unit length antigenomic RNA, is then rapidly processed into monomers by the embedded ribozyme. The self-cleavage product is a linear molecule that can ligate on itself to form a circular RNA. In turn, the circular antigenome serves as a template for synthesis of genomic RNA catalyzed by cellular pol II in transcription factories of the nucleoplasm, through a rolling-circle mechanism that also includes self-cleavage and circularization by intramolecular ligation.[92] Overall, the replication strategy of HDV RNA resembles that of some plant viroids but differs from the latter in including the synthesis of an mRNA.[75]

S-HDAg is central to HDV RNA replication. Beside its role as a structural protein, it displays several characteristics of a transcription factor, such as the presence of coiled-coil and helix-loop-helix domains and a propensity to posttranslational phosphorylation, acetylation, methylation, and sumoylation. S-HDAg shows limited sequence similarity to negative elongation factor A (NELF-A),[193] and in an *in vitro* transcription model, S-HDAg binding to Pol II increases the rate of RNA synthesis and fidelity by promoting elongation upon displacement of NELF.[194] S-HDAg can also interact with cellular transcription factor YY1 and its associated acetyltransferases CBP and p300 in a large nuclear complex, which has the capacity to modulate HDV RNA replication.[80] Furthermore, a recent report shows that acetylation of S-HDAg is crucial for replication in allowing the protein to interact with cellular chromatin remodeling factors. More precisely, S-HDAg acetylated at lysine 72 can bind to the bromodomain associated to zinc-finger protein-2B (BAZ2B), an integral component of chromatin remodeling imitation switch complexes (ISWI) that include BAZ2B-associated remodeling factors (BRFs). Acetylated S-HDAg would thus mimic acetylated histone H3 to recruit chromatin remodelers and pol II on

the HDV genome. These findings are in agreement with pol II carrying out RNA synthesis—HDAg mRNA and eventually antigenome—from genomic template.[1,123]

HDV ribozymes are essential elements of the genome replication mechanism (Fig. 19.9). They are embedded in both genomic and antigenomic RNAs; they differ from each other by their nucleic acid sequences but adopt a similar secondary structure, referred to as nested double pseudoknot that is quite distinct from that of hammerhead or hairpin ribozymes of viroids or satellites of plant viruses.[47,143] The auto-cleavage reaction is a transesterification mediated by divalent metal ions, which converts a 3′-5′ phosphodiester bond to a 2′-3′ cyclic monophosphate group and a 5′ hydroxyl group. Self-cleavage activity is assisted by HDAg proteins and easily observed *in vitro*, requiring a minimal size of approximately 85 nucleotides for activity.[143] After the discovery of HDV, several cellular HDV-like ribozymes have been found to play a role in a variety of biological events in different branches of life, raising the possibility of HDV RNA itself derived from the cell transcriptome.[185] The latter is notorious to contain abundant amounts of circular RNA species that can be exported from the nucleus through a circular RNA nuclear export pathway.[101]

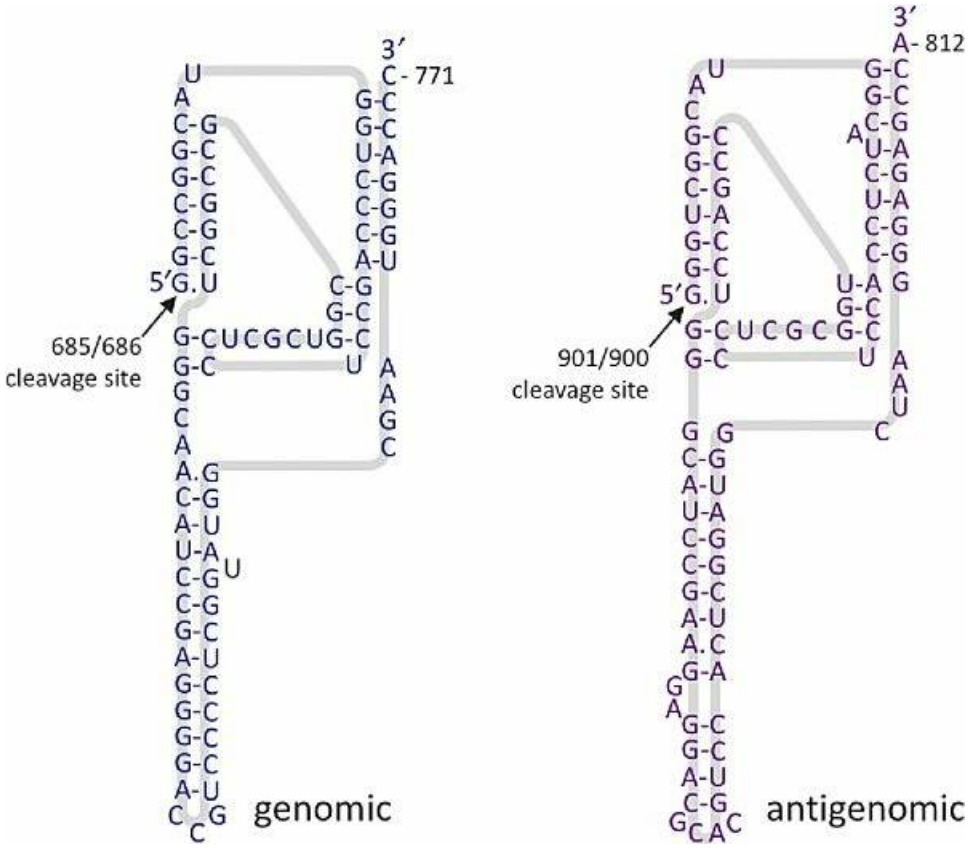

FIGURE 19.9 Secondary structures of genomic and antigenomic HDV ribozymes. Numbering of the nucleotides is indicated as positions on the genomic strand of HDV-1 (GeneBank accession number M21012.1).

Indirectly, ADAR1 regulates HDV RNA replication by controlling the switch between an

early phase of active replication and a late phase of replication suppression and viral assembly (Fig. 19.5).[24] *In vitro*, the two known isoforms of ADAR1, that is, nuclear ADAR1-S and cytoplasmic ADAR1-L, can mediate editing. However, ADAR1-S is believed to perform most of the editing in the nucleus, whereas ADAR1-L would act only in response to IFN-alpha stimulation.[69]

Overall, the mechanism of HDV genome replication is based on a complex trafficking of both viral RNAs and proteins within the nucleus—from RNA pol II transcription factories to nucleolus—and between nucleus and cytoplasm. It can be tentatively summarized as indicated in Figure 19.8. After transport of the incoming RNP to the nucleus through the action of S-HDAg NLS, the HDV genome is either use as template for mRNA synthesis by pol II in the nucleoplasm, or directed to the nucleolus for synthesis of full-length antigenomic RNA by pol II or pol I/III.[62,115] Neosynthesized antigenomic RNA then migrates from nucleoli to RNA pol II transcription factories in the nucleoplasm for synthesis of genomic RNA. While antigenomes are retained in the nucleus, genomes are rapidly exported to the cytoplasm through a Crm1-independent pathway.[115] A disruption of nuclear paraspeckles and the delocalization of the paraspeckles protein 1 to the cytoplasm has been described to occur upon HDV replication, but it is uncertain to what degree it participates to the cytoplasmic sorting of HDV RNA.[9]

HDV genome replication appears very efficient if one considers the accumulation of up to 300,000 genomes per cell, 50,000 antigenomes, and approximately 1,000 copies of mRNA. Nonetheless, the peak of viral RNA accumulation generally occurs over a long period of time post entry—6 to 9 days—suggesting that the recruited host RNA polymerases are in fact substantially impeded when using a single-stranded HDV RNA instead of their natural double-stranded cellular DNA as template.

HDV Virion Assembly

The Assembly of HDV RNP

A possible scenario for RNP assembly is that HDAg proteins would first form dimers through antiparallel coiled coils (residues 13 to 48) prior to formation of octamers and binding to rod-like HDV RNA.[104,200] This arrangement is reminiscent of the histone octamer structure in nucleosomes. An octamer binding requires a minimum of approximately 300 nt in length of HDV RNA folded as an unbranched rod.[94,104] In *in vitro* assembled RNPs, the viral RNA is flexible enough to bend and condense with HDAg proteins. The flexibility of the rod structure is likely to result from the presence of unpaired bases.[58]

The cellular compartment in which genome-bearing RNPs are assembled prior to envelopment in the cytoplasm is not known. During replication in the nucleus, the genomic RNA —and not antigenomic—is actively exported to the cytoplasm, possibly complexed with S-HDAg, but independently of L-HDAg.[115] Yet, L-HDAg must integrate cytoplasmic RNP that are predestined to virion assembly because its farnesylated C-terminus drives the RNP to the ER membrane where the HBV envelope proteins accumulate. Then, binding of HDV RNP to envelope proteins is thought to involve a proline-rich sequence located just upstream of the farnesylation site.[89] The same C-terminus of L-HDAg contains an NES and a clathrin box, both eventually instrumental in particle morphogenesis, but it is still unclear how these elements fit

into the virion assembly process.[76,89,98] Whether formation of genome-bearing RNPs takes place in the nucleus or cytoplasm and whether assembly of HDV virions require a direct binding of the C-terminal sequence of L-HDAg to HBV envelope proteins is presently unknown.

Upon electron microscopy examination, the HDV RNPs appear as spheres of approximately 20 nm in diameter with no apparent icosahedral symmetry. The molar ratio of HDAg proteins to HDV RNA in a virion-associated RNP was first measured at 70,[156] in agreement with the estimation by Lin and colleagues of approximately 32 to 40 HDAg subunits per HDV RNA,[104] but in a subsequent study, this number was revised to 220.[62]

Assembly and Release of HDV Virions

For cell egress, as for entry, HDV relies on the assistance of the HBV envelope proteins (Fig. 19.7). This is in fact the only HBV contribution to the HDV life cycle, because HDV can propagate in a liver free of HBV replication, in which production of S- and L-HBsAg proteins is directed by integrated HBV DNA sequences.[48,49]

The distinctive feature of the HBV life cycle that makes this virus the ideal partner for HDV resides in the unique properties of its envelope proteins. They are produced in amounts far exceeding the need for HBV virion assembly; they self-assemble at the ER membrane and are secreted in abundance as SVPs.[72] HBV virion assembly is a rare event in comparison with SVPs, leading to an average infectious serum containing approximately 10^{12} to 10^{13} SVPs per mL for only 10^{8} to 10^{9} virions (Fig. 19.7). For comparison, at the peak of an acute HDV infection, titers of HDV virions can reach 10^{11} per mL. Thus, paradoxically, HDV makes a more efficient use of HBV envelope proteins than does HBV.

The HBV envelope proteins are membrane-spanning glycoproteins that differ from each other by the size of their N-terminal ectodomain (Fig. 19.10).[72] L-HBsAg contains an N-terminal pre-S1, central pre-S2, and C-terminal S domains. M-HBsAg is shorter than L-HBsAg in lacking pre-S1, whereas S-HBsAg lacks both pre-S1 and pre-S2. Synthesis occurs at the ER membrane, and SVPs bud at a pre-Golgi intermediate compartment, before export through the secretory pathway.[137] Assembly of HBV virions requires L-HBsAg—in addition to S-HBsAg—because it bears the matrix domain for HBV nucleocapsid envelopment. But the high proportion of L-HBsAg required for assembly of HBV virion prevents its spontaneous budding in the post-ER lumen, which is achieved only with the assistance of the host endosomal sorting complex required for transport (ESCRT) in the late endosomal multivesicular bodies (MVBs).[184]

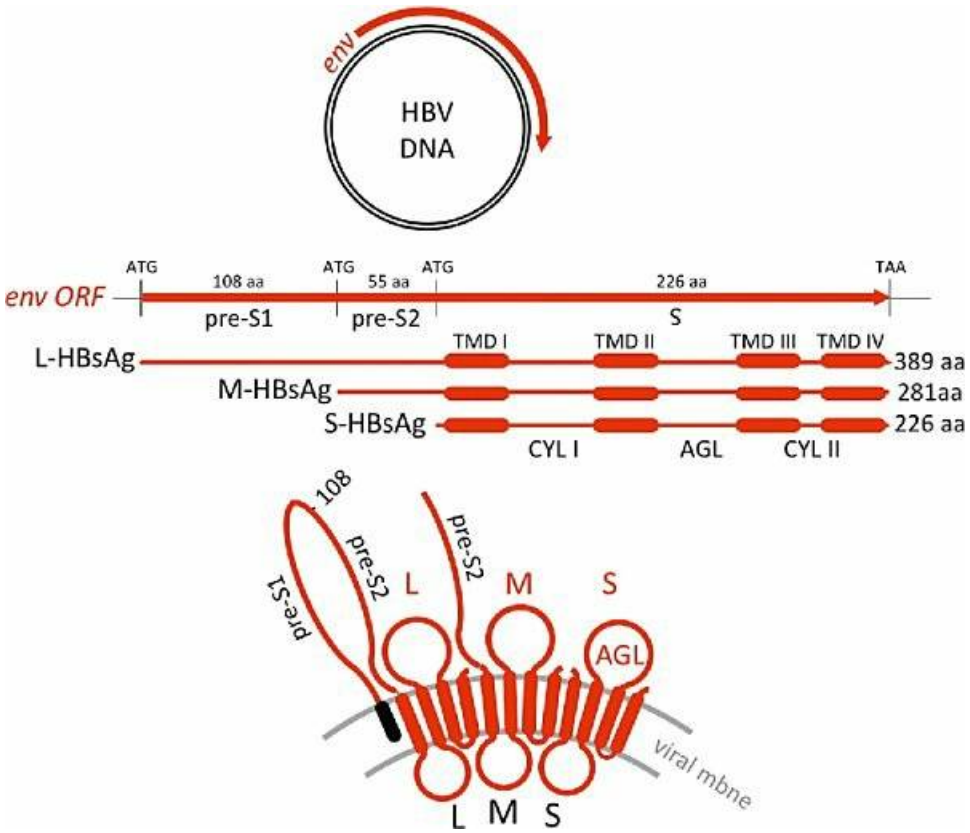

FIGURE 19.10 The HBV envelope proteins. The open reading frame for the HBV envelope proteins is indicated on the HBV genome (**top panel**). The L-HBsAg, M-HBsAg, and S-HBsAg proteins are translated from three in-frame initiation sites located at the amino terminus of the pre-S1, pre-S2, and S domains, respectively (**middle panel**). *Thick red lines* indicate transmembrane domains (TMDs). *Thick black line* represents myristic acid covalently linked to the L-HBsAg N-terminus. Secondary structure model (**bottom panel**) for L-, M-, and S-HBsAg at the viral membrane (mbne) is represented, including in the antigenic loop (AGL) and the pre-S1 and pre-S2 domains. CYL-I and II, cytosolic domain I and II, respectively.

In contrast to HBV, HDV virion assembly can be achieved by the sole S-HBsAg protein, resulting in S-HBsAg-coated HDV particles that are noninfectious for lacking L-HBsAg (Fig. 19.11).[167] The signal for binding to HDV RNP within S-HBsAg, referred to as HDV matrix domain, (Fig. 19.12) maps to the carboxyl terminus of the protein and consists of aromatic residues W196, W199, Y200, and W201 that are conserved in the envelope proteins of all *Orthohepadnaviruses*.[89] In nature, HDV infection occurs only in association with HBV, but it can be experimentally conducted in woodchucks infected with the woodchuck hepatitis virus (WHV). Furthermore, the envelope proteins of other *Orthohepadnaviruses*, such as the woolly monkey HBV (WMHBV), the tent-making bat HBV (TBHBV), or capuchin monkey hepatitis B virus (CMHBV) are competent for HDV virion production when tested in an *in vitro* culture model.[7,23,39,140,155] By contrast, the envelope proteins of the duck hepatitis B virus (DHBV) lack a HDV matrix domain, and, consequently, DHBV cannot serve as helper.[134]

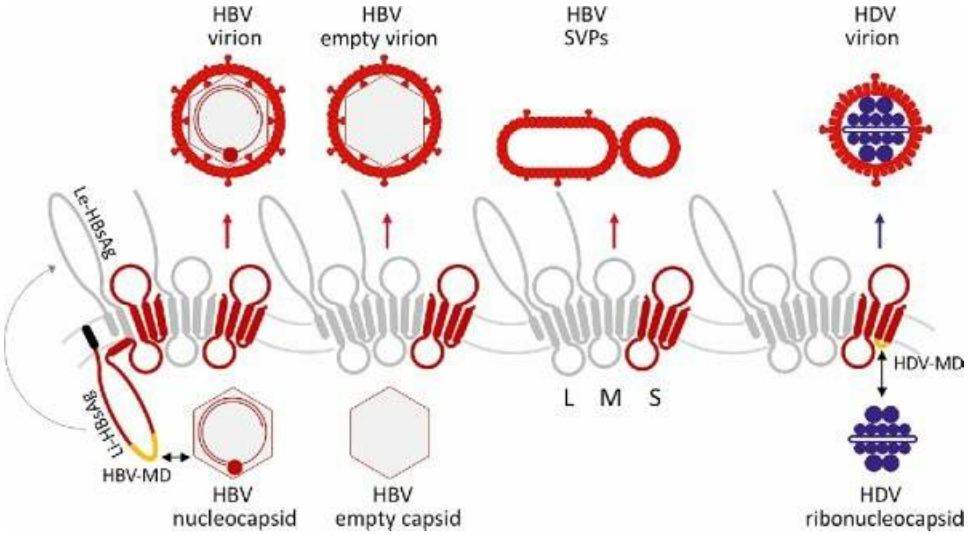

FIGURE 19.11 Model for HDV and HBV virions assembly. HBV and HDV particles assemble and bud into the lumen of the cellular intermediate compartment (IC) between ER and Golgi. Aggregates of HBV envelope protein bud spontaneously at the IC membrane. When aggregates include S-HBsAg proteins only, or S-HBsAg + M-HBsAg, it leads to secretion of spherical SVPs. When aggregates include L-HBsAg in the presence of HBV nucleocapsid, budding of HBV virions occurs in multi vesicular bodies. In case of HDV coinfection, the HDV RNP is addressed to the ER membrane and interacts with the HBV proteins, irrespective of the presence of L-HBsAg, leading to the release of HDV virion. Incorporation of the L-HBsAg protein in the HDV envelope confers infectivity. Alternative topologies of L-HBsAg are represented: N-terminal pre-S domain is cytosolic at the ER membrane (Li-HBsAg) for recruiting DNA-containing nucleocapsid in virion assembly, or luminal (Le-HBsAg), that is, external on secreted HBV virions for receptor-binding function. HDV-MD, HDV matrix domain in S-HBsAg. HBV-MD, HBV matrix domain in L-HBsAg.

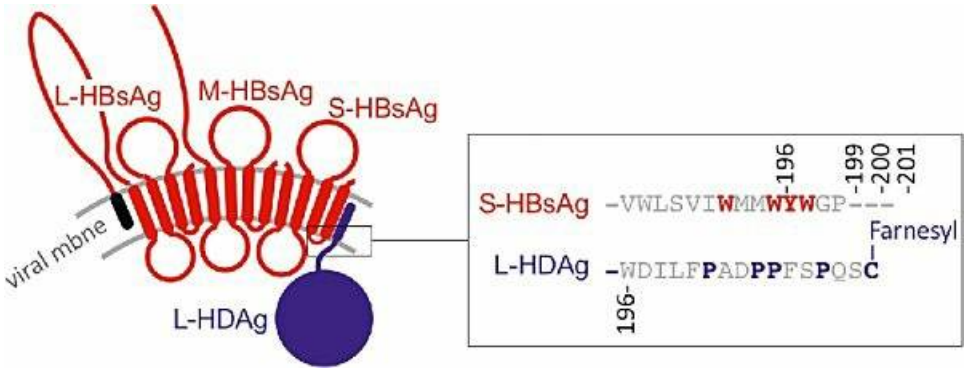

FIGURE 19.12 HBV–HDV interaction. The HDV matrix domain consists of tryptophan -196, -199, -201, and Tyr-200 in the S domain of the HBV envelope proteins. The matrix domain is assumed to interact (directly or indirectly) with the C-terminus of the RNP-associated L-HDAg protein. Within the C-terminus of L-HDAg, the CXXQ sequence is a signal for farnesylation at cysteine-211, which is essential for HDV virion assembly. Proline residues are important for interaction with HBV

envelope proteins.

The HDV matrix domain is conserved among all HBV genotypes, and even all *Orthohepadnaviruses* but paradoxically, it is dispensable for the HBV life cycle.[13] A likely explanation is that its conservation is a consequence of the overlap between ORFs for polymerase (*pol*) and envelope proteins (*env*) in the HBV genome (Fig. 19.13). As a matter of fact, the HBV DNA sequence that codes for the HDV matrix domain in *env* also encodes, in the minus-one frame, the reverse transcriptase catalytic domain (YMDD) in *pol*, and it is likely that the strict requirement of YMDD for reverse transcriptase activity imposes in *env* a tryptophan-rich domain that is used by HDV as a matrix domain.

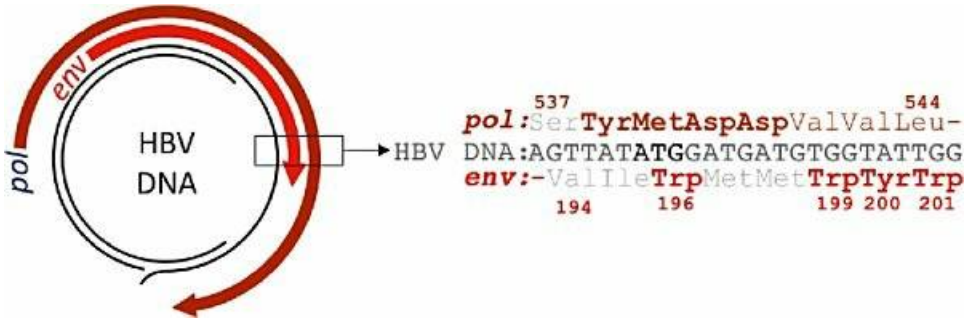

FIGURE 19.13 Conservation of the HDV matrix domain. The HDV matrix domain in HBV envelope proteins (env) consists of Trp-196, -199, -201, and Tyr-200. It is assumed to be conserved as a consequence of the HBV *env* and *pol* genes overlap in the HBV genome. The HBV DNA sequence that codes for the HDV matrix domain, also codes, in the minus-one reading, for the YMDD catalytic motif of HBV reverse transcriptase. It is hypothesized that the strict requirement for YMDD motif in *pol-RT* is at the origin of the HDV matrix domain conservation in HBV *env* proteins.

HDV virions released in the extracellular space have an average diameter of 36 nm and a buoyant density of 1.25 g/cm^3 in CsCl.[148] The HDV envelope is identical to that of HBV SVPs, consisting of cell-derived lipids associated to HBV envelope proteins surrounding the inner RNP of approximately 20 nm in diameter and assumed to contain a single copy of genomic RNA.[17,62,70,148]

Since HDV RNA can replicate within cells of different species and tissues in the absence of HBV, there is a theoretical possibility that HDV could propagate using the envelope proteins of non-HBV. When this hypothesis was tested experimentally, it was found that envelope proteins of *Vesiculovirus*, *Flavivirus*, and *Hepacivirus* could, to some extent, package the HDV RNP and lead to the production and release of pseudotyped HDV particles. Moreover, HDV was shown to propagate in the liver of immune-deficient liver-humanized mice coinfected with HCV, suggesting that the latter could serve as a helper.[138] However, this hypothesis is supported by neither clinical observations nor serological testing.

PATHOGENESIS AND PATHOLOGY

Natural Host and Animal Models

In nature, HDV infection occurs only in humans infected with HBV, but it was achieved experimentally in the chimpanzee model under both coinfection and superinfection settings (Fig. 19.14).[147] In this animal model, coinfection resulted in hepatitis characterized by a transient elevation of serum alanine aminotransferase (ALT); the infection was self-limited but progressed to chronicity in 50% of superinfected animals.[125] Superinfection in this model was characterized by a transient suppression of HBV replication at the acute phase of HDV infection.[172] As in humans, the liver was the only infected organ, but it was affected with a more severe disease in comparison to other viral hepatitis. In theory, HDV should be able to propagate in species susceptible to other *Orthohepadnaviruses*, as long as their envelope proteins contain the HDV matrix domain.[7,23,39,155] In reality, HDV infection has been achieved experimentally in woodchucks infected with WHV, causing acute hepatitis, with a high proportion of animals becoming chronically infected.[140]

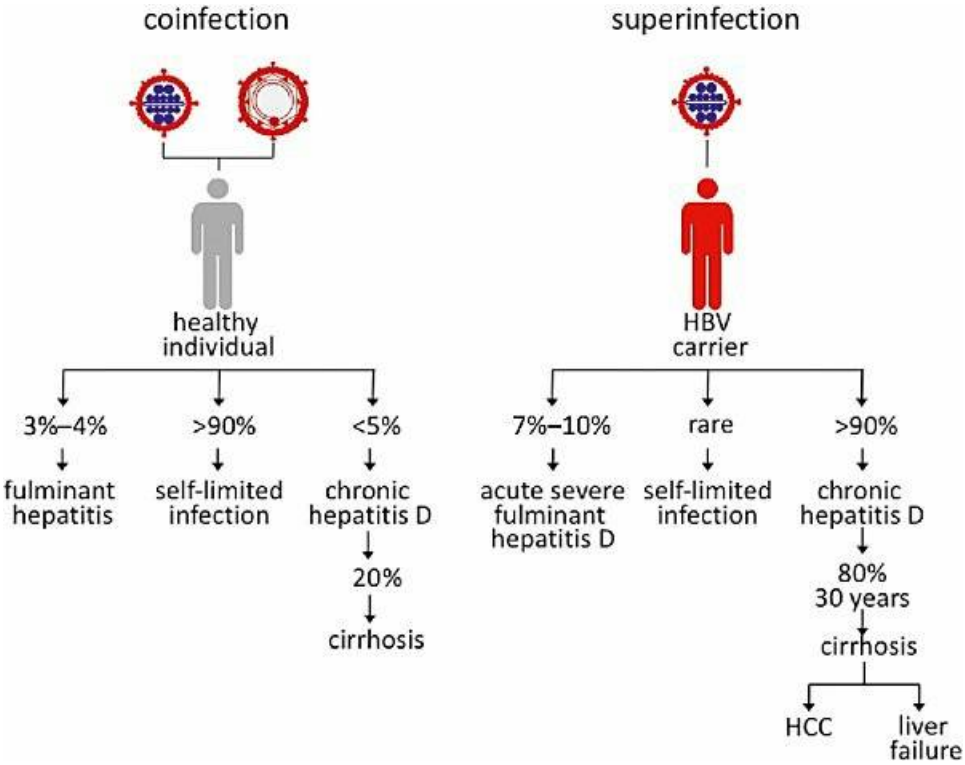

FIGURE 19.14 Clinical sequelae of HDV coinfection and superinfection. Comparison between coinfection of an individual by both HBV and HDV, and superinfection of a HBV-chronic carrier by HDV.

In recent years, numerous mouse models have been developed, including immune competent

mice inoculated with HDV, HDV cDNA, or HDV RNA, in which low levels of genome replication in the liver could be documented.[126] But, in the absence of helper HBV replication, HDV propagation was not possible. In transgenic mice created to express S- or L-HDAg, or to sustain HDV RNA replication, no cytopathic effect in the liver could be observed.[66] More recently, several immune-deficient liver-humanized mouse models have been established that are susceptible and permissive to HBV/HDV infection, but again without evidence of cytopathy for the human hepatocytes.[18,112,138] Finally, transgenic mice expressing hNTCP have been generated that are also readily susceptible to infection, leading to replication of HDV RNA in the liver. Yet the animals remained resistant to HBV for lacking cellular factor(s) required for productive HBV infection.[71] Further improvement is thus required to generate an immunocompetent mouse model that could sustain chronic HDV infection.

Entry Into the Host and Site of Primary Replication

HDV enters into the host following the same parenteral route of transmission as that used by the helper HBV, via blood or body fluids. As a highly vascularized organ, the liver is directly exposed to HBV/HDV circulating in the bloodstream. Infectious particles are assumed to reach the liver sinusoids through the portal vein or hepatic artery and the space of Disse through fenestrations of the sinusoid endothelium. It is then taken up by hepatocytes after an initial binding to HSPG at the basolateral membrane followed by a secondary interaction of L-HBsAg to the hNTCP.[195] Primary replication of HDV occurs in human hepatocytes that are either already infected with HBV—a superinfection setting characterized by short incubation period—or to become coinfected by HBV (Fig. 19.14). In all cases, the direct pathologic effects of infection are limited to the liver.

Release From Host and Transmission

Within the liver, HBV and HDV virions egress coinfected hepatocytes through the basolateral membrane to reach the space of Disse and the blood circulation through the central vein. At the peak of an acute infection, serum titers of HDV virions can reach 10^{11} per mL. Therefore, HDV infection occurs, as for HBV, through percutaneous exposure to infected blood or blood products. The most efficient transmission occurs in the context of HDV superinfection of HBsAg-positive individuals.[149]

Sexual transmission of HDV is suggested by the observation that infections are more prevalent in individuals under 40 years old in regions of high endemicity.[19] Furthermore, a recent meta-analysis study has shown a HDV seroprevalence in HBsAg carriers with high-risk sexual behavior at 17% in comparison with 10% in a population without risk factors.[33]

By contrast, there is a low rate of mother-to-child transmission (MTCT) of HDV, which might correspond to the HDV suppressive effect on HBV viremia in coinfected mothers who, consequently, would not transmit HBV to their newborn.[162]

HDV transmission varies according to the prevalence in the general population. In industrialized countries, transmission occurs mainly through contact with infected blood, in particular among intravenous drug users (IVDUs).[33] Intrafamilial transmission has been documented in low-income communities through unapparent exchange of body fluids.[11,130] In Mongolia, the high HDV prevalence is attributed to horizontal transmission including inadequate

dental/medical procedures in addition to sexual activity.[32]

Mechanisms of Liver Damage and Immune Response

HDV is strictly hepatotropic, inducing direct pathologic effects only in the liver. However, experiments conducted using *in vitro* and *in vivo* models could not demonstrate that HDAg proteins expression, or the production of HDV virions, were cytopathic.[35,66,114] In tissue culture, HDV RNA replication does not induce cytotoxicity *per se*, but may, at most, partially impair cell division. This effect could be detrimental to liver regeneration in the setting of CHD.[182] Because HBV is generally suppressed by HDV replication, liver damage is more likely induced by HDV rather than HBV. In CHD patients, the HDV and HBV markers fluctuate in alternation over time with repeated flares of hepatitis. Liver injury in CHD patients is, for the most part, immune-mediated, consisting essentially of hepatocyte necrosis and the presence of inflammatory infiltrates.[124] In a particular study of CHD patients selected for different stages of fibrosis, the levels of HDV replication in the liver could not be correlated to a specific histology pattern.[198] Instead, there was a correlation between an increase of HDAg-specific T-cell response and a decrease of liver disease.[133] In a cytokine profiling study, interleukin (IL)-2, IFN-gamma, IFN-inducible protein-10, and IL-10 responses were detectable in 53%, 35%, 65%, and 6% of CHD patients, respectively, with an HDV-specific IFN-gamma response occurring preferentially in patients with low-level HDV viremia.[56] Noteworthy, among all chronic viral hepatitis, the highest frequency of CD4+ cytotoxic T lymphocytes is found in CHD patients.[6]

Virus-specific CD8 T-cell response seems to play a role in the outcome of HDV infection. Yet, the HDV-specific T-cell epitope repertoire and mechanisms of CD8 T-cell failure have been poorly characterized. Only in a recent study, mutations within L-HDAg-specific CD8 T-cell epitopes of CHD patients could be associated with escape from the HLA-B27-restricted CD8 T-cell response and correlated with the clinical outcome.[87] In comparison to chronic hepatitis B (CHB) patients, CHD patients have lower levels of mucosa-associated invariant T (MAIT) cells in both peripheral blood and liver. MAIT cells appear as activated, functionally impaired, and severely depleted.[38] Overall, the HDV-specific adaptive immune responses in CHD patients fails to contain the infection.

In cell culture, the IFN signaling pathway is activated by HDV.[3,71,118,187] L-HDAg alone can activate the MxA ISG and inhibit HBV transcription.[188] But even if the IFN response of cells replicating HDV appears to be intact, IFN-alpha modestly inhibits HDV replication.[118]

In the liver-humanized mouse model, HDV infection can provoke a clear enhancement of the antiviral state in human hepatocytes, which might contribute to HBV suppression,[51] but the STAT1 ISG is barely detected in hepatocytes highly positive for HDAg, as if inhibited by the latter. This is in agreement with an *in vitro* study showing that HDV replication is associated with the inhibition of STAT1 and STAT2 response to IFN-alpha.[141] In the peripheral blood of CHD patients responding to IFN-alpha treatment, the number of NK cells is increased in comparison to healthy controls, suggesting a role of NK cells in HDV pathogenesis, but long-term treatments may cause changes in NK cell differentiation and functional impairment.[110]

Clinical Features and Natural History

Both coinfection and superinfection can induce the most aggressive form of hepatitis, although the severity of liver damage may vary from totally asymptomatic to acute liver failure and death.

Acute HDV Infection

The clinical course of acute hepatitis D is similar to that of an acute hepatitis B[164]; symptoms include fatigue, nausea, and hyporexia, accompanied by an elevation of serum ALT/AST levels.

Coinfection may lead to acute hepatitis D characterized by two sequential flares of liver enzymes and, occasionally, a cholestatic course. An icteric phase, characterized by an elevation of serum bilirubin, is not always observed. By contrast, in case of superinfection, the acute phase of HDV replication may lead to liver failure, especially when superinfection occurs in CHB patients already affected by massive necrosis of hepatocytes.[164] A study conducted in Taiwan reported a lesser frequency of acute liver failure related to hepatitis D in patients infected with HDV-2 genotype as compared to HDV-1.[191] By contrast, HDV-3, which prevails in South America, is associated with the highest risk of acute liver failure.[25] The aggressive course of HDV-3 has been tentatively assigned to a specific mutation in HDAg protein, but it is likely to also depend upon other factors, such as the genotype of the helper HBV.[173] Individuals simultaneously coinfected with HDV and HBV progress to chronicity for both viruses at a similar rate as in acute HBV monoinfection, that is, less than 5% in adults.

Chronic HDV Infection

HDV superinfection of HBV carriers leads to chronic HDV infection in the vast majority of patients and, eventually, to CHD (Fig. 19.14).[44] Once HDV chronicity is established, the preexisting liver disease worsen, even though HBV replication is typically, but not invariably, suppressed.[42,90] CHD is characterized by inflammatory infiltrates and progressive deposition of fibrosis often followed by cirrhosis through a wound-healing process. Accordingly, serum ALT/AST levels are persistently elevated in most cases. Longitudinal studies have shown that CHD patients are at a 3-fold higher risk of progression to cirrhosis in comparison to HBV monoinfection.[45] For CHD patients, the risk of cirrhosis was estimated to reach 77% after 30 years of infection.[196] Risk factors of disease progression include HDV genotypes 1 and 3 that are associated with more severe disease than that induced by HDV-2 and -4.[25,166] Severe liver damage in CHD patients is also observed when a high level of HBV replication is maintained during the chronic phase in the absence of, or despite, the HDV suppressive effect on the helper. To what extent HBV genotypes also play a role in the course of CHD remains to be explored.[196]

The fact that CHD-related cirrhosis may remain stable for long periods of time before progressing to liver decompensation or HCC was suggested to result from a decline in HDV replication over time.[154] In HDV-related cirrhosis, liver decompensation occurs at a rate twice that of HBV-related cirrhosis, with a probability of survival at 5 and 10 years estimated at 49% and 40%, respectively.[46,154]

Whether HDV infection increases the risk of developing HCC as compared to HBV monoinfection is still debated. Experiments conducted in mice transgenic for HDAg proteins failed to show any direct carcinogenic role.[66] Nonetheless, a retrospective study from the Eurohep cohort reported that patients with HDV-related cirrhosis had a 5-year risk of developing

HCC of 13%, that is, 3.2-fold above that of HBV-related cirrhosis.[46] Subsequent studies pointed to liver decompensation and death, rather than HCC, as the major complication of CHD. In a large study conducted in Italy, the 5- and 10-year event-free survivals were at 83.9% and 59.4%, respectively, with a worse outcome among males. The cumulative probability of liver decompensation was at 75% at 17 years, with an incidence rate of complication of 2.47 per year. Cirrhosis evolved to HCC at a cumulative rate of 0.55 at 17 years, and an annual incidence rate of 1.0.[132] In another Italian study, the main cause of death among CHD patients with cirrhosis was liver failure in 59% of cases, whereas HCC occurred at a rate of 2.8% per year. Interestingly, HDV viremia was an independent predictor of HCC development and mortality.[153] A study from Sweden showed a standardized incidence ratio of 6.11 (95% CI = 2.77 to 11.65) for HCC in CHD as compared to HBV infection.[84] Although the above-mentioned studies indicate that HDV may indeed be a risk factor for HCC, there are discrepancies that may be explained by the very high genetic diversity of HDV and, to a lesser degree, that of coinfecting HBV strains. As shown by a Taiwanese study, the HDV-1/HBV-C coinfection correlated with more adverse outcomes of CHD than HDV-2/HBV-B.[166] In Asia, HDV-2 is associated with milder CHD compared to HDV-1, whereas in the Amazon region of South America, HDV-3 is associated with a particularly severe clinical presentation. In Africa where HDV-5 to -8 prevail, CHD patients are generally affected with a mild form of disease.

HDV Host Cell Interaction

HDV must interact with several components of the cell machinery to compensate for the lack of viral enzyme necessary to replication.[57] Furthermore, the accumulation at high levels of intracellular HDV RNA and proteins during the course of infection is likely to result in multiple host cell interactions and to impact cell metabolism. Numerous host proteins interacting with HDV RNA or proteins have been identified upon different screening approaches in HEK-293 or Huh-7 cell lines (for a review, see Goodrum and Pelchat[54]). Many of them are relevant to HDV replication, and some are likely to disrupt host processes related to nucleic acids and protein metabolism, transport, signal transduction, apoptosis, and cell growth. For instance, HDV replication was shown to increase histone H3 acetylation within the clusterin promoter, leading to an enhanced clusterin expression.[103] It is therefore conceivable that this epigenetic regulation contributes to carcinogenesis because clusterin overexpression has been reported in 89% of human HCC cases.[86] In that particular study, there was no mention of HDV markers, but 73% of clusterin-positive HCC were HBsAg-positive.

The observations concerning the relationship between HDV and cell proliferation are far from conclusive, because HDV replication has been shown to either impair cell proliferation in tissue culture,[182] or induce cell cycle arrest[28] and cell death.[35] By contrast, the expression of L-HDAg in cell culture led to activation of the serum response factor (SRF) and serum response element (SRE) signaling pathways, possibly in synergy with the HBV x (HBx) protein to activate cell proliferation.[55]

The analysis of the HEK-293 cell proteome changes upon expression of S-HDAg, or HDV RNP, identified differentially expressed proteins that, for the most part, were related to cell-cycle regulation and pyruvate metabolism. Interestingly, p53 was down-regulated, and the G2/M DNA damage checkpoint was among the most affected pathways, suggesting a possible mechanism of HCC induction by HDV.[119] In HEK-293 or Huh-7 cells, L-HDAg was shown to modulate the

NF-kappaB signaling pathway.[136] NF-kappaB activation in L-HDAg-expressing cells may result from an increased ER stress or the production of reactive oxygen species.[187] In addition, L-HDAg may induce liver fibrogenesis by activating TGF-beta–induced signal transduction. In cell culture, L-HDAg has been shown to regulate TGF-beta–mediated signaling in a farnesylation-dependent manner, and the effect was synergistically activated by HBx.[34]

Finally, in a recent study, a screening of HDV-infected cells with siRNA and small molecules identified the carbamoyl-phosphatesynthetase 2, aspartate transcarbamylase and dihydroorotase (CAD), and estrogen receptor alpha (ESR1) as key host factors for HDV RNA replication. Since CAD and ESR1 inhibitors could suppress HDV replication, they may have potential as anti-HDV drugs.[179]

Persistence

In vivo, HDV RNA can survive in the absence of HBV, as demonstrated in the liver-humanized mouse model in which HDV RNA and proteins could be maintained for at least 6 weeks in absence of HBV.[52] In the same mouse model, HDV RNA could even persist during liver regeneration and be amplified through cell division.[4] HDV may thus cause latent, HBV-free infection as observed in the setting of liver transplantation.[135] Moreover, considering that HDV RNA and HDAg proteins accumulate at up to 300,000 and 6,000,000 copies per cell, respectively,[62] their persistence in the liver could even be maintained through several cell divisions without HDV RNA replication. Nevertheless, *de novo* infection of naive hepatocytes requires that the HBV envelope proteins be provided to assemble infectious particles.

Interference

HDV exerts a suppressive effect on HBV replication, which has been documented in both humans and animal models.[90,139,157] HDV is hence considered as dominant over HBV.[113] In a superinfection setting, HDV leads to a transient suppression of HBV markers in both serum and liver during the acute phase of HDV replication.[140,147,172] In CHD patients, longitudinal studies show a considerable variation of one or both viruses activities over time, including alternating predominance, fluctuation of both viruses in parallel, or stability of one virus with fluctuation of the other.[160] The underlying mechanism of interference is only partially understood, but it is likely to involve both a direct repression of HBV transcription exerted by HDAg proteins in coinfected cells[188,190] and an indirect, cytokine-mediated inhibition.[3,51] In Huh-7 cells, the sole expression of HDAg proteins could repress HBV enhancers 1 and 2, while activating transcription of the MxA ISG.[188] In differentiated HepaRG cells, HDV superinfection could activate the IFN pathway via MDA5, without change in the NF-kappaB pathway, and partially suppress HBV replication.[3,199] These findings are in agreement with the notion that HepaRG cells and primary cultures of human hepatocytes (PHH) do express innate immunity sensors and respond to IFN.[109] However, IFN-alpha–induced signaling might be repressed by HDV through a mechanism that inhibit the JAK/STAT signaling pathway.[141]

EPIDEMIOLOGY

Prevalence

HDV is always found in association with HBV infection. Until recently, it was estimated that 5% of the HBV carriers were coinfected with HDV, for a total of 15 to 20 million HDV carriers worldwide. Regions of highest prevalence include Central and West Africa, Central and Northern Asia, the Pacific Islands of Kiribati and Nauru, countries of the Middle East, Eastern Europe and the Mediterranean countries, the Amazonian basin, and Greenland.[40] Surprisingly, the HDV worldwide distribution does not exactly match that of HBV. Moreover, it is unclear why HDV prevalence may differ substantially between neighboring countries or even between neighboring regions, or villages, such as in Africa or the Amazon basin.[11,19] But one has to keep in mind that HDV prevalence has not been investigated, or reported, in many countries and hence, its global prevalence and geographic distribution remain incomplete.

To generate a better estimate of HDV prevalence, Chen and colleagues[33] performed a meta-analysis of studies published prior to 2017. They concluded that the pooled prevalence of HDV infection worldwide could be as high as 10% in the population of HBsAg carriers, that is, a rate double that reported in 2003.[40] Furthermore, seroprevalence—anti-HDAg antibodies—was estimated at 37% in the populations of HBsAg-positive IVDUs, and at 17% in the high-risk sexual behavior population. Based on this reassessment, HDV prevalence appears lower in asymptomatic HBsAg carriers compared to patients with active hepatitis, and the current HDV epidemics seem to mainly result from IVD use (37% of HBsAg carriers are anti-HDAg positive) and high-risk sexual behavior (17% of HBsAg carriers are anti-HDAg positive). Yet, this might not be true in countries such as Mongolia where iatrogenic infections are considered to play a major role. In a similar meta-analysis,[120] the pooled prevalence was reported at 13% among HBV carriers, corresponding to 48 to 60 million infections globally. HDV was most prevalent in HBV carriers suffering from fulminant hepatitis (26.7% HDV prevalence), cirrhosis (25.7%), and HCC (19.8%). In this study, the main risk factors for HDV transmission were IVDU and HIV or HCV coinfections. Even though, there were methodological weaknesses in both of the above-mentioned studies, they confirm that the global prevalence of HDV had been largely underestimated, and they agree on a real prevalence of 10% to 13% in the population of HBsAg carriers worldwide.

In Europe, because of universal HBV vaccination and improved socioeconomic conditions, there has been a significant decline in the incidence of HDV infection over the past two decades[145] and a consequential change of epidemiological data, with a preponderance of HDV-infected individuals with advanced cirrhosis.[154] However, recent HDV infections are still observed among high-risk groups such as IVDUs and immigrants from hepatitis D endemic countries.[145] Overall, the new data on HDV prevalence should advocate for all HBsAg-positive individuals to be tested for HDV as a public health measure aimed at reducing transmission and at providing better treatment to CHD patients.

Genetic Diversity

Eight different HDV clades, or genotypes (HDV-1 to -8), have been described (Fig. 19.15), and each has distinct geographic distribution. The classification has been extended from 1 to 4 subgenotypes per genotype.[96] HDV genotypes display an extensive divergence of their nucleotide sequences, with up to 40% divergence between genotypes 1 and 3, while maintaining

the same genome structure and organization.[37] But despite a high divergence at the nucleotide sequence level, the functional domains of HDAg proteins are highly conserved.

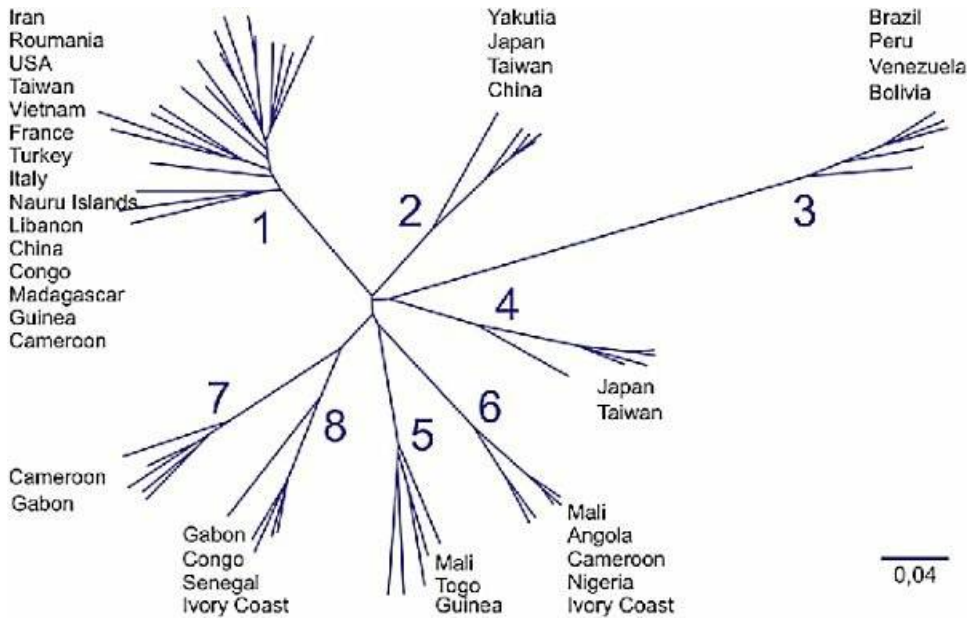

FIGURE 19.15 Unrooted phylogenetic network of HDV genomic sequences, computed with the SplitTree4 application using Clustal Omega, MAFFT, MUSCLE, T-COFFEE, and M-COFFEE alignments, with individual tree reconstruction. Results were obtained through Bayesian analyses using a general time reversible model with proportion of invariable sites and gamma distribution of four classes. At the end of analyses, 25% of the initial tree search was discarded. Note that all the eight genotypes are well defined.

HDV-1 is the most prevalent worldwide and predominant in Europe and North America. HDV-1 strains might have evolved for a long time from an ancient ancestor that spread to the rest of the world through human migrations. HDV-1 and -5-to-8 appear to originate from central and eastern Africa, emphasizing the wide diversity of HDV in the African continent.[96] HDV-1 is generally associated with mild-to-severe disease, often followed over time by liver cirrhosis and hepatocellular carcinoma.[166] HDV-2 is prevalent in East Asia and the Yakutia Republic of the Russian Federation. It generally causes a mild disease,[189] although in a particular population of Yakutia, it appears as aggressive as HDV-1.[81] HDV-3 is found almost exclusively in the north part of South America. It displays the highest genetic divergence compared to the other genotypes (30% to 40%), with an intragenotype divergence of approximately 10%. HDV-3 is the most aggressive genotype, often associated with fulminant hepatitis and death.[25] HDV-4 is present in Taiwan and Japan. A prospective study of HBsAg carriers in Taiwan revealed that HDV-4 was prevalent (72.2%) among IVDUs, whereas HDV-2 was predominant in the non-IVDU population (73.3%).[106] In the Japanese Miyako Islands, HDV-4 appeared to cause a particularly severe disease.[183] With regard to the African strains, HDV-1 and HDV-5 to -8, the characterization of the associated disease is not yet well documented.

Finally, genetic diversity of HDV might also result from RNA recombination upon mixed infections, allowing the sudden emergence of new strains with functional genomic structure.[105] This phenomenon may add to the difficulty of detecting and quantifying HDV RNA, particularly in patients infected with African strains.[97]

CLINICAL FEATURES

As an obligate HBV satellite, HDV can establish an infection only in the presence of its helper and under circumstances of simultaneous coinfection with HBV, or superinfection of individuals already infected with HBV (Fig. 19.16).[40] In most immunocompetent adults, coinfection progresses to resolution of both HBV and HDV infections, evolving to chronicity in less than 5% of cases.[43] The clinical course of acute coinfection ranges from mild to fulminant hepatitis during which elevation of serum ALT/AST levels may follow a biphasic course, assumed to result from an initial HBV spread followed by HDV propagation.[164] Symptoms include episodes of fatigue, nausea, and hyporexia. The risk of acute liver failure—fulminant hepatitis—is nonetheless much higher than that observed during acute HBV monoinfection.[41,196]

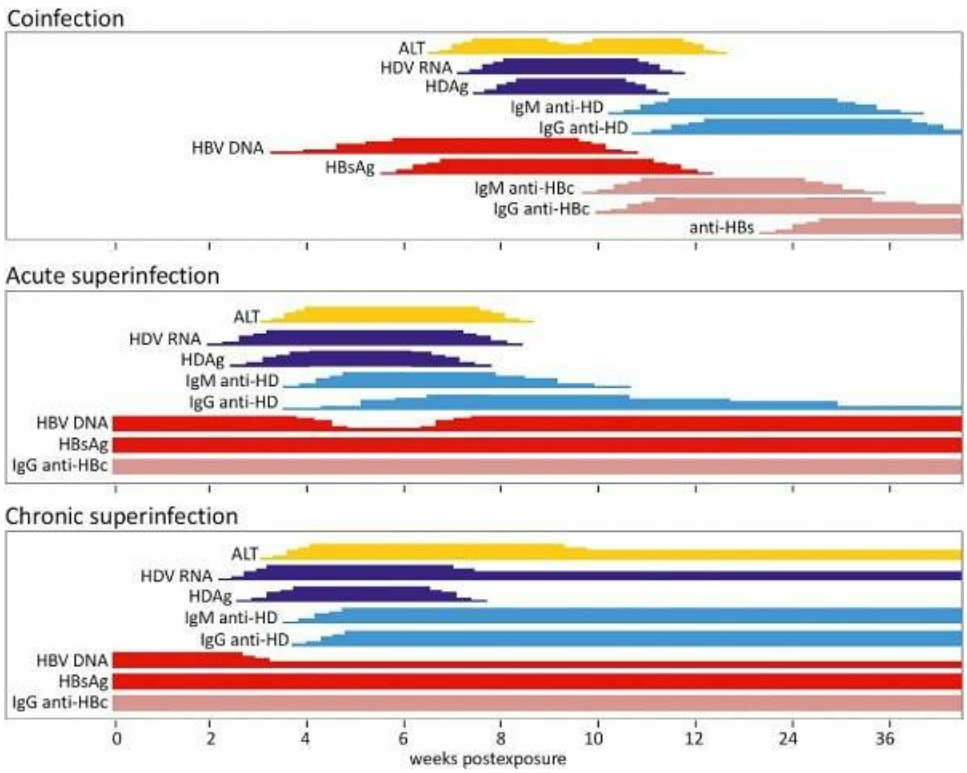

FIGURE 19.16 Virological and serological markers in the settings of coinfection, acute superinfection, and chronic superinfection. HBV markers are indicated in *red*; HDV markers in *blue*.

Superinfection of a patient chronically infected with HBV is associated with an episode of acute hepatitis that occurs after a short incubation period and is associated with a high risk of fulminant hepatitis.[41] Strikingly, more than 90% of superinfected HBV carriers progress to chronic HDV infection.[41,196] The resulting CHD is considered the most severe form of chronic viral hepatitis, and it evolves more rapidly toward cirrhosis and liver failure in comparison to CHB.[46] Liver failure is the most frequent evolution of CHD,[132] with 10% to 15% of patients developing cirrhosis within 5 years, and 80% within 30 years.[45] The risk of HCC is also higher in CHD as compared to CHB.[46,84] Risk factors of disease progression are male sex, cirrhosis at presentation, and lack of antiviral therapy.[132] CHD patients with detectable HDV-RNA in the serum are also the most exposed to liver decompensation and HCC.[153] The clinical outcome of HDV infection depends also on the HBV- and HDV-respective genotypes as observed in populations of the Amazon Basin where the most severe form of acute hepatitis D is caused by HDV-3 associated to HBV-F.[25]

DIAGNOSIS

Screening for HDV infection is too often neglected. Ideally, it should be performed in all HBsAg carriers and in priority in IVDUs, in individuals with high-risk sexual behaviors and immigrants from endemic regions. For a very short period of time (2 to 3 weeks) at the acute phase of replication, and before clinical hepatitis, serum HDAg can be measured by enzyme-linked immunosorbent assay (ELISA) (Fig. 19.16). But, due to its lack of sensitivity, it is no longer in use for diagnosis. Intrahepatic detection of HDAg by immunohistochemistry can only be used when a liver biopsy sample is available. In immune-competent patients, immunoglobulins M and G (IgM and IgG) are the serological markers to test. IgM anti-HDAg appear 2 to 3 weeks after the onset of symptoms; they generally disappear 2 to 3 months after the acute phase of infection but may persist for months in chronically infected individuals. IgG anti-HDAg appear at later times in patients who resolve HDV infection or those who remain chronically infected. Testing for total anti-HDAg antibodies using commercial ELISAs is currently the first step for the detection of HDV infection. Recently, a highly sensitive assay revealed that 60% of HBsAg carriers in a Mongolian population were seropositive.[32] In case of positive serology, serum should be tested for HDV RNA, a procedure now accessible to diagnostic laboratories using commercially available quantitative real-time PCR assays to detect as few as 10 copies of HDV RNA per mL.[97] Still, the robustness of the HDV RNA assay with regard to highly divergent HDV genotypes remains to be confirmed. A WHO international HDV RNA standard has become available for reporting viremia in international units (IU).

PREVENTION AND CONTROL

Vaccine

No HDV-specific vaccine is currently available to protect the large population—estimated at 257 million worldwide—of HBV chronic carriers from becoming superinfected with HDV. An efficient HDV vaccine would be of great benefit to this population because 90% of HBV carriers become chronically infected with HDV and, consequently, at higher risk of liver disease progression to cirrhosis and HCC. Experiments on vaccine development for prevention of HDV superinfection have been conducted in the woodchuck model, but with only limited success. A DNA-prime/viral-vector-boost immunization approach was used that could induce an HDV-specific CD8 T-cell response and prevent coinfection. However, the T-cell response was considered insufficient to inhibit the spread of HDV in chronic HBV carriers.[152] Obviously, new strategies are needed to develop an HDV-specific vaccine.

Since HDV is an obligate satellite of HBV, HBV vaccination protects naive individuals against coinfection. At the population level, the HBV vaccination programs implemented in regions of high endemicity for HBV has helped contain the overall incidence of HDV infection, notably in Italy where circulation of HDV has decreased at a rate of 1.5% per year between 1987 and 1997 as a consequence of universal HBV vaccination in newborns and adolescents.[50]

Treatment

Current Treatment

Current guidelines do not mention specific treatment for acute hepatitis D, except for a liver transplantation in case of fulminant, end-stage liver disease.[131] For CHD patients, the elimination of both HDV and HBV is the ideal endpoint, yet not achievable in the absence of an efficient treatment to cure HBV infection. The major difficulty with HDV infection lies with its intrinsic characteristics; most of the genome replication mechanism is carried out by cellular enzymes that are essential for cell metabolism. Eventually, the HDV ribozymes could be targeted, but the presence of HDV-like ribozymes within host cells may limit the adequacy of such an antiviral approach.[185]

The only effective current treatment is a prolonged administration of IFN-alpha. Long-term IFN treatment decreases the risk of disease progression, irrespective of the on-treatment response pattern, but the rate of sustained virological response—that is, loss of serum HDV RNA—is low. The use of the more active pegylated IFN-alpha (pegIFN-alpha) has led to a more sustained viral response, but in only 25% to 30% of patients, 50% of whom eventually relapsed at 6-month follow-up. The currently recommended course of treatment is a weekly administration of pegIFN-alpha for a 48-week duration. The mechanism through which pegIFN suppresses HDV remains uncertain. When tested in PHH, or in the liver-humanized mouse model, IFN-alpha demonstrated an antiviral effect that appeared to occur at an early phase of infection, that is, viral entry, and/or initiation of replication.[53,67]

Future Treatments

Peg IFN-lambda, a type III interferon, is currently being evaluated in phase III clinical trials based on its better tolerability as compared to IFN-alpha for an equivalent efficacy.[20] In the United States, pegIFN-lambda benefits from an “Orphan Drug” designation that allows to fast-track its evaluation in clinical trials.

Myrcludex-B (also referred to as Bulevirtide) (Fig. 19.17) is a myristoylated pre-S1 peptide that inhibits HBV and HDV entry into human hepatocytes.[112] The receptor-blocking lipopeptide prevents HBV and HDV virions from binding to hNTCP at the basolateral hepatocyte membrane. Data from preclinical trials indicate that the antiviral effect is observed at doses 2 log10 lower than those required for inhibition of the bile acid transport activity of hNTCP. In Ib/IIa clinical trials, CHD patients who received Myrcludex B as monotherapy showed a significant reduction on serum HDV RNA and ALT levels. A combination of Myrcludex and pegIFN-alpha had a synergistic antiviral effect on HDV RNA and HBV DNA but no impact on serum HBsAg.[108]

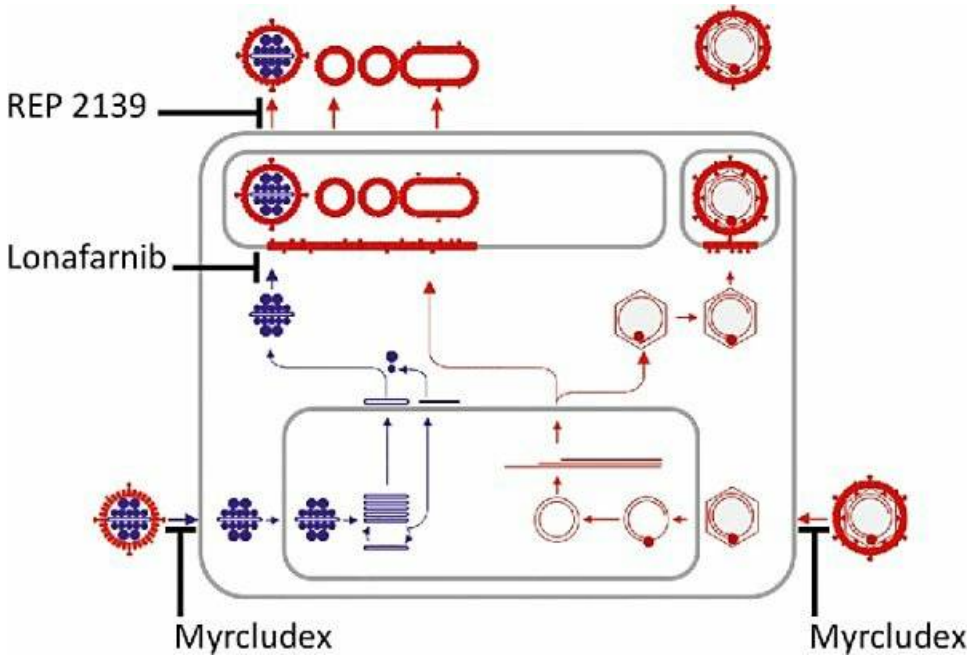

FIGURE 19.17 Novel treatments for HDV infection. Novel antiviral targets in the HDV replication cycle are at the steps of viral entry (Myrcludex), HDV virion assembly by HBV envelope proteins (Lonafarnib), and release of HDV virions and HBV SVPs (REP 2139).

Nucleic acid polymers (NAPs) are amphipathic phosphorothioate oligonucleotides that are able to establish interactions with a wide variety of integral membrane proteins in a sequence-independent manner. NAPs are assumed to interact with the hydrophobic alpha-helices such as transmembrane domains of viral glycoproteins. In tissue culture, NAPs were shown to interfere with the release of HBV SVPs (HBsAg),[12] and with HDV entry in susceptible cells.[10] In a phase II trial, a small cohort of CHD patients who received NAPs (REP 2139) for 15 weeks achieved a drastic reduction of circulating HBsAg and HDV RNA during the initial phase of NAPs-alone treatment. Combined with pegIFN, a high rate of HBsAg loss and anti-HBsAg seroconversion was observed, with clinical benefits to the patients.[8]

Lonafarnib is a farnesyl-transferase inhibitor that was developed as anticancer drug. When used *in vitro* on cells permissive for the production of HDV virions, it inhibits the farnesylation

of L-HDAg, thereby preventing HDV RNP interaction with the HBV envelope proteins and the subsequent production of infectious HDV particles.[18] In a phase II clinical study, CHD patients treated with Lonafarnib for 4 weeks had a 1.5 log10 decline of serum HDV RNA at the end of treatment, but this was accompanied by significant adverse effects.[88] The combination of Lonafarnib with pegIFN-alpha achieved a better reduction of HDV-RNA as compared to pegIFN-alpha alone.[197]

PERSPECTIVES

HDV is unique among animal viruses in many aspects of its biology. It is a subviral agent with a small ssRNA genome and a single viral protein devoid of any enzymatic activity. Yet, with the help of HBV, it manages to cause the most severe form of viral hepatitis in humans.

We are still at the early stages of deciphering the mechanism of HDV RNA replication, and even though there is a growing consensus for genome and mRNA synthesis taking place in pol II–associated transcription factories in the nucleoplasm, and for antigenome synthesis restricted to the nucleolus, the identity of the enzyme(s) involved in antigenome production is still a matter of debate, and neither one of pol II, pol I, pol III, or even a cellular RdRp can be definitely excluded. However, the mechanism by which HDV usurps the cell transcription machinery for replication has begun to unravel when S-HDAg was shown to mimic the activity of acetylated histones in nucleosome as a means to recruit chromatin remodelers for HDV RNA synthesis by pol II. Progress in this area will undoubtedly help understand HDV persistence.

We know that in chimeric mice, HDV RNA can survive through cell division and even replicate in daughter cells in the absence of its helper. If true in humans, HDV RNA would then behave opposite to HBV circular covalently closed (ccc) DNA, by amplifying itself through cell division, while the latter would be lost in the process. Obviously, such distinctive features add a further degree of complexity to the interplay between HDV and its helper, especially in the context of CHD when hepatocyte turnover is increased, and upon antiviral treatment.

There are other gaps to fill in our knowledge of the complex relationship between HDV, the helper HBV, and the host immune system. To this end, the recent development of liver-humanized mouse models permissive for HBV/HDV coinfection has already provided insights into the interplay between the two viruses,[53,138] and it is expected that the forthcoming models of mice humanized for both liver and the immune system will broaden our understanding of the HDV/host interaction.[165]

Although progress has been made in the understanding of the interaction between HDV RNP and HBV envelope proteins, the binding—direct or indirect—between L-HDAg and S-HBsAg, which is at the center of the HBV/HDV interaction, should be further characterized as it may represent a new target for antiviral development.

The role of HDV in HCC development also requires further investigation as it is still questionable whether HDV plays a direct role in carcinogenesis. The long-lasting viral RNA replication and HDAg production in hepatocytes can either instigate cell transformation or induce cell death and compensatory proliferation.

With regard to virus taxonomy, the recent, and surprising, news is that HDV may not stand alone anymore in the classification of viruses. HDV and the recently identified HDV-like RNAs may have arisen from a common ancestor.[30] But at this point, it is still questionable whether these circular RNAs are infectious agent, and eventually satellites of viruses in their respective hosts. Undoubtedly, more of such HDV-like RNAs will be discovered when metatranscriptomic analyses are extended to more species, and eventually to humans or other species susceptible to *Orthohepadnaviruses* infection. Since the latter have adapted to bats, a species known as a reservoir to many viral species, including *Hepadnaviruses*, it wouldn't be surprising to find HDV-like RNAs in the bat's transcriptome.

Finally, based upon the recent reevaluation of global prevalence of HDV infection at 10% to 13% of HBV-infected individuals,[33,120] HDV infection appears to be more frequent than previously thought, giving further incentive to screen all HBsAg-positive individuals for anti-HDAg and test for HDV RNA in case of positive serology. A larger population of HDV carriers may also indicate a greater diversity that could eventually preclude detection with the actual commercial assays. Taking into account the large number of HDV carriers worldwide, the severity of HDV-related disease, the absence of a specific HDV vaccine, and the scarcity of treatment options, HDV infection now rises as a major public health challenge that requires intensifying efforts to develop innovative antiviral strategies.

Acknowledgments

INTRODUCTION AND HISTORY

Mimiviruses are double-stranded DNA viruses with genomes in the megabase range that infect a variety of eukaryotic hosts and are especially prominent among protists. Due to the size and complexity of their genomes and particles, giant viruses have challenged our definition of viruses and their roles in evolution. Whereas unusually large virus particles had been observed early in various protists by electron microscopy,[45,69,147] and algae-infecting DNA viruses with genome lengths exceeding those of herpes- and poxviruses were known since the 1980s,[106,164,165] the first giant virus with a genome longer than one million base pairs was described in 2004.[129] The

serendipitous discovery of Acanthamoeba polyphaga mimivirus (APMV, mimivirus stands for mimicking microbe) followed the search for the causative agent of a 1992 pneumonia outbreak in Bradford, England. The team of Dr. T.J. Rowbotham isolated an obligate intracellular parasite of amoebae from the water of a cooling tower but failed to identify the pathogenic microorganism, which stained Gram positive and was named Bradford coccus.[128] The viral nature of this microbe was revealed only years later at the Unité des Rickettsies in Marseille, France, when electron micrographs showed isometric capsids with a diameter of approximately 500 nm.[95] DNA sequencing and bioinformatic analysis of the 1.2 megabase genome of mimivirus[129] heralded a new era in virology, and hundreds of giant viruses were isolated in subsequent years using the freshwater protist *Acanthamoeba polyphaga* as a host.[1,5,7,8,22,23,27,97,102,103,123] However, mimiviruses are not restricted to amoebae and infect many different protists[41,55,110,116,137,167] as well as animal hosts such as worms, sponges, and even vertebrates.[37,146]

CLASSIFICATION OF VIRUSES WITHIN THE FAMILY *MIMIVIRIDAE*

The family *Mimiviridae* was established in 2005 within the Nucleo-Cytoplasmic Large DNA Viruses (NCLDV), an unofficial grouping of several families of large dsDNA viruses that, at the time, included the *Poxviridae*, *Asfarviridae*, *Iridoviridae*, and *Phycodnaviridae*.[74,75,129] *Acanthamoeba polyphaga mimivirus* remained the only member of the sole genus *Mimivirus* until *Cafeteria roenbergensis virus* (CroV) was added to the family in 2011 within its own genus *Cafeteriavirus*.[55] With the 2020 reclassification of the global taxonomic framework of viruses, *Mimiviridae* are now found in the realm *Varidnaviria*, the kingdom *Bamfordvirae*, the phylum *Nucleocytoviricota*, the class *Megaviricetes*, and the order *Imitervirales*.[87] With this new classification scheme, previously proposed taxa such as the order Megavirales and the family *Megaviridae* have become obsolete.[8,40] Prompted by the serendipitous discovery of APMV, dozens of closely and more distantly related giant viruses were isolated in the following decade. Currently, hundreds of isolates and thousands of metagenomic sequences call for a refined classification within the family *Mimiviridae*.[22,34,59,64,97,143] Whereas the family was initially composed only of viruses that infected heterotrophic protists and had genome sizes upward of 600 kbp (APMV, CroV), it became soon apparent that algae-infecting viruses with shorter genomes (300 to 600 kbp) shared essential properties with the larger mimiviruses.[65,78,108,110,137,144,173] These viruses would thus no longer be classified automatically within the family *Phycodnaviridae*, which until then exclusively harbored large algal DNA viruses. In addition to isolates, various metagenomic studies revealed a high diversity of mimiviruses in different environments such as open ocean, forest soil, and waste water.[72,117,141_143] These genomes helped to refine the taxonomic structure within the *Mimiviridae*, and the following subfamilies have been proposed (Fig. 20.1): the *Megamimivirinae* would comprise the *Acanthamoeba*-infecting mimiviruses[64]; the *Megamimivirinae* would group together algae-infecting mimiviruses with medium-sized genomes[34,64]; the *Klosneuvirinae* would contain various metagenome-assembled giant viruses as

well as the cultured *Bodo saltans* virus (BsV-1) and Yasminevirus[10,41,141,142]; and finally, CroV and several related viruses[55,117,142] could constitute a separate subfamily. Furthermore, a genus-level classification is justifiable for the proposed *Megamimivirinae*, because this clade has been sampled in sufficient depth by dozens of isolates, which fall into four well-defined groups. The first group, also known as lineage A, comprises APMV and its close relatives, with genome lengths of 1.18 megabase pairs (Mbp) and a virion diameter of 750 nm (including fibers) and would correspond to the genus *Mimivirus*.[62,129] The second group (lineage B) comprises *Megavirus chilensis* and its relatives, with genome lengths of 1.26 Mbp and a virion diameter of 680 nm.[8] This group would be classified as the proposed genus Megavirus. The third group (lineage C) is made of *Acanthamoeba polyphaga* moumouvirus and its relatives, with genome lengths of 1.02 Mbp and a virion diameter of 620 nm, resulting in the proposed genus Moumouvirus.[174] The fourth proposed genus is called Tupanvirus and includes the tailed mimiviruses Tupanvirus soda lake and Tupanvirus deep ocean, with genome lengths of 1.4 to 1.5 Mbp and a virion length of approximately 1.2 μm (including fibers and tail structure).[5] Further subdivisions and rearrangements within the family *Mimiviridae* will be necessary as new isolates and metagenomes become available. In particular, the proposed subfamily *Mesomimivirinae* with giant viruses infecting mostly photosynthetic protists appears to harbor an enormous diversity that is yet to be explored.[143]

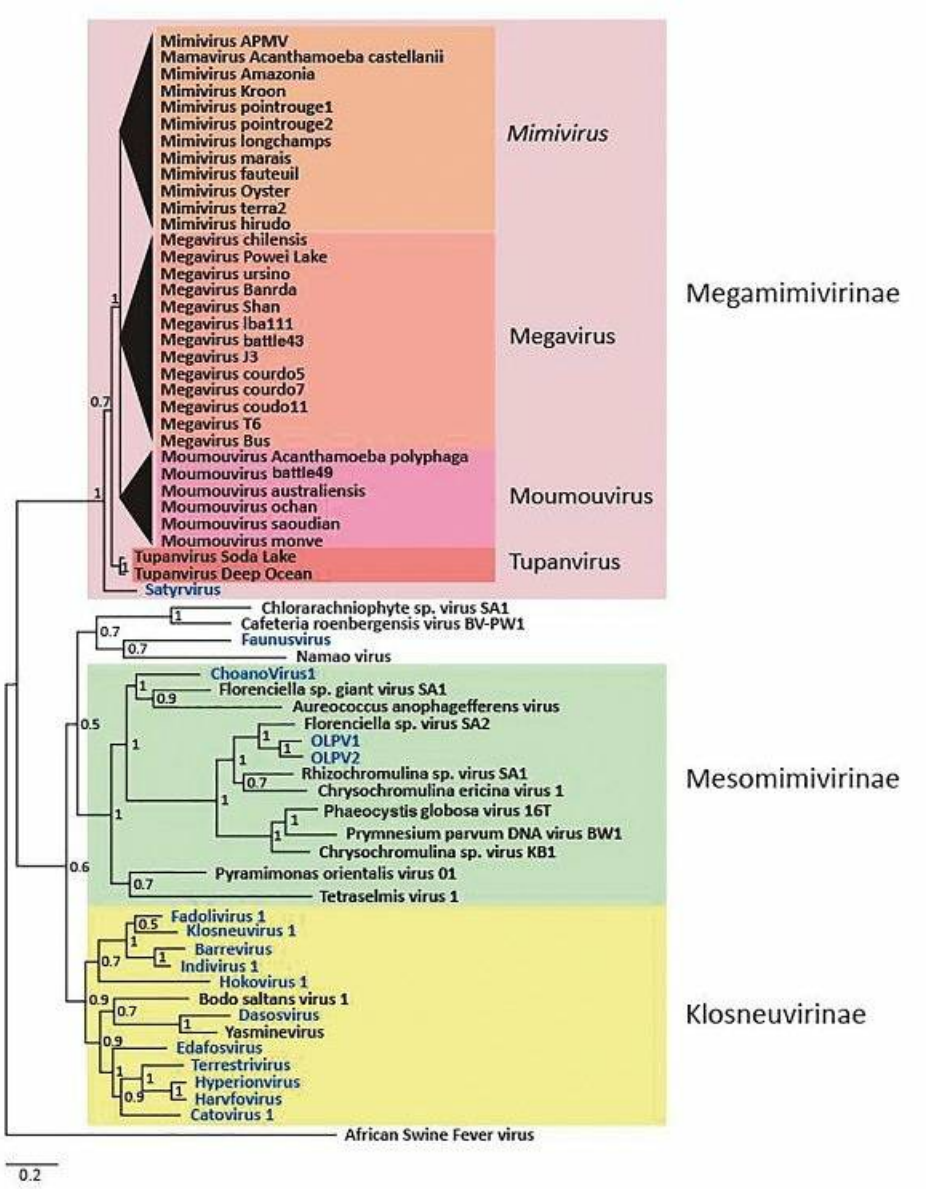

FIGURE 20.1 Phylogenetic relationship within the family *Mimiviridae* based on DNA polymerase B. This Bayesian tree shows the proposed substructure of viral clades within the family. Note that the only ICTV-approved taxon within the family *Mimiviridae* shown in this tree is the genus *Mimivirus* with its sole member *Acanthamoeba polyphaga mimivirus*; other taxa have not been approved and may be subject to changes. Genomes assembled from metagenomic data are printed in blue. Nodes are labeled with posterior probabilities. The unpublished genomes of Chlorarachniophyte sp. virus SA1, Florenciella sp. giant viruses SA1 and SA2, Rhizochromulina sp. virus SA1, and Chrysochromulina sp. virus KB1 were kindly provided by Dr. Christopher Schvarcz and Dr. Grieg Steward, Univ. of Hawai'i at Manoa, USA.

VIRION STRUCTURE

The infectious particles of mimiviruses are composed of multiple layers and substructures that involve hundreds of viral proteins. While all viruses in the family *Mimiviridae* have capsids with icosahedral symmetry that enclose the viral DNA genome in an internal lipid membrane, they differ remarkably in their diameter, triangulation number, exit portal structure, and other morphological features such as external fibers and tail structures (Fig. 20.2). The best-studied representative is APMV, whose virions have been examined by various techniques including thin-section electron microscopy, cryo-electron microscopy and tomography, scanning electron microscopy, STEM tomography, atomic force microscopy, and x-ray free electron lasers.[6,113_115,138,145,159,170,171,179] The APMV virion is a multilayered structure, composed of an external fiber layer, an outer capsid shell, an inner capsid shell, an internal membrane, and a core wall enclosing the genome and accessory proteins (Fig. 20.3). The outer protein shell of the capsid is 500 nm in diameter. The capsid has icosahedral symmetry and its 20 faces are composed of pseudo-hexagonal capsomers that contain trimers of the major capsid protein (MCP) encoded by gene *L425*. The MCPs of mimiviruses adopt a double jelly-roll fold, similar to other NCLDVs with icosahedral capsids.[81] Each jelly-roll consists of eight β-strands named A to H, which are connected by loops. The surface-exposed parts of the MCP between the DE and FG loops contain insertions of variable lengths that protrude from capsomers as tower-like structures.[171] APMV and CroV encode three additional capsid protein homologs with predicted double jelly-roll architecture.[57,171] The capsid vertices with their fivefold symmetry are made of pentameric capsomers formed by the penton protein. With recent advances in high-resolution imaging of macromolecular structures by cryo-electron microscopy, we have begun to understand the molecular machinery that determines the exact dimensions of large icosahedral capsids. Cryo-EM studies of the phycodnavirus PBCV-1 revealed a protein network beneath the outer capsid layer, which includes the minor capsid protein P2 that acts as a molecular ruler and is therefore called the tape-measure protein.[48] The P2 protein connects neighboring fivefold vertices and thus likely determines the PBCV-1 capsid size. Homologs of this tape-measure protein are present in other phycodnaviruses, in APMV (*L454* gene product) and CroV (*crov185* gene product), as well as in asfarviruses,[105,168] and the length of the tape-measure protein roughly correlates with the dimensions of the respective capsid: 566 aa and 190 nm for PBCV-1; 869 aa and 300 nm for CroV; and 1257 aa and 500 nm for APMV. These findings suggest that the capsid sizing mechanism is conserved in different families of viruses with icosahedral capsids in the phylum *Nucleocytoviricota*.

Membrane assembly during the Infection cycle of the giant mimivirus. *PLoS Pathog* 2013;9:e1003367.)

Members of the *Mimiviridae* have the largest icosahedral capsids that have been described so far and accordingly, these capsids possess the highest triangulation (*T*) numbers. The largest capsid for which a *T* number is currently known is that of CroV with $T = 499$ (h = 7, k = 18).[172] Based on the limited resolution of structural studies with larger mimiviruses, the *T* number of the APMV capsid has not been determined accurately, but it is estimated to be between 972 and 1,200 ($h = 19 \pm 1$, $k = 19 \pm 1$).[81]

Members of the *Mimiviridae* often exhibit a single modified vertex structure and various surface modifications on their capsids. A common feature of mimiviruses is an exit portal structure at one of the twelve vertices, where the nucleocapsid underneath the portal shows a characteristic concave depression (Fig. 20.4). In APMV, this unique vertex has been called the stargate, as it opens in a star-like formation to expose the lipid layer below.[179] The stargate portal is sealed by a large proteinaceous complex known as the starfish, because it consists of five 40-nm-thick and 50-nm-wide arms that extend about 200 nm toward the nearest fivefold vertices.[138,171] During phagocytosis of APMV and Tupanvirus particles, these structures enable a controlled opening of the capsid to release the genome into the host cytoplasm.

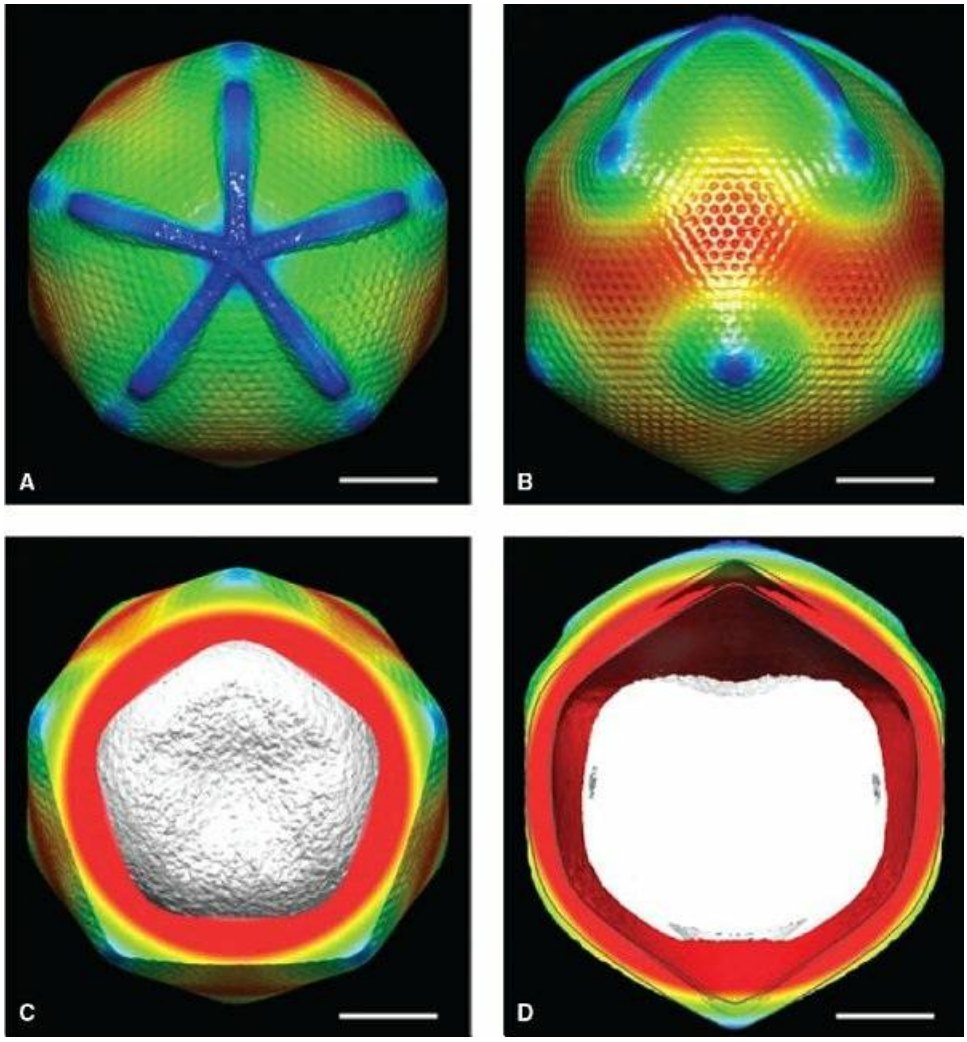

FIGURE 20.4 Cryo-electron microscopy reconstruction of the APMV capsid. Colors are based on the distance from the center of the capsid. **A:** Top-down view onto the unique pentameric vertex with the starfish structure (blue). **B:** Side view of the capsid with the unique vertex on top. **C and D:** Cross sections of the images shown in **(A)** and **(B)**, respectively, visualizing the concave depression of the nucleocapsid beneath the exit portal. **(C)** is sliced just below the stargate portal; **(D)** is a central cross section. All scale bars are 100 nm. (Adapted from Xiao C, et al. Structural studies of the giant mimivirus. *PLoS Biol* 2009;7:e92.)

Whereas isometric viruses of eukaryotes generally lack recognizable tail structures, some mimiviruses such as Tupanvirus soda lake and Tupanvirus deep ocean present capsids with cylindrical tails that are typically approximately 550 nm long and approximately 450 nm thick.[5] The total length of a Tupanvirus particle amounts to approximately 1.2 μm, but variations in tail length can lead to particles that are up to 2.3 μm long.[132] In electron micrographs, Tupanvirus tails are attached to the capsid at the vertex opposite of the unique stargate vertex, but the tail is not continuous with the outer layer of the icosahedral capsid and appears to be partially filled with electron-dense material that may be released upon cell entry.[5] The biological role of this tail

and its content remain to be studied.

The capsid surface of APMV and related mimiviruses of the proposed subfamily *Megamimivirinae* is decorated with a dense layer of fibers that spare only the starfish structure. In APMV, these outer capsid fibers are 120 to 140 nm long and approximately 1.4 nm thick, whereas *Megavirus chilensis* capsids feature shorter (approximately 75 nm) fibers with occasional patches of longer fibers named “cowlicks”.[8,82,169,171] Tupanvirus fibers are slightly thicker and shorter than those of APMV and also cover the outside of the tail structures.[132] The fibers consist of heavily glycosylated proteins that form a peptidoglycan-like structure. As a result, the fiber layer stains Gram positive, which contributed to the initial misclassification of APMV as a bacterium.[95,128] Components of the fibers include APMV gene products R135, L725, and L829.[24] *R135* encodes a highly antigenic protein whose structure is similar to glucose–methanol–choline oxidoreductases.[83] However, despite the proteinaceous nature of the fibers, proteolysis only occurs after treatment with lysozyme.[171] Several glycosyltransferases are involved in fiber formation and maturation, including the APMV *L136* gene that encodes a pyridoxal phosphate-dependent sugar aminotransferase that catalyzes the biosynthesis of UDP-viosamine, one of the major components of viral fibers.[124] Together with other sugar modifications, the fibers mediate adhesion of APMV virions to host sugars such as mannose and *N*-acetylglucosamine, which are present on the amoebal cell surface.[134] Overall, by mimicking the peptidoglycan layers of Gram-positive bacteria, the outer fiber layer of mimivirus capsids may facilitate recognition and uptake of virions by phagocytosis into the amoebal host. The fiber layer also contributes to the stability of the virion, making it resistant to most proteases.[92] The composition of the fiber layer may vary even within a genus, since fibers of the APMV-related Samba virus are resistant to lysozyme/proteinase K/bromelain treatment, whereas APMV fibers can be removed with this method.[139] Another role of the fiber layer has been proposed in connection with entry of the Sputnik virophage (see p.15), which may attach to the APMV fibers and enter the host cell as a composite with the giant virus.[24]

Virions of mimiviruses are composed of more than one hundred virus-encoded proteins, with 236 different proteins identified in APMV particles, 141 in CroV, and 127 in Tupanvirus.[5,35,57,61,107] Structural proteins form the icosahedral shell, outer fibers, and tail structures (if present); they position the internal lipid membrane and compose the inner core layer. In addition, mimiviruses package a considerable number of nonstructural proteins with various enzymatic functions. Notably, this includes the presence of a presumably complete transcription machinery with six to eight DNA-dependent RNA polymerase subunits, homologs of vaccinia virus transcription factors A7, D6, and D11, a trifunctional mRNA capping enzyme, polyadenylate polymerase, and associated helicases.[5,57,131] Other functional categories are DNA repair, redox pathways, and protein modification.

[1]Note that "structural proteins" is not synonymous with "virion proteins", that is, not every viral protein that is part of the virion is automatically classified as a structural protein. The difference is made between viral proteins that contribute to the architecture and integrity of the virus particle, and packaged viral proteins whose function is required during the intracellular stage of the viral replication cycle, often during early phase. This distinction is especially important for giant viruses, which package many nonstructural proteins with various enzymatic activities.

Similar to poxviruses, whose infection cycles also take place exclusively in the cytoplasm,[140] enzymatic functions present in mimivirus capsids are probably essential for the initial infection

stages, in particular viral genome maintenance and early gene expression. These enzymes are thus located in the inner nucleocapsid, also known as the viral core, which is embedded in the internal lipid layer of the virion. The structure of the viral core is mainly formed by the major core protein that is encoded by the APMV *L410* gene and its orthologs in other mimiviruses.[131]

GENOME STRUCTURE AND ORGANIZATION

Genome length varies considerably among different mimiviruses, currently ranging from 371 kbp in Aureococcus anophagefferens virus (AaV) to 1,516 kbp in Tupanvirus deep ocean (Table 20.1).[5,110] The DNA packaging density of APMV and other mimiviruses is low compared to other eukaryotic viruses and bacteriophages, prompting speculations about the upper genome size limits for giant viruses.[36] With the exception of Yasminevirus that has a GC content of 40.2% and Tetraselmis viridis virus 1, whose genome has a GC content of 41.2% and was assembled into a circular sequence, members of the *Mimiviridae* have linear genomes and low GC contents between 23% and 32%.[10,64,144] Their coding density is typically around 90% and the number of predicted proteins encoded by mimiviruses ranges from a few hundred (377 for AaV) to more than one thousand (1,359 for Tupanvirus deep ocean). Open reading frames (ORFs) are usually nonoverlapping, distributed approximately equally on both DNA strands, and separated by short intergenic regions (157 nt on average for APMV) that feature an elevated AT-content and harbor gene promoter and terminator elements.[26,121] The low GC content of the viral genome leads to a strong bias toward AT-rich codons and a shift in the amino acid composition toward asparagine, isoleucine, lysine, and other amino acids encoded by AT-rich codons.[39] In contrast to the AT-rich genomes of mimiviruses and their distinct codon usage profile, the genomes of their protist hosts often display high GC contents and opposing amino acid frequencies (Fig. 20.5).[71,129,148]

TABLE 20.1 Genome features of cultured *Mimiviridae* members

Virus	Genome Length (bp)	Genome Topology	GC Content	Predicted Genes	Coding Density	Reference
Aureococcus anophagefferens virus (AaV)	370,920	Linear	28.7%	377	88%	110
Acanthamoeba polyphaga mimivirus (APMV)	1,181,549	Linear	28.0%	979	90%	129
Acanthamoeba polyphaga moumouvirus	1,021,348	Linear	24.6%	930	91%	174
Bodo saltans virus (BsV-1)	1,385,869	Linear	25.3%	1,227	85%	41
Cafeteria roenbergensis virus (CroV BV-PW1)	691,790	Linear	23.3%	631	91%	55
Chrysochromulina ericina virus (CeV-1)	473,538	Linear	26.3%	512	91%	64

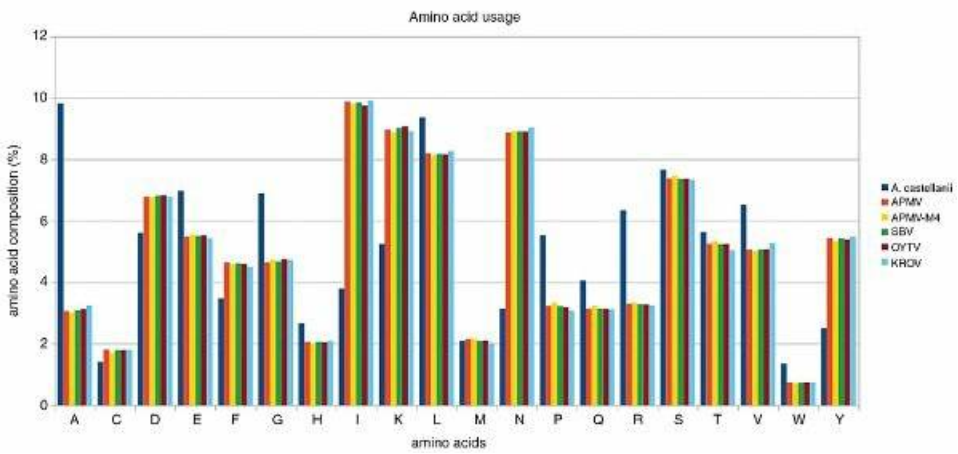

FIGURE 20.5 Amino acid frequencies of several mimivirus strains compared to their host *A. castellanii*. The amino acid usage profiles of APMV, the APMV deletion variant M4, Samba virus (SBV), oyster virus (OYTV), and Kroon virus (KROV) differ substantially from that of *A. castellanii*. (Adapted from Silva LCF, et al. Modulation of the expression of mimivirus-encoded translation-related genes in response to nutrient availability during Acanthamoeba castellanii infection. *Front Microbiol* 2015;6:539.)

The best-studied genome of a *Mimiviridae* member is that of APMV.[129] Its 1,181,549 bp linear dsDNA genome is predicted to encode 1,018 genes, including 979 protein-coding genes, 6 tRNA genes, and 33 noncoding RNAs.[100,101] The genes lack spliceosomal introns, with the notable exception of the MCP *L425* gene that consists of three exons and two introns.[9,20] The APMV genome has no terminal inverted repeats as observed in other large DNA viruses but contains a 617-bp long inverted repeat at positions 22,515 and 1,180,529 that are suggested to be involved in genome replication through base pairing of these regions and loop formation into a Q-like configuration.[35]

Genes appear to be clustered by function, rather than by their temporal expression pattern.[125] Similar to poxviruses, the genome termini contain fewer conserved genes and are enriched in nonessential genes, horizontally acquired genes, and DNA repeats.[8,41,52,98] Proteins that are expressed during infection and present in the cytoplasmic viral factory are mostly encoded by the central part of the APMV genome.[61] Experimental evidence that the terminally located APMV genes are dispensable comes from passaging the virus 150 times under allopatric conditions, which led to the isolation of a deletion mutant called M4.[24] The M4 genome was only 993 kb long and contained two large deletions at either genome terminus, a 90.7-kb deletion starting at position 81,626 and a 95.6-kb deletion starting at position 1,074,695. These deletions removed 155 APMV genes, including several duplicated genes, as well as genes that are presumably involved in carbohydrate metabolism. Although the M4 mutant was still infective in cell culture, the M4 virions lacked the outer fiber layer that is present in wild-type virions. The deletions therefore affected fiber proteins and their glycosylation, leading to a bald mimivirus mutant.[24]

VIRAL TRANSLATION COMPONENTS AND

THE EVOLUTIONARY ORIGIN OF GIANT VIRUSES

Arguably, the most striking feature about the coding potential of mimiviruses is their suite of protein biosynthesis genes (Table 20.2).[3,133] Translation is a hallmark of cells and as obligate intracellular parasites, viruses use the host ribosome and the associated translation machinery to produce viral proteins. Most viruses thus do not encode their own versions of translation proteins. It therefore came as a surprise to find four aminoacyl-tRNA synthetases (aaRS; namely *ArgRS*, *CysRS*, *MetRS*, and *TyrRS*) and five translation factors in the APMV genome.[129] Analysis of the Megavirus chilensis genome revealed the four aaRS genes previously seen in APMV, an *IleRS* gene also present in CroV, and two additional aaRS genes (*AsnRS*, *TrpRS*).[8] This striking pattern of scattered aaRS genes, some of them shared by different giant viruses, led to the hypothesis that the translation components encoded by mimiviruses could represent the remnants of a once complete machinery derived from a cellular ancestor that had undergone massive reductive evolution.[99] This so-called forth domain scenario was based on the hypothesis that deeper taxon sampling of the mimivirus clade will yield additional puzzle pieces that would allow reconstruction of the ancestral set of translation proteins. In 2017, the metagenome of Klosneuvirus was published and it contained 19 aaRS genes.[141] Finally, Tupanvirus and Yasminevirus were found to encode 20 aaRS genes, covering all 20 amino acid specificities.[5,10] A central underlying assumption of the reductive evolutionary origin of giant viruses was that if mimiviruses were descendants of a lost cellular domain, then their translation genes should be deeply rooted and yield similar phyletic patterns. However, phylogenetic analysis of the viral aaRS proteins revealed a mixed pattern with some genes (e.g., IleRS) being monophyletic for mimiviruses, but the majority of viral aaRS genes were affiliated with various eukaryotic groups.[133,141] These results indicate that some aaRS genes have indeed resided for a long time in mimivirus genomes, whereas translation genes in general were transferred horizontally on multiple occasions from various hosts. Such scenarios are not in line with the forth domain hypothesis and current data rather suggest an evolutionary origin of mimiviruses from a smaller ancestor by net gene gain and gene duplications.[86] Evidence for loss of translation genes comes from genome analysis of BsV, a member of the proposed subfamily *Klosneuvirinae*.[41] In contrast to its relatives Yasminevirus with 20 aaRS genes and Klosneuvirus with 19 aaRS genes, BsV carries only five aaRS genes, three of which are pseudogenes with degenerated ORFs. These observations suggest that in BsV, aaRS genes are in the process of being lost, perhaps following a recent host switch that made these translation components obsolete.[41] The genomic flexibility of large dsDNA viruses was demonstrated in Vaccinia virus, where experimentally imposed selection pressure led to duplication of the K3L gene that encodes an antihost protein.[47] Subsequent genome reduction and retention of the best-adapted K3L copies resulted in a “gene accordion” scenario, where gene duplication, diversification, and selection, may help the virus to adapt rapidly to new environmental niches. This evolutionary mechanism may be a general feature of large and giant dsDNA viruses, as suggested by lineage-specific gene duplications in mimiviruses.[50,51] In APMV, genes encoding the 33 amino acid–long ankyrin repeat constitute the most prominent class of duplications, with up to 98 members identified.[61,155] Another example is the massive expansion in the CroV genome of genes that code for a 22-amino acid-

long domain called FNIP or IP22 repeat.[55,60,118] Interestingly, both ankyrin and FNIP/IP22 repeats mediate protein–protein interactions, implying a possible function in targeting host proteins or contributing to intracellular protein networks during viral replication.

TABLE 20.2 Translation components encoded by giant viruses of the family *Mimiviridae*

Virus	aaRS Genes	tRNA Genes	Translation Factors
APMV	4	6	5
Megavirus chilensis	7	3	4
Moumouvirus	5	3	3
CroV	1	57	8
Tupanvirus	20	70	11
Yasminevirus	20	70	7
BsV-1	5 (including 3 pseudogenes)	0	10
Klosneuvirus	19	25	2
Hokovirus	13	0	10
Indivirus	3	1	8
Catovirus	15	3	9

STAGES OF REPLICATION

Host Range

Members of the *Mimiviridae* infect eukaryotic hosts of different supergroups, including Amoebozoa (e.g., APMV), Archaeplastida (e.g., Tetraselmis viridis virus), Stramenopiles (e.g., CroV), Excavates (e.g., BsV), and presumably also Rhizaria (e.g., chlorarachniophytes) and Opisthokonts (e.g., choanoflagellates).[18,41,55,116,129,144] Few virus–host systems have been studied in sufficient detail to delineate specific steps of the viral infection cycle, and most data on viruses of the *Mimiviridae* family have been published on APMV and tupanviruses in their freshwater hosts *Acanthamoeba polyphaga*, *A. castellanii*, and *Vermamoeba vermiformis*. Despite the efficient infection of this host in the laboratory and the practical advantages of working with the amoebal system, it is not clear whether *Acanthamoeba* sp. represents the main

natural host for viruses of the proposed subfamily *Megamimivirinae*. Although tupanviruses were not reported to replicate in protists other than *Acanthamoeba*, they are able to enter the ciliate *Tetrahymena* sp. and cause cytotoxicity at high multiplicities of infection.[5] The ecological role of mimiviruses in controlling natural protist populations is therefore an important area of research that is still in its beginnings. Mimiviruses are also part of the human microbiome as demonstrated by PCR detection, serological studies, and isolation of viruses such as Lentille virus from a keratitis patient.[43,97] APMV replicates in macrophages[66] and amoeba-associated mimiviruses have been suggested as opportunistic pneumonia agents,[80,94,127,136]; however, the clinical relevance of giant viruses remains controversial.[4,38]

Attachment and Entry

Attachment of APMV to the host cell is mediated by the outer 120- to 140-nm-thick fiber layer of the capsid, probably via the 25 kDa proteinaceous head group at the tip of the fibers.[92] Based on the peptidoglycan-mimicking surface and the large (750 nm) diameter of the virion, the APMV particle resembles bacteria that may fall within the prey scheme of the amoeba, resulting in uptake by phagocytosis. Virus particles attach either directly to the cell surface or to elongated cell protrusions, which then engulf the virion.[66] Within 30 minutes postinfection (p.i.), phagocytic vacuoles containing APMV particles are observed by transmission electron microscopy (TEM).[159] Infection studies in RAW 264.7 macrophages ruled out clathrin- and caveolin-mediated endocytosis and micropinocytosis, while inhibition of phagocytosis regulators reduced APMV entry.[66] Treatment with the phagocytosis inhibitor cytochalasin significantly reduced both APMV uptake by *Acanthamoeba* cells as well as viral titers, providing further evidence that phagocytosis is the preferred mode of entry for APMV.[6] Phagocytosis is not restricted to the uptake of single virions, and multiple APMV particles per phagosome can be observed.[179]

Similar to APMV, phagocytic entry has been proposed for Yasminevirus in the host *Vermamoeba vermiformis*. With a capsid of 330 nm in diameter and an outer 20- to 40-nm-thick fiber layer, the Yasminevirus particle is much smaller than that of APMV, yet virion-containing phagosomes are visible by TEM.[10] By contrast, no internalized capsids have been observed for CroV in the phagotrophic flagellate *Cafeteria burkhardae*. Instead, open empty capsid shell structures can be seen in close proximity to host cells, suggesting that CroV capsids open upon contact with the host cell and that the internal virion membrane fuses with the cytoplasmic membrane, releasing the genome-containing viral core into the cytoplasm (Fig. 20.6) (U. Mersdorf and M. Fischer, unpublished data). Phagocytosis thus appears to be the main entry mode for amoeba-infecting mimiviruses, whereas other entry mechanisms may be employed by different members of the family.

Uncoating and Virion Factory Formation

After internalization of the virus particle, APMV uncoating depends on acidification of the vacuole via fusion with lysosomes. When amoebae are treated with the vacuolar-type H^+-ATPase inhibitor Bafilomycin, APMV titers are greatly reduced.[6] Low pH conditions also trigger the opening of the viral capsid *in vitro*, as shown for Samba virus, APMV, and Tupanvirus.[138] The APMV capsid always opens at the unique stargate vertex. For this, the outer starfish seal must be removed, which probably occurs through an "unzipping" mechanism whereby the seal maintains contact with the capsid layer during opening.[138] The stargate portal then opens at the unique vertex with the five flanking trisymmetrons folding back like flower petals, exposing the internal virion lipid layer for fusion with the phagolysosome membrane (Fig. 20.7).[138,159,179] Little is known about the membrane fusion step and release of the viral core (also referred to as the nucleocapsid or the viral seed) into the host cytoplasm. However, stargate opening and fusion of viral and host membranes create a conduit for delivery of the genome-containing core. At this stage, the core is still surrounded by a layer that is presumably composed of the major core protein. Immediately after release from the capsid, early transcription commences in the viral core[115] and over the course of the first 4 hours, the core develops into a micrometer-sized pseudo-organelle termed the viral factory.[159] The early viral factory is visible after an eclipse phase of about 3 to 4 hours (Fig. 20.8).[32,95,149,160] Multiple cores can be present in a single cell, and each core will seed a separate factory, which may eventually fuse into a single large factory.[61,115] The viral factory is a hallmark structure of all mimiviruses studied so far and represents the subcellular location in which viral transcription, DNA replication, particle assembly, and various other viral enzymatic activities take place.

Transcription

The mode of gene expression in mimiviruses resembles that of poxviruses,[25] because viruses of both families package a multisubunit transcriptase complex into the viral particle and execute transcription in the cytoplasm of infected cells in a temporally regulated fashion.[25,115] Mimiviruses are therefore independent from the nuclear host transcription system, although it cannot be excluded that certain host factors are recruited for viral transcription. The genomes of APMV, CroV, and Bodo saltans virus encode a large number of proteins with predicted functions in transcription, including DNA-dependent RNA polymerase subunits Rpb1, Rpb2, Rpb3/11, Rpb5, Rpb6, Rpb7, Rpb9, and Rpb10.[41,55,100,129] In addition, mimiviruses encode at least six transcription factors involved in initiation, elongation, and termination, as well as RNA helicases and a catalytic subunit of polyadenylate polymerase.[125] Similar to poxviruses, mimiviruses encode a trifunctional mRNA capping enzyme that consists of RNA triphosphatase, guanylyltransferase, and guanine-N7 methyltransferase domains.[16] Mass spectrometric analysis of purified APMV and CroV virions revealed that most of these transcription components are packaged in the viral particle.[57,131] Following the release of the inner core into the cytoplasm, transcription of early viral genes commences.[115]

Gene expression in mimiviruses follows a temporally regulated cascade similar to that described for poxviruses, with successive transcription of genes expressed during early, intermediate, and late phases. Early phase in APMV starts with the release of the viral core into the cytoplasm and ends around 3 hours p.i., followed by an intermediate phase proposed to last from 3 to 6 hours p.i., and a late phase that lasts from 6 to 12 hours p.i.[101] In CroV, early phase lasts approximately until 3 hours p.i. and late phase starts between 3 and 6 hours p.i.[55] Each temporal class is associated with its own set of transcription factors and gene regulatory sequences. Early gene products include transcription factors for intermediate phase, intermediate gene products include late transcription factors, and the early transcription factors are expressed during late phase and must be packaged in the capsid to initiate the expression of early genes in the next round of infection.[166] Indeed, proteins with homology to the Vaccinia virus early transcription factors A7 and D6 were found in the virion proteomes of APMV and CroV.[57,131] The early transcription factors may recognize the conserved "AAAATTGA" promoter motif that was found to be associated with early genes in the APMV genome.[101,156] This early promoter is conserved within the *Mimiviridae* family, including mega- and moumouviruses, AaV, BsV, CroV, and tupanviruses[8,41,55,109,132,174] and is similar to the early promoter motifs in pox- and iridoviruses.[121] Most of the early genes in APMV and CroV encode hypothetical proteins of unknown function, but RNA polymerase subunits are also found in this class. Some transcription genes have both early and late promoters, presumably for boosting viral gene expression during the onset of infection and for providing transcription proteins to be packaged into capsids during late phase. The intermediate phase is poorly defined in mimiviruses and has not been linked to specific regulatory signals. Intermediate gene products include the DNA polymerase and other associated replication proteins. Late gene products are involved in virion morphogenesis and include capsid proteins as well as assembly and packaging factors. In contrast to the widely conserved early gene promoter, the late gene promoters vary among different members of the *Mimiviridae*, with some viruses exhibiting a strong consensus sequence (e.g., "TCTA" in CroV), while others appear to have more degenerate late promoter motifs.[101,121] Nearly all APMV transcripts are polyadenylated at palindromic sequences that give rise to hairpin structures with a length of 26 to 46 nucleotides.[26] Polyadenylation is catalyzed by the highly processive virus-encoded poly(A) polymerase.[125] These hairpin structures have been proposed to act as transcription termination signals.[101] Two convergent genes may use the same hairpin and polycistronic mRNAs have also been observed.[26]

Translation

Translation-related genes are frequently encoded by mimiviruses and are particularly frequent in tupanviruses as well as in members of the proposed subfamily *Klosneuvirinae*.[5,10,141]

Despite the impressive number of virus-encoded translation genes, members of the *Mimiviridae* are still obligate intracellular parasites and thus depend on host ribosomes for protein biosynthesis. However, their extensive coding content and genomic flexibility may allow them to modulate many metabolic processes of the host to their advantage, including translation.[3,12] Given that APMV and its host *Acanthamoeba* sp. differ substantially in their GC contents and codon usages, viral substitution of translation components such as aaRS enzymes could lead to more efficient translation of viral proteins.[39] A comparative gene expression analysis of eight viral translation factors (4 tRNAs and 4 aaRS genes) during infection of *A.*

castellanii with different members of the genus *Mimivirus* conducted under different nutrient conditions showed that expression levels were lowest in nutrient-replete conditions and highest when cells were starving.[148] Viral translation proteins could therefore provide a temporary selective benefit to host cells when competition for nutrients with other microorganisms is high. For instance, APMV translation initiation factor eIF4E was shown to be present in infected amoebae, where it was localized in the cytoplasm but not in the viral replication factory.[61] Functional assays conducted on selected viral translation proteins confirmed their predicted activity, such as for various mimivirus-encoded translational GTPases of the elongation factor 1 family[184] and two of the four APMV-encoded aaRS enzymes.[2] Experimental silencing of the APMV *R458*-encoded translation initiation factor eIF4a during viral infection resulted in changes of the APMV proteome and decreased viral fitness by delaying formation of the viral factory.[12] These experiments strongly suggest that mimivirus-encoded translation proteins perform important functions during infection.

Genome Replication and Repair

Viral genome replication takes place in the cytoplasmic viral factory. Bromodeoxyuridine (BrdU) labeling and DAPI staining of APMV-infected *A. polyphaga* cells showed that viral genome replication starts concomitantly with the release of the core from the phagosome and DNA decondensation.[115]

Members of the *Mimiviridae* encode multiple proteins involved in DNA replication. The B-family DNA polymerase is one of the few genes that are uniformly conserved among nucleocytoviruses, emphasizing its importance as the main processive enzyme in viral genome replication.[75] In addition to DNA polymerase B, the DNA replication core machinery of mimiviruses consists of a DNA helicase, primase, and a proliferating cell nuclear antigen (PCNA)-like DNA clamp. Further gene products involved in DNA replication are replication factor C subunits, RNase H, and topoisomerase II.[176] It is possible that additional proteins will be recognized as key players in viral replication. For instance, based on its primary sequence, APMV ORF *L537* was predicted to be a member of the archaeo-eukaryotic primase family.[76] Biochemical characterization revealed that this protein is a jack-of-all-trades, possessing terminal transferase, translesion synthesis, as well as DNA and RNA polymerase activities on DNA and RNA templates.[70] L437 is therefore a combined primase, polymerase, reverse transcriptase, and terminal transferase. Nothing is known about the molecular steps of DNA replication in mimivirus. Claverie, Abergel, and Ogata noted that the aforementioned 617-bp long inverted repeat of the APMV genome and the ORFs located at the 5′ terminus of the genome could be involved in DNA replication.[35] Mimiviruses encode up to three different DNA topoisomerases (types IA, IB, and II), which may reflect the need for topology control of such large DNA genomes. APMV topoisomerase IB was characterized biochemically and shown to relax supercoiled DNA.[15] This enzyme is structurally and functionally related to the vaccinia virus homolog, whereas its primary sequence suggests a closer relationship with bacteria.[15]

Owing to the bacterial-sized genomes of mimiviruses and their cytoplasmic replication, which separates them from host DNA maintenance mechanisms in the nucleus, mimiviruses encode DNA repair enzymes of several different pathways, namely base excision repair (BER), nucleotide excision repair (NER), mismatch repair, double-strand break repair, and direct damage reversal processes such as photocatalyzed repair.[19] BER is present in all three domains

of life and involves recognition, excision, gap filling, and ligation of a damaged DNA base.[44] Recognition and base excision are catalyzed by glycosylases such as uracil-DNA glycosylase (UDG), resulting in an apurinic/apyrimidinic (AP) site. An AP endonuclease then cuts the DNA backbone and a family X DNA polymerase fills the cleaved gap with a nucleotide. Finally, a DNA ligase seals the repaired lesion site. Mimiviruses encode homologs of UDG,[93] AP endonuclease, DNA polymerase X, DNA ligase, and additional BER-related enzymes such as flap endonuclease.[130] Gene products found in *Mimiviridae* members that are predicted to function in other ATP-dependent DNA repair mechanisms include the NER-associated XPG protein,[19] DNA mismatch repair proteins MutS7 and MutS8,[119] and the double-strand break repair catalytic domains of Mre11 and Rad50 proteins.[175] Interestingly, viral DNA repair enzymes were found in the particles of APMV (DNA pol X, Alkylated DNA repair protein AlkB R406, repair endonuclease L687), Tupanvirus (AlkB homolog ORF72, DNA pol X, and 5′-3′ exonuclease ORF327), and CroV (DNA pol X, AP endonuclease, DNA ligase, 3′-5′ exonuclease CROV200, and a predicted DNA glycosylase).[5,35,57,131] CroV also packages a predicted (6–4) photolyase and encodes a CPD photolyase, indicating that DNA damage caused by ultraviolet light could be repaired in the particle, similar to observations in fowlpox virus.[151] In summary, mimiviruses appear to follow Drake's rule,[46] which states that the mutation rate is inversely proportional to the genome size of microorganisms, including DNA viruses. Accordingly, larger genomes require more DNA repair enzymes, which is confirmed by the large array of repair genes encoded by mimiviruses.[130]

Virion Assembly and Release

Capsid assembly of mimiviruses occurs at the periphery of the viral factory, visible in TEMs as a zone of lower electron density.[179] Within the periphery, distinct areas have been identified for membrane/capsid assembly, genome packaging, and fiber acquisition (Fig. 20.9). As each step of the assembly process is completed, APMV particles move sequentially away from the center of the factory. The cytoplasmic factory is therefore ordered spatially and functionally, and a variety of biochemical pathways must be accommodated by its infrastructure. The viral factory has received considerable attention due to its organelle-like appearance, its dimensions, and the various viral enzymatic activities that take place within.[61,159] Conceptually, the viral factory has been considered the true living stage of the virus, in contrast to the seed-like capsid state that lacks metabolic activity.[32] The realization that the factories of large dsDNA viruses such as poxviruses concentrate viral enzymes whose cellular homologs are normally located in the nucleus has even inspired far-reaching evolutionary scenarios that postulate a viral origin for the eukaryotic nucleus ("viral eukaryogenesis").[13,14,161]

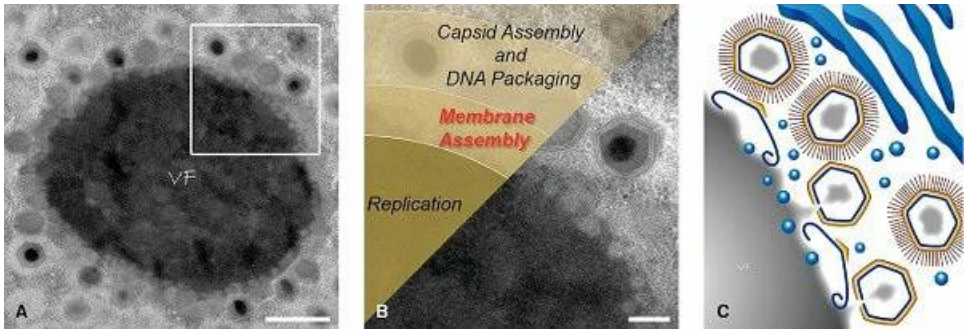

FIGURE 20.9 Spatial organization of the APMV factory in *Acanthamoeba*. A: Late-stage cytoplasmic viral factory (VF) with an electron-dense center and a translucent periphery. **B:** Magnification of the area shown in **(A)**, depicting distinct zones for replication, membrane assembly, and capsid assembly and maturation. **C:** Proposed sequence of events for APMV membrane assembly. Small membrane vesicles (*blue spheres*) that bud out from host ER cisternae (*elongated blue structures*) diffuse toward the VF and form multivesicular bodies that eventually rupture into open membrane sheets (*blue lines*). Icosahedral capsids (*yellow*) are assembled on top of these sheets. Scale bars are 2 μm for **(A)** and 500 nm for **(B)**. (**A and B** are adapted from Mutsafi Y, Fridmann-Sirkis Y, Milrot E, et al. Infection cycles of large DNA viruses: emerging themes and underlying questions. *Virology* 2014;466–467:3–14, **(C)** is adapted from Mutsafi Y, Shimoni E, Shimon A, et al. Membrane assembly during the Infection cycle of the giant mimivirus. *PLoS Pathog* 2013;9:e1003367.)

Yet, our understanding of viral factories remains superficial. Although the overall appearance is similar for viruses throughout the family *Mimiviridae*, they must differ according to the structural variety of mimivirus capsids that includes icosahedrons of various diameters with short fibers, long fibers, or no fibers, different exit portal architectures, tail structures, and more. Fridmann-Sirkis and colleagues purified APMV factories from different stages of infection in *A. polyphaga* and analyzed their morphologies and protein compositions.[61] Approximately one-third of the predicted APMV proteins were identified in purified factories by mass spectrometry, including 30 membrane proteins. Proteins involved in DNA replication and repair, transcription, and protein degradation were present in factories at all three time points sampled (4, 5.5., and 7 hours p.i.). Factories at 7 hours p.i. already contained most of the proteins that are packaged in the virions. They also noted that the viral factory is surrounded by ribosomes, although no ribosomes are present in the factory itself.

Particles assemble with the unique stargate portal facing away from the center of the factory[179] and newly synthesized particles with stargate structures first appear between 4 and 5.5 hours p.i. (Fig. 20.10).[61] Stargate formation may thus be involved in the symmetry-breaking early events of capsid assembly.[113] Capsid assembly initiates at a fivefold vertex and presumably involves the MCP as a scaffolding component.[114] After seeding a new capsid structure, capsomers could then be added in a spiral fashion around the first pentameric vertex, as suggested by cryo-EM studies of the CroV particle (Fig. 20.11).[172] The incorporation of other scaffolding proteins into the nascent capsid structure, such as the proposed tape-measure protein, remains to be studied.[48] The origin of the internal virion membrane in APMV was initially puzzling, because the viral factory was neither membrane bound nor connected to the

endomembrane system of the host cell. A combination of diverse electron microscopy techniques revealed that the APMV membrane is derived from the endoplasmic reticulum (ER). Vesicles from the ER are transported to the viral factory, where they fuse into multivesicular bodies that then rupture to give rise to open membrane sheets. These open membrane intermediates have a diameter of approximately 90 nm for APMV.[114,153] Capsid and membrane assembly happen concomitantly as the growing capsid draws from the multivesicular bodies that feed membranes into the assembly zone, suggesting an early interaction between scaffolding proteins and the lipid layer. Upon completion of the icosahedral container, nonassembled open membrane overhang structures protrude from the residual capsid opening. These extra membranes are then trimmed in preparation for genome packaging.[114] Similar processes have been reported for poxviruses and asfarviruses, suggesting that membrane assembly via open membrane intermediates may be a common feature of nucleocytoviruses.[29,153,154]

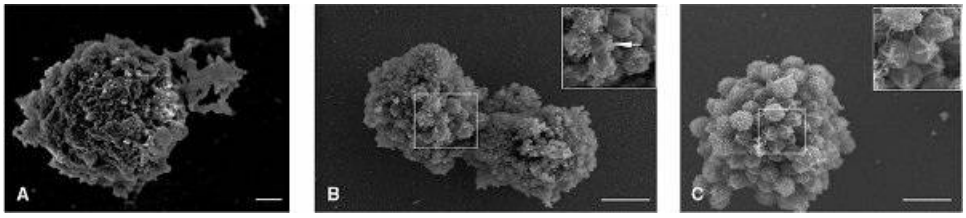

FIGURE 20.10 Scanning electron micrographs of isolated APMV factories from different stages of infection. A: At 4 hours p.i., replication centers have formed, but no capsid structures are visible yet. **B:** At 5.5 hours p.i., first capsids with stargate structures (inset, *arrow*) are discernible at the periphery of the viral factory. This image shows two fusing viral factories that are likely derived from two individual virus entry events. **C:** At 7 hours p.i., the factory is covered with newly synthesized APMV capsids; some are still naked with visible stargate portals (*inset*), and others have already acquired their fiber coat. Scale bars are 200 nm for **(A)** and 1 μm for **(B)** and **(C)**. (Adapted from Fridmann-Sirkis Y, et al. Efficiency in complexity: composition and dynamic nature of mimivirus replication factories. *J Virol* 2016;90:10039–10047.)

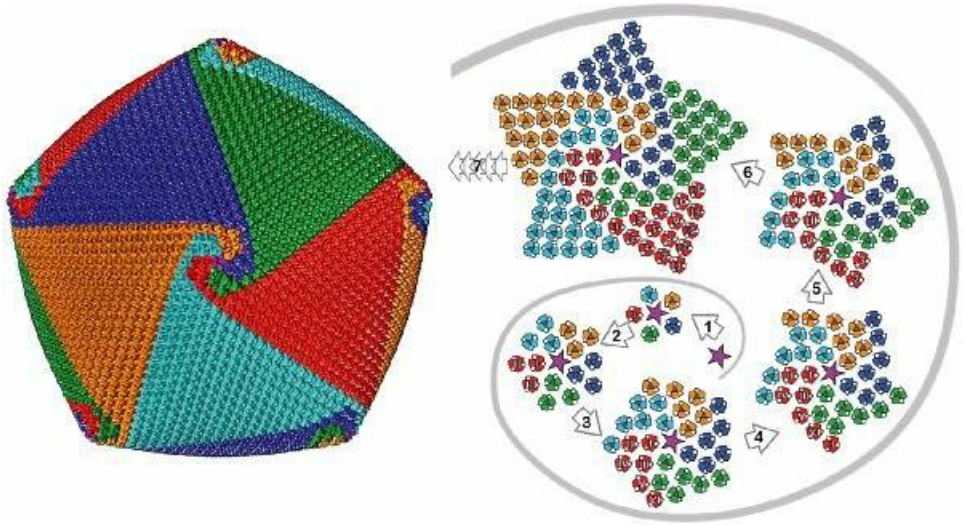

FIGURE 20.11 Cryo-electron microscopy reconstruction of the CroV capsid and proposed spiral assembly pathway. Capsomers are colored based on their orientation in *red*, *blue*, *green*, *cyan*, and *orange*. The pentameric capsomers are depicted as *purple stars*. The schematic on the right shows the proposed spiral assembly pathway. First, capsomers assemble in two layers around the pentameric capsomer (1+2). For the third layer, newly added capsomers spiral counterclockwise, according to their orientation (3+4), and will then seed the trisymmetron (forming one icosahedral face) by recruiting more capsomers of the same orientation (5–7). One set of capsomers (*red*) is labeled by Roman numerals if they are part of the pentasymmetron and by Arabic numerals if they are part of a trisymmetron. (Adapted from Xiao C, et al. Cryo-EM reconstruction of the Cafeteria roenbergensis virus capsid suggests novel assembly pathway for giant viruses. *Sci Rep* 2017;7:5484.)

As the nascent capsids move further from the center of the viral factory, they pass a zone that is characterized by lower electron density in thin-section TEMs and has been named the fibril acquisition area.[6] In this area, APMV capsids acquire the 120- to 140-nm-thick outer layer of glycosylated fibers (Fig. 20.9). Fiber-coated particles are first visible around 7 hours p.i.[61] Around the same time, the genome is delivered into the preassembled capsid via a transient 18- to 20-nm-wide portal that is located at an icosahedral face opposite of the stargate vertex (Fig. 20.12).[179] Viruses of the family *Mimiviridae* encode a DNA-pumping ATPase of the HerA-FtsK superfamily, which could catalyze the packaging of the viral genome into the preformed capsid. These viral motor proteins are similar to the bacterial apparatus for chromosome segregation.[28] At approximately 8 hours p.i., the viral factory of APMV is surrounded by fully assembled icosahedral capsids.[114] Mature virus particles are released from the infected amoeba by lysis at approximately 24 hours p.i. (Fig. 20.13).[160] The burst size of APMV is approximately 300 to 1,000 virions per cell, for Megavirus chilensis, and for CroV, the burst size is about 500 per cell.[8,35,163]

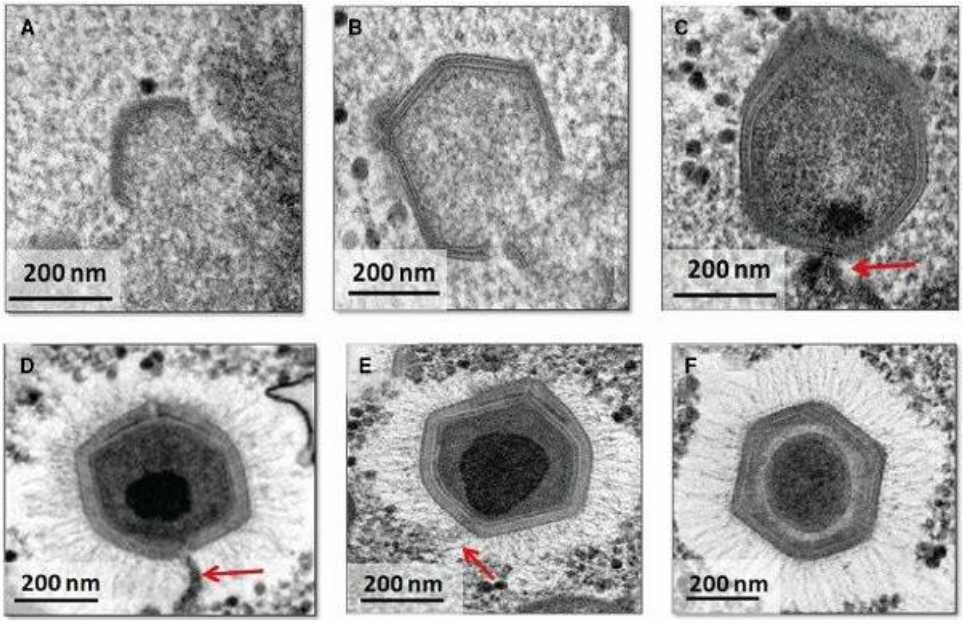

FIGURE 20.12 Transmission electron microscopy images showing stages of APMV particle formation. A: Initiation of capsid assembly at a pentameric vertex. **B:** Near-complete capsid shell prior to genome packaging. **C–E:** Capsids undergoing genome packaging (*red arrows*) through a portal opposite of the stargate vertex. Surface fibers are visible in **(D and E)**. **F:** Mature APMV particle. (Modified from Andrade ACDSP, et al. Filling knowledge gaps for mimivirus entry, uncoating, and morphogenesis. *J Virol* 2017;91:1–12.)

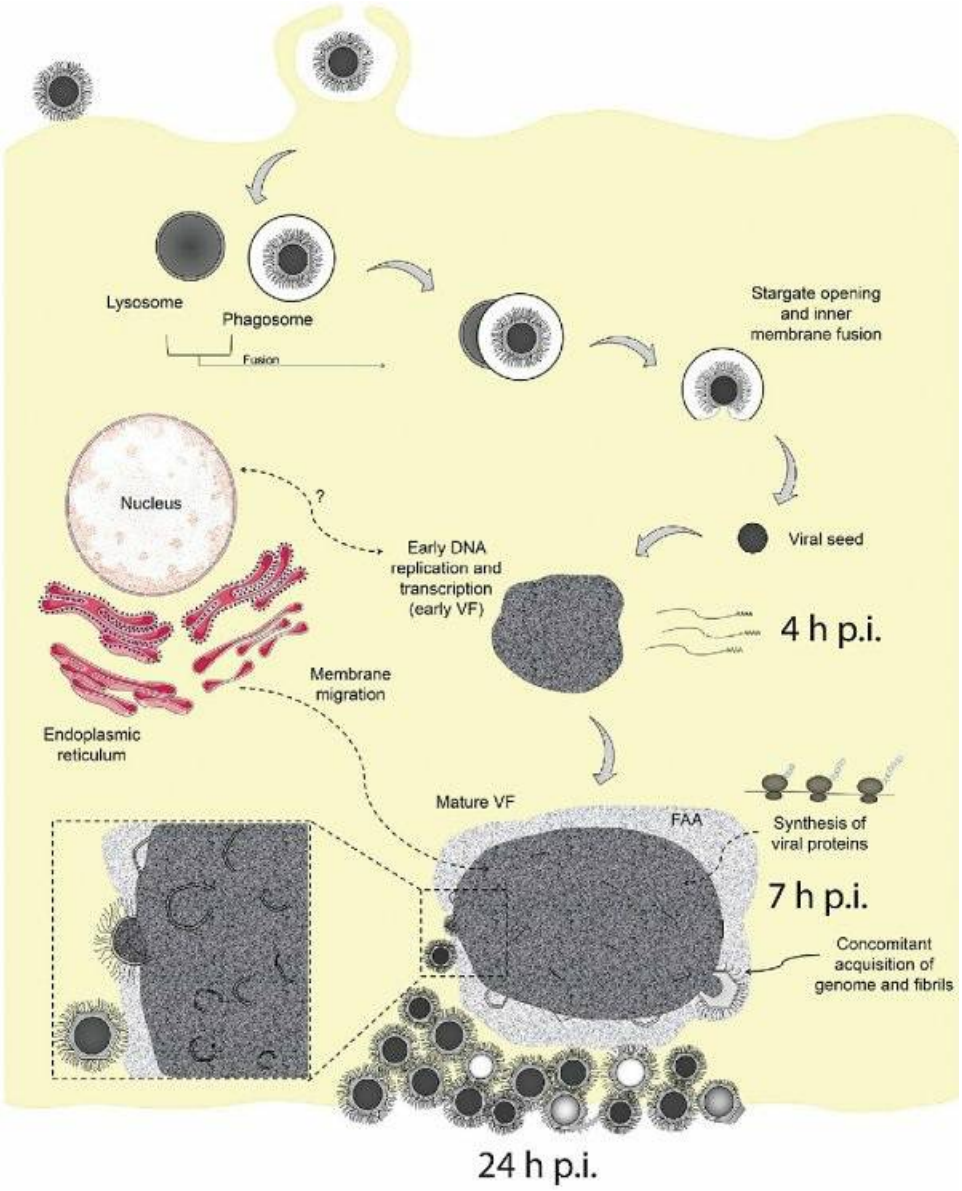

FIGURE 20.13 Schematic overview of the APMV replication cycle. Infectious APMV particles enter the amoebal host cell by phagocytosis. Fusion of the phagosome with a lysosome occurs and opening of the stargate is followed by release of the viral seed (nucleocapsid). An early viral factory (VF) is established at 3 to 4 hours p.i., and viral proteins are synthesized outside the factory. It is uncertain whether the cell nucleus is involved in mimivirus genome replication. Viral particle assembly commences at the periphery of the VF, and preformed capsids might acquire genomic material and fibers simultaneously. As the particles move further from the center of the VF, they enter the fibril acquisition area (FAA) where surface fibers are attached. Some of the newly synthesized viral particles may present with atypical morphologies and may not be infectious. The viral progeny are released by cell lysis at approximately 24 hours p.i. (Adapted from Andrade ACDSP, et al. Filling knowledge gaps for mimivirus entry, uncoating, and morphogenesis. *J Virol* 2017;91:1–12.)

VIROPHAGES AND OTHER MOBILE GENETIC ELEMENTS OF MIMIVIRUSES

Following the initial discovery of APMV in *Acanthamoeba* sp.,[95,129] a targeted search for additional giant viruses infecting amoebae was initiated. In 2008, La Scola et al. reported the isolation of an APMV strain named mamavirus.[96] Unexpectedly, they coisolated a smaller virus named Sputnik from the same sample. Sputnik was not able to replicate in host cells alone but required the presence of mamavirus, akin to several satellite-helper virus systems described previously.[30,91,96,150,183] A few other virophages have been isolated subsequently in culture, mostly in combination with *Acanthamoeba*-specific mimiviruses,[27,43,62,63,112,152] but also for the flagellate-infecting CroV.[58] Based on these cultured representatives, thousands of virophage-like sequences were found in metagenomic datasets, indicating that virophages are widespread and diverse in the environment.[68,120,122,135,173,181,182]

Classification of Virophages in the Family *Lavidaviridae*

Based on their biological property of replicating exclusively in the presence of a coinfecting giant virus, Sputnik was initially grouped with satellite viruses in the obscure category of "subviral agents".[49] Following a debate on virophages versus traditional satellite viruses,[53,89,90] virophages and satellite viruses were eventually classified into their own families.[91] The family *Lavidaviridae* (large virus-depending or associated viruses) currently comprises two genera, *Sputnik* and *Mavirus*, although additional genera are likely to be added in the future.[135] The *Lavidaviridae* are part of the realm *Varidnaviria*, the kingdom *Bamfordvirae*, the phylum *Preplasmiviricota*, the class *Maveriviricetes*, and the order *Priklausovirales*.[87]

Structure of Virophage Particles

The virophages that have been cultured and studied so far have icosahedral particles with a diameter of 50 to 75 nm. In contrast to the much larger mimiviruses (Fig. 20.14), virophage particles lack a lipid component.[180] The capsid is composed of an MCP that folds into a double jelly-roll conformation and forms trimeric capsomers. The minor capsid protein, or penton protein, presents in a single jelly-roll conformation and occupies the fivefold vertices of the icosahedral particle.[158,180] Despite low primary sequence conservation, the overall structures of Sputnik and mavirus capsids are remarkably similar[21] and lavidaviruses have capsids with a quasisymmetry of $T = 27$.[180] Capsid modifications such as asymmetric portals or APMV-like fibers have not been reported.

Genomics of Virophages

Viruses of the family *Lavidaviridae* have linear or circular dsDNA genomes with lengths ranging from 17 kb to more than 30 kb for some metagenome-assembled representatives.[11,54] With some exceptions,[182] virophage genomes tend to have low GC contents of 27% to 37%. Terminal inverted repeats of several hundred bases flank the mavirus genome and are also found in metagenomic virophages.[56,177] Whereas the overall coding content of virophages varies considerably, most genomes share four core genes for capsid morphogenesis.[91,122] The *MCP* gene is typically adjacent to the *penton* gene, and these two gene products are sufficient for self-assembly of icosahedral mavirus-like capsids.[21] The capsid genes are complemented by an MCP-processing cysteine protease and a DNA-pumping ATPase of the FtsK-HerA family. Additional conserved functions found in lavidaviruses are genome integration and DNA replication/remodeling, which are represented by nonhomologous versions of integrases, DNA polymerases, and primase/helicases. The pan genome of virophages also includes a variety of accessory genes that may be derived from their hosts, associated giant viruses, or other mobile genetic elements.[85,122,135,173]

The Virophage Infection Cycle

Virophage particles enter their host cells either independently of their giant virus by endocytosis (e.g., mavirus) or as a composite with the giant virus by phagocytosis (e.g., Sputnik).[42,58,162] Upon cell entry, the viral genome is released into the cytoplasm and targeted to the virion factory of the giant virus, if present. Transcription and genome replication of the virophage then occur within the virion factory (Fig. 20.15), often clustered in a specific region thereof.[42,112] The

molecular mechanism of virophage DNA replication has not been studied yet, but it is assumed that virophages are self-sufficient for this process since they encode their own DNA polymerases: Mavirus carries a predicted protein-primed B-family DNA polymerase and Sputnik encodes a superfamily A polymerase (TV-Pol) fused to a D5-like helicase.[73] Newly synthesized virophage particles then accumulate within or close to the virion factory (Fig. 20.14) and are released from the cell during lysis.

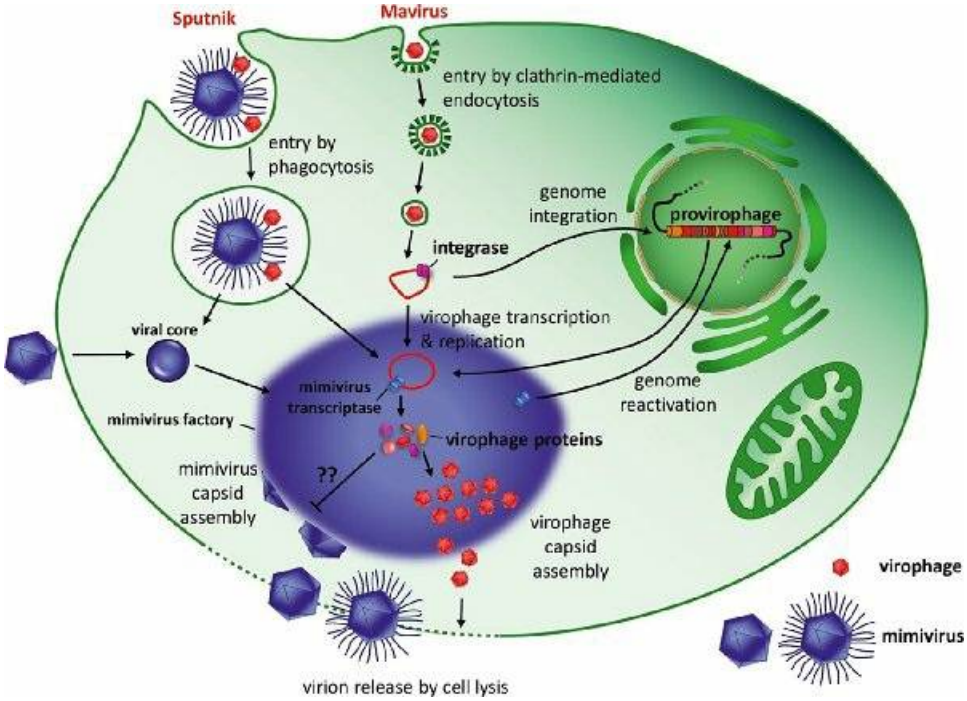

FIGURE 20.15 Schematic overview of the virophage replication cycle. Virophage particles enter the host cell either by endocytosis (mavirus) or by phagocytosis as a composite with an associated mimivirus (Sputnik). After release from the endosome, the virophage genome is translocated to the mimivirus factory where transcription, DNA replication, and capsid assembly occur. During these processes, the replication cycle of the mimivirus may be inhibited. Alternatively, mavirus can integrate into the host genome in the absence of a coinfecting giant virus, allowing persistence as an inactive provirophage. Reactivation of the provirophage occurs after infection of the host cell with a compatible mimivirus. (Adapted from Duponchel S, Fischer MG. Viva lavidaviruses! Five features of virophages that parasitize giant DNA viruses. *PLoS Pathog* 2019;15:e1007592.)

Although virophages do not actively replicate in the absence of a coinfecting mimivirus, their integrase enzymes allow them to enter a persistent state by coupling to another genome. Sputnik encodes a tyrosine recombinase and integration as a provirophage in the APMV genome has been reported.[43] Mavirus virions contain an rve-family integrase enzyme and this virophage is able to integrate into its eukaryotic host genome in the absence of a coinfecting giant virus.[21,56] The provirophage can resume active replication and horizontal transmission when the provirophage-bearing host cell is infected by a compatible mimivirus.

Virophages Depend on a Coinfecting Mimivirus

No virophage isolated to date is able to replicate on its own in a host cell. Sputnik and Guarani replicate in the presence of a virus of the genus *Mimivirus*, or of the proposed genera Moumouvirus and Megavirus.[112] Zamilon also replicates with the latter two, but not with members of the genus *Mimivirus*.[63] Mavirus requires a coinfection with CroV for active replication.[58] Given that virophages encode capsid and DNA polymerase genes, their dependence on a giant virus is not rooted in deficiencies regarding DNA replication or encapsidation. Instead, since gene expression occurs outside the nucleus and virophages lack their own RNA polymerase, they depend on the cytoplasmic transcription machinery provided by the mimivirus. Accordingly, the transcriptional initiation and termination signals were found to be highly similar between a virophage and its associated giant virus.[31,58,101] In particular, virophage gene promoters resemble those of giant virus late genes, and virophage gene expression thus would commence at the onset of late phase of the giant virus infection cycle. A Sputnik-related virophage strain named Guarani was shown to start replicating at 4 hours p.i. and to produce particles late (12 to 16 hours p.i.) during a coinfection with APMV, with virophage particles still absent at 12 hours p.i.[112] Virophages thus likely hijack the mimiviral factory at the onset of late phase, with the mimivirus-encoded transcriptase complex recognizing and expressing the virophage genes.

In theory, other large dsDNA viruses such as poxviruses that possess cytoplasmic transcription capacity could also be prone to parasitism by virophage-like entities.

Host–Virus Symbioses and Defense Systems Involving Giant Viruses

Compared to other viruses, mimiviruses have reached a remarkable degree of enzymatic autonomy and biological complexity. The viral transcription complex enables mimiviruses to express their genes independently of the host machinery, which may facilitate host switching and evasion of host defenses. At the same time, cytoplasmic transcription bears the potential cost of attracting a virophage that interferes with replication of the giant virus.

During a virophage–mimivirus coinfection, Sputnik reduces the yield of infectious mamavirus particles by about two-thirds, Guarani reduces APMV yields by up to 90%, and mavirus reduces CroV yields by more than 99%, depending on the multiplicity of infection.[56,96,112] Initially, the presence of Sputnik was linked to abnormal capsid structures of mimivirus, such as multiple capsid layers and open-ended capsid extensions.[96] However, Andrade et al. observed such structures also in *Acanthamoeba* cells infected with APMV only, in the absence of virophages.[6] Similarly, abnormal APMV particles were reported at a rate of approximately 1% for both, Guarani coinfected, and Guarani-free infections.[112] It appears thus rather unlikely that the presence of virophages induces structural anomalies in APMV. Instead, the virophage might suppress late gene expression of the mimivirus by recruiting its transcription machinery. Interestingly, the Zamilon virophage replicates with APMV in a commensal manner, because coinfection has no measurable negative impact on APMV production.[63] The symbiotic relationship between virophages and giant viruses thus ranges from commensalism to strong parasitism and has important implications for the infected host cell population. While a Zamilon–mimivirus coinfection does not reduce host mortality compared to a mimivirus infection,[63]

Sputnik, Guarani, and mavirus significantly increase host population survival in the presence of their respective lytic giant viruses.[56,96,112] The latter virophages therefore act as mutualists of their host organisms.

The genome integration capacity of mavirus adds another level of ecological significance to the tripartite host–virus–virophage relationship. Mavirus not only integrates rather efficiently into the nuclear genome of *Cafeteria* sp. but is also reactivated in response to CroV infection.[56] By retaining a functional yet transcriptionally silent provirophage in the host genome, a population of protists may increase its survival chances when infiltrated by a lytic mimivirus, compared to a provirophage-naive population.[17] Mavirus protection of host populations may thus be regarded as a case of adaptive immunity in unicellular eukaryotes.[84]

Mimiviruses, on the other hand, are not defenseless against virophage parasitism. The "mimivirus virophage resistance element" (MIMIVIRE) in APMV consists of a gene cassette that involves a Cas4-like nuclease R354, a helicase–nuclease R350, and the *R349* gene that contains a 28 nt long sequence and four repeats of a 15 nt long sequence matching ORF4 of the Zamilon genome.[104] Presence of the MIMIVIRE system in members of the *Mimivirus* genus was linked to resistance of these viruses to Zamilon replication. Silencing the APMV *R349*, *R354*, and *R350* genes by RNA interference led to increased Zamilon replication with the otherwise nonpermissive mimivirus.[104] Furthermore, an *R349* knockout in APMV restored Zamilon replication, and Zamilon also replicated with a *Mimivirus* member that had only one of the four 15 nt repeats.[111] The proposed analogy of MIMIVIRE to CRISPR-Cas systems has been criticized[33] and the molecular basis for this defense system remains to be studied. However, defense systems of this or other types may exist in a variety of giant viruses to fend off genetic parasites.

Other Mobile Genetic Elements Associated With Mimiviruses

In addition to virophages, mimiviruses contain a diverse mobilome that includes transposases, self-splicing introns, inteins, and a class of linear plasmid-like elements called transpovirons.[43,137,178] Transpovirons are approximately 7 kb long and encode 6 to 8 genes, some of which are shared with other mobile genetic elements including Sputnik and linear yeast plasmids.[178] They replicate in extremely high copy numbers in the presence of a mimivirus, can integrate themselves into the mimivirus genome, and are packaged as episomes in both mimivirus and virophage particles.[43,77] Moreover, different versions of transpovirons are associated with specific mimivirus and virophage strains, suggestive of adaptive coevolution between these entities.[77] Phylogenetic analysis indicates that transpovirons may be evolutionarily derived from maverick/polinton elements (MPEs) or related polinton-like viruses.[85] The MPEs were originally described as eukaryotic self-replicating transposons,[79,126] but after two conserved MPE genes were identified as distant capsid protein homologs, it is likely that many of them represent endogenous viruses.[88] MPEs are genetically related to virophages, in particular those of the genus *Mavirus*. Indeed, MPEs and virophages not only share the same set of morphogenesis genes, the rve-family integrase, DNA polymerase B, and helicase genes of MPEs are homologous to those found in mavirus.[58] Moreover, MPEs are flanked by terminal inverted repeats and target site duplications very similar to those of integrated mavirus genomes.[56] The emerging picture of the mimivirus mobilome, and that of large and giant DNA viruses in

general,[67,157] is an expansive gene-sharing network, where different types of genetic parasites interact and recombine with one another.[85]

PERSPECTIVE

Mimiviruses have profoundly changed our perception of viruses. Their genome lengths and particle sizes, coding content, structural and enzymatic complexity, and their entourage of various mobile genetic elements have pushed these viruses into the range of single-celled organisms and have blurred some of the boundaries that once firmly separated viruses from cells. Despite these fascinating features, however, they remain bona fide viruses based on their obligate dependence on a cellular host for propagation, and their mode of replication via de novo synthesis and structural discontinuity. The past two decades have revealed an astounding diversity of giant viruses, many of which have been isolated from *Acanthamoeba polyphaga*, and many more were identified by metagenomics. These combined findings prove that the serendipitous discovery of APMV was not just that of a freak virus, but representative of a widespread and ancient group of viruses that we had previously missed because of our own technical and conceptual limitations.

Despite the great advances made on the genetic diversity, structure, infection biology, and biochemistry of mimiviruses, much remains to be discovered. Their host range presumably covers all major eukaryotic supergroups, yet little is known about individual virus–host interactions. The ecological impact of their role in regulating natural protist populations has been hardly addressed so far, yet the implications must be far-reaching, from affecting species composition and controlling algal blooms to influencing global biogeochemical cycles. Owing to their tremendous genetic storage capacity, mimiviruses offer a window into the past through phylogenomic analysis, allowing us to reconstruct gene flows and ancient evolutionary events, but they also provide many opportunities to observe evolution in action. Detailed investigations into the diverse spectrum of mimivirus-associated mobile genetic elements such as virophages and transpovirons may uncover previously unknown types of symbiotic interactions, including novel types of defense systems.

LMP1, 327–329, 334, 342–345, 344*f*
LMP2A and LMP2B, 345–347, 346*f*
miRNAs, 347–348
gene organization of, 325, 327, 328*f*
genes in, latent and lytic, 335*t*

genome of, 324–325, 328*f*
structure of, 330
history of, 324
Hodgkin lymphoma, 370
human immunodeficiency virus and, 362*t*, 370–371
hydroa vacciniforme-like lymphoma, 361
immune response in, 353–358
antibody, 353–354, 354*f*
cellular
in acute infection, 353
in healthy carriers, 358–359
escape in, 345–346, 374
evasion of, 356–358, 357*t*
innate, 353
T-cell immunity, 354–356
in immunocompromised, 329
infection with, primary
healthy carriers of, 358–359
infectious mononucleosis in, 359, 359*f*
inflammatory pseudotumor-like follicular dendritic cell sarcoma, 370
Kaposi's sarcoma herpesvirus, 514
genes and homologs, 516, 518*t*–519*t*
latency gene expression patterns in, 334, 335*t*
life cycle of, 352*f*
LMP1 in, 339
lymphoepitheliomas, 367–369
in lymphomas in nonimmunocompromised, 364*t*
lymphoproliferative diseases, 374
malignancies in immunocompromised, 362*t*
malignancies in nonimmunocompromised, 364*t*
posttransplant lymphoproliferative disease, 374
lytic replication, 348–351
early genes, 350
immediate-early viral genes, 349–350
late genes, 350–351
multiple sclerosis, 372
nasopharyngeal carcinoma, 367–369, 368*f*
oncogenesis model for, 371–372, 372*f*
perspectives on, 376
prevention of, 375–376
pyothorax-associated lymphoma, 369
replication inhibitors, 373–374
replication steps for, 330–351

attachment and entry in, 330
in B lymphocytes, 330–333
in epithelial cells, 333
latency programs, 333–334
rheumatoid arthritis, 372
severe mosquito bite allergy, 361
structure of, virus, 329–330, 329*f*
systemic lupus erythematosus, 372–373
treatment of, 374–375
for Hodgkin lymphoma, 374
for infectious mononucleosis, 374
for malignancies, 364*t*
for nasopharyngeal carcinoma, 374–375
other therapies in, 375
for posttransplant lymphoproliferative disease, 374
types 1 and 2, 358
vaccines, 375–376
Epstein-Barr virus (EBV) vaccines, 375–376
Epstein-Barr virus-associated diseases with, 359–373
aggressive NK-cell leukemia/lymphoma, 370
angioimmunoblastic T-cell lymphoma, 370
breast cancer, 370
Burkitt lymphoma, 363–365, 364*t*, 365*f*
Burkitt lymphomas, 362*t*, 363–365, 364*t*
chronic active Epstein-Barr virus, 361
chronic lymphocytic leukemia, 372
diffuse large B-cell lymphoma associated with chronic inflammation, 369, 371
diffuse large B-cell lymphomas, 369, 371
EBV-positive diffuse large B-cell lymphoma of the elderly, 369
EBV-positive mucocutaneous ulcers, 369
extranodal NK/T-cell lymphoma-nasal type, 370
gastric carcinoma, 369
Hodgkin lymphoma, 365–366
leiomyomas, 371
leiomyosarcomas, 371
lymphoid interstitial pneumonitis, 370
lymphomatoid granulomatis, 369
non-Hodgkin lymphomas, 371
oral hairy leukoplakia, 370
peripheral T-cell lymphomas, 369–370
plasmablastic lymphomas, 371
primary effusion lymphomas, 371
X-linked lymphoproliferative disease, 359–361, 360*f*

ER-Golgi intermediate compartment (ERGIC), 413
Erythroviruses
classification of, 173, 173*t*
genome of, 174–175, 174*f*
Expression vectors, poxvirus, 573–574, 601–602
Extranodal NK/T-cell lymphoma-nasal type, with Epstein-Barr virus, 370

F

Famciclovir
herpes labialis, 318
for varicella–zoster virus, 478
Feline panleukopenia virus (FPV)
capsid structure and cell infection in, 176
cell receptor binding in, 177
diseases from, 187*t*
endocytosis and endosomal release in, 177
epidemiology of, antiviral immunity and, 175
history of, 172
in older cats, 185–187
pathogenesis of, 188
vaccines for, 188
Fetal infections
with Aleutian mink disease virus, 185
with canine parvovirus, 185
with minute virus of mice, 185
with parvoviruses, 185
Fibroma viruses, 615*t*–616*t*, 635–636, 635*f*
Focal epithelial hyperplasia (FEH), human papillomavirus in, 77
Foscarnet
for cytomegalovirus, 431–432
for HHV-6B, 507
Fowlpox, 618–619, 636

G

Gamma herpes virus, 327–329
Gammaherpesvirinae, 216
Gammaherpesvirus, 333
Ganciclovir, 507
for adenoviruses, 156–157
for cytomegalovirus, 431
for Epstein-Barr virus, 375
for HHV-6B, 507
for Kaposi’s sarcoma herpesvirus, 547
Gangliosides, in polyomaviruses, 10–11, 12*f*–13*f*

Gastric carcinoma, with Epstein-Barr virus, 364*t*, 369
Gastrointestinal diseases, adenoviruses, 146–147
    celiac disease, 147
Gene functions, latency, EBV, 336–348
    BALF1, 358
    BHRF1, 358, 365
    EBERs, 347
    EBNA-1, 334*f*, 336–338, 337*f*
    EBNA-2, 334*f*, 338–339
    EBNA-3A, EBNA-3B, and EBNA- 3C, 340–342, 341*f*
    EBNA-LP, 329, 333, 334*f*, 335*t*, 339–340
    LMP1, 327–329, 334, 342–345, 344*f*
    LMP2A and LMP2B, 345–347, 346*f*
    miRNAs, 347–348
Gene therapy vectors, adeno-associated virus, 189
Generalized vaccinia, 626–627, 627*f*
Genetic diversity, for cytomegalovirus, human, 427
Genital infection, herpes simplex viruses, 317, 317*t*
Genome chromatinization, 418
Genome replication, in roseoloviruses
    genome packaging and cleavage, 499
    initiation and elongation, 498–499
    nucleotide metabolism, 498
Germinotropic lymphoproliferative disorder, 560
Glycoprotein B, in varicella–zoster virus, 458
Glycoprotein C, in varicella–zoster virus, 458
Glycoprotein E, in varicella–zoster virus, 458–459
Glycoprotein H, in varicella–zoster virus, 459
Glycoprotein I, in varicella–zoster virus, 459
Glycoprotein K, in varicella–zoster virus, 459
Glycoprotein L, in varicella–zoster virus, 459
Glycoprotein M, in varicella–zoster virus, 459–460
Glycoprotein N, in varicella–zoster virus, 459–460
GM1 ganglioside, in SV40, 10–11, 12*f*–13*f*
Goatpox, 615*t*–616*t*, 634–635, 635*f*
Goose parvovirus, 185
gp350, 375
Ground squirrel hepatitis virus (GSHV), 642
Guarneri bodies, in poxviruses, 620, 620*f*

H

HAdV infection
    adult and pediatric patients in, 149

clinical presentation and outcome, solid organ and allogeneic stem cell transplantation in, 150
Head and neck cancers, human papillomavirus in, 77–78, 78*f*
Hematopoietic cell transplants, 504
Hematopoietic differentiation, 421
Hematopoietic stem cell transplantation (HSCT), cytomegalovirus infection after, 429
Hemophagocytic lymphohistiocytosis (HLH), 361
Hemophagocytic lymphohistiocytosis, with Epstein-Barr virus, 361
Hemorrhagic cystitis (HC), adenoviruses, 146
Hepadnaviridae (hepadnaviruses), 641–682
classification, 643–644, 643*f*
clinical manifestations, 667–669, 668*f*
differential diagnosis, 670
acute hepatitis B, 670
chronic hepatitis B, 670
epidemiology, 666–667
genotypes, 667
global prevalence, 666
transmission mode, 666–667
genome structure and organization, 646–647, 646*f*
HBeAg seroconversion, 669
history of, 641–642
laboratory diagnosis, 670–671
assays, 668*f*, 670
HBcrAg, 670–671
serum viral RNA, 671
occult HBV infections, 669
pathogenesis and pathology, 660–666
cell and tissue tropism, 660–661
cirrhosis and hepatocellular carcinoma, 663–666
cellular factors, 664–665
chronic infections, 664*f*, 663–664
viral factors, 665–666
immune response, 661–663, 662*f*–663*f*
liver infection, 660
reactivation, 663
perspective on, 674
prevention and control, 671–674
replication stages, 648–660
assembly and release, 659–660
attachment to hepatocytes, 648
entry, intracellular trafficking, and uncoating, 648–649, 649*f*
genomic nucleic acid

amplification and stability of cccDNA, 658–659
cccDNA formation, 656
minus strand DNA synthesis, 657*f*, 657–658
pgRNA packaging, 657*f*, 656–657
plus strand DNA synthesis, 657*f*, 658
transcription, 649–651, 650*f*, 651*f*
viral proteins, 651–656
core protein, 651*f*, 651–652
envelope protein, 646*f*, 653*f*, 652–653
HBx, 656*f*, 654–656
reverse transcriptase, 654*f*, 655*f*, 653–654
structure of, virion, 644–645, 644*f*–646*f*
treatment, 671–673
drugs, 672–673
general considerations, 671
interferon (IFN) therapy, 671–672
nucleoside analogue (NUC) therapy, 672
vaccines, 673–674
variants and HBeAg-negative chronic hepatitis B, 662*f*–663*f*, 669
Heparan sulfate (HS), in Kaposi's sarcoma herpesvirus, 517, 520*f*
Hepatitis, adenoviruses, 147
Hepatitis B virus (HBV)
classification, 643–644, 643*f*, 683–684
clinical features, 667–669, 698–699, 698*f*
clinical manifestations, 667–669, 668*f*
HBeAg seroconversion, 669
occult HBV infection, 669
variants and HBeAg-negative chronic hepatitis B, 669
current treatment, 699
detection using endogenous DNA polymerase assay, 642, 642*f*
differential diagnosis of
acute hepatitis B, 670
chronic hepatitis B, 670
discovery of, 641–642, 642*f*
future treatments, 700, 700*f*
genome structure and organization, 646–647, 646*f*
genotypes, 667
history, 641–642, 683
laboratory diagnosis
assays for, 670
HBcrAg, 670–671
serum viral RNA, 671
main routes of transmission, 666–667

pathogenesis and pathology, 660–666, 694–697
acute HDV infection, 695
cell and tissue tropism, 660–661
chronic HDV infection, 695–696
cirrhosis and hepatocellular carcinoma, 663–666
cellular factors, 664–665
chronic infections, 664*f*, 663–664
viral factors, 665–666
clinical features and natural history, 695–696
coinfection and superinfection settings, 694, 694*f*
entry into host and primary replication site, 694
host cell interaction, 696
immune response, 661–663, 662*f*–663*f*, 695
interference, 697
liver infection, 660
in liver mechanism, 695
natural host and animal models, 694, 694*f*
persistence, 696–697
reactivation, 663
release from host and transmission, 694–695
perspective on, 674, 700
prevalence, 697
replication, 648–660, 685–693
assembly and release, 659–660
attachment mechanism, 685–686, 686*f*
attachment to hepatocytes, 648
entry, intracellular trafficking, and uncoating, 648–649, 649*f*
genomic nucleic acid
amplification and stability of cccDNA, 658–659
cccDNA formation, 656
minus strand DNA synthesis, 657*f*, 657–658
pgRNA packaging, 657*f*, 656–657
plus strand DNA synthesis, 657*f*, 658

control of gene expression for, 417–418
establishment and maintenance, 416
hematopoietic differentiation, 421
and reactivation, 417*f*
viral determinants, associated with latency and reactivation, 418–421
in Kaposi's sarcoma herpesvirus, 521–524, 523*f* *See also* (Kaposi's sarcoma herpesvirus (KSHV))
latent proteins in, 524–531
in parvoviruses, 185, 186*f*
in varicella–zoster virus, 445, 468–470, 469*f*, 470*f*
Latency-associated nuclear antigen 2 (LANA2), in Kaposi's sarcoma herpesvirus, 517*f*, 528–530, 529*f*
Latency-associated nuclear antigen (LANA), in Kaposi's sarcoma herpesvirus, 524–526, 525*f*, 529*f*
Latent membrane proteins (LMPs), 345
Leaky late (LL) genes, in human cytomegalovirus, 410
Leiomyoma, with Epstein-Barr virus and human immunodeficiency virus, 371
Leiomyosarcoma, with Epstein-Barr virus and human immunodeficiency virus, 371
Leporipoxvirus, 615*t*–616*t*, 635–636, 635*f*
Letermovir, 431–432
Lipid rafts

in Epstein-Barr virus, 345, 346*f*
for HHV-6, 496
in Kaposi's sarcoma herpesvirus, 543
Liver dysfunction, 504
LMP1, 327–329, 334, 342–345, 344*f*
LMP2, 334
LMP2A, 345–347, 346*f*
LMP2B, 345–347, 346*f*
Lonafarnib, anticancer drug, 700
Lumpy skin disease, 615*t*–616*t*, 634–635
Lymphoblastoid cell lines (LCLs), Epstein-Barr virus in, 325
Lymphocryptovirus (LCV, lymphocryptoviruses), 324–325, 514
Lymphoepitheliomas, with Epstein-Barr virus, 364*t*, 369
Lymphoid interstitial pneumonitis, with Epstein-Barr virus and human immunodeficiency virus, 370
Lymphomas
with Epstein-Barr virus
aggressive NK-cell leukemia/lymphoma, 370
angioimmunoblastic T-cell lymphoma, 364*t*, 370
Burkitt lymphoma, 362*t*, 363–365, 364*t*, 365*f*, 370
diffuse large B-cell lymphoma associated with chronic inflammation, 369, 371
diffuse large B-cell lymphomas, 369, 371
EBV-positive diffuse large B-cell lymphoma of the elderly, 369–370
extranodal NK/T-cell lymphoma-nasal type, 370
Hodgkin lymphoma, 362*t*, 364*t*, 365–366, 370, 374
hydroa vacciniforme-like lymphoma, 361
lymphomatoid granulomatis, 369
non-Hodgkin lymphomas, 369–371
peripheral T-cell lymphomas, 364*t*, 369–370
pyothorax-associated lymphoma, 369
treatment of, for Hodgkin lymphoma, 362–363
hydroa vacciniforme-like, 361
in multicentric Castleman disease, 560
plasmablastic, 560
primary effusion, with Epstein-Barr virus and human immunodeficiency virus, 371
T-cell
angioimmunoblastic, 364*t*, 370
peripheral, 364*t*, 369–370
Lymphomatoid granulomatosis, 369
with Epstein- Barr virus, 369
Lymphoproliferative diseases, with Epstein- Barr virus, 361–363, 362*t*
in immunosuppressed solid organ transplant recipients, 362–363, 375
malignancies in

in immunocompromised, 376
in nonimmunocompromised, 364*t*, 369–370
posttransplant lymphoproliferative disease in, 362, 362*t*, 363*f*, 374
Lytic replication
EBV, 348–351
early genes, 350
immediate-early viral genes, 349–350
late genes, 350–351
herpesviridae
assembly and egress in, virion, 224–225
genome replication in, 224
lytic gene expression and activities in, 222–224

M

Maculopapular eruption (MPE), 497
Major IE promoter (MIEP) enhancer, in human cytomegalovirus, 404*f*–405*f*
functions of, 404–405
genome location of, 404–405
regulation of, 405
transcription and expression of
Malacoherpesviridae, 212, 214*t*–215*t*
Maribavir
for cytomegalovirus, 432
on Epstein-Barr virus, 373–374
Mastadenovirus, 98–99, 99*t*
Maverick/polinton elements (MPEs), 721
MCD. *See* Multicentric Castleman disease (MCD)
MCPyV. *See* Merkel cell polyomavirus (MCPyV)
Men who have sex with men (MSMs), anal cancer risk in, 77
Meningitis, HSV infection, 311
Meningoencephalitis, adenoviruses, 146
Merkel cell carcinoma (MCC), 34, 35*f*
Merkel cell polyomavirus (MCPyV), 25*t*. *See also* Polyomaviruses
genome structure and organization, 5, 6*f*, 7–8, 10, 10*f*
history of, 3
infection with, 24
integration, 21, 22*f*
and Merkel cell carcinoma, 34, 35*f*
pathogenesis and pathology, 20
perspective, 38
replication, 14, 16
taxonomic classification, 2*t*, 3*f*
transforming activity of, 3–4

Messenger RNAs (mRNAs), synthesis in hepatitis D virus, 686–687, 687*f*
MicroRNAs (miRNAs), 497
in Kaposi's sarcoma herpesvirus (KSHV), 523*f*, 530–531
MIEP enhancer, in human cytomegalovirus
functions of, 404–405
genome location of, 404–405
regulation of, 405
transcription and expression of, 405*f*
Mimiviridae (mimiviruses), 704–724
Acanthamoeba castellanii mamavirus, 710*f*, 711, 714
Acanthamoeba polyphaga see (*Acanthamoeba polyphaga*mimivirus (APMV))
Cafeteria roenbergensis virus *see* (*Cafeteria roenbergensis*virus (CroV))
classification of, 704–705
double-stranded DNA viruses, 704
genome structure and organization, 709, 710*t*
history of, 704
mobile genetic elements associated with, 721
perspective in, 721–722
phylogenetic relationship with, 704–705, 706*f*
replication stages, 711–716
assembly and release in, 715–716, 717*f*–718*f*
attachment and entry, 711–712, 712*f*
genome replication and repair, 714–715
host range, 711
transcription in, 712–713
translation in, 714
uncoating and virion factory formation, 712, 713*f*–714*f*
structure, virions, 705–709, 707*f*–708*f*
translation components encoded by giant viruses, 709–711, 711*t*
viruses infecting (virophages), 718–721 *see also* (Virophages)
Minute virus of canines, 188
Minute virus of mice (MVM)
assembly of, virion, 178–180, 180*f*–181*f*
DNA replication in, 175, 178
endocytosis and endosomal release in, 177
fetal and neonatal infections with, 185
MiRNAs, 347–348
pathogenesis and control of tissue tropism in, 188
transcription of autonomous parvoviruses in, 178–180, 180*f*–181*f*
viral DNA release from capsid in, 177
MIR1, 539, 540*f*
MIR2, 539, 540*f*
miRNAs, 347–348

Mitogen signaling pathways, papillomavirus E5 proteins in, 61
Molluscum contagiosum (MOCV), 615*t*–616*t*. *See also Poxviridae*
characteristics, 631
clinical features, 631
diagnosis, 631–632

N

Nasopharyngeal carcinoma, 367–369, 368*f*, 374–375
with Epstein-Barr virus, 364*t*, 367–369, 367*f*, 368*f*, 374–375
treatment of, 374–375
Natural killer (NK) cells, 82–83, 423–424, 426
Necrosis/necroptosis, 274–275
Neonatal HSV infection
acquisition and presentation of infection, 309–310
congenital infection, 309
intrapartum infection, 309–310
newborn, incidence and transmission of, 309
postnatal acquisition, 310
prevention of, 313
Neonatal infections
with Aleutian mink disease virus, 185
with canine parvovirus, 185
with minute virus of mice, 185
with parvoviruses, pathogenesis and control of tissue tropism in, 185
Neoplasia, 505
Neurologic disorders, 505
Neuropilin-2 (NRP-2), 402

NF-kB, in poxviruses, 599–600
NK cells, primary immune responses, 299
NK-cell inhibitor, secreted, in poxviruses, 598
NK-cell leukemia/lymphoma, aggressive, 369
Nongenital skin warts, 79
Non-Hodgkin lymphomas, 371
    with Epstein-Barr virus and human immunodeficiency virus, 369–370
Noninfectious enveloped particles (NIEPs), 394
Nonmelanoma skin cancer (NMSCs), human papillomavirus and, 79–80
Nucleic acid amplification technologies (NAATs), 430
Nucleic acid polymers (NAPs), 700
Nucleocapsid proteins, in VZV-infected cells, 457
    ORF23, 457–458
    ORF33, 457
    ORF40, 457
Nucleocapsids assembly, 410–412, 411*f*–412*f*
Nucleoside analogue (NUC) therapy, hepatitis B virus, 672

O

Obesity, adenoviruses, 148
Occult HBV infection (OBI), 669
Ocular infections, adenoviruses, 145–146
Oka-Merck varicella vaccine, 480
Oncogenes and oncogenesis
    Herpesviridae, 229–230
    Kaposi's sarcoma, 230
    Kaposi's sarcoma herpesvirus, viral lytic proteins in, 547–548
    model for EBV, 371–372, 372*f*
Oncolytic therapy, herpes simplex viruses
    G207, 316
    G47⊗, 316

in trichodysplasia spinulosa and TSPyV, 34–36, 35*f*–36*f*
epidemiology of, 23–24, 23*f*
genome structure and organization of, 5–10, 6*f*
fundamentals of, 5–8, 9*f*
T antigen structure in, 7*f*, 8–10, 9*f*, 10*f*, 11*f*

history of, 1–4
pathogenesis and pathology of, 19–23
entry into host, 19–20
immune response in, 20
persistence in, 20–21
transformation in, 21–23, 22*f*
perspectives on, 38–39
replication stages of, 10–19
assembly in, 5*f*–6*f*, 18–19
attachment in, 10–11, 12*f*–13*f*
entry, intracellular trafficking, and uncoating in, 12–13, 13*f*
release in, 19
transcription in, 13–16, 15*f*
translation in, 16
viral genome DNA replication in, 9*f*, 16–18, 17*f*
taxonomy of, 2*t*, 3*f*, 4
virion structure of, 4–5, 5*f*–6*f*
Porcine circovirus (PCV), 197–205
classification of, 197
clinical features of, 202–204, 204*f*–205*f*
diagnosis, prevention, and control of, 204–205
epidemiology, 202–204, 204*f*–205*f*
genome structure and organization in, 198, 200*f*
history of, 197
pathogenesis and pathology of, 202
in porcine circovirus–associated diseases, 202
in psittacine beak and feather disease, 202
perspective, 205
replication stages of, 198–202
attachment, entry, and uncoating in, 198–199, 201*f*
genomic DNA replication, assembly, and release in, 201–202, 203*f*
transcription in, 199–200, 202*f*
translation in, 200–201
structure of, virion, 197–198, 198*f*–199*f*
Porcine circovirus–associated disease (PCVAD)
diagnosis, prevention, and control of, 204–205
epidemiology and clinical features of, 202–204, 204*f*–205*f*
history of, 197
pathogenesis and pathology of, 202, 204*f*
perspective, 205
Porcine dermatitis and nephropathy syndrome (PDNS), 202, 204*f*–205*f*
Porcine parvoviruses, 188
Postherpetic neuralgia (PHN), 469*f*, 471, 474–475, 476. *See also* Varicella–zoster virus (VZV)

Posttransplant lymphoproliferative disease (PTLD), 374
Epstein-Barr virus in, 362, 362*t*, 363*f*, 374
treatment of, 362, 362*t*, 363*f*, 374
Postvaccination encephalomyelitis (PVEM), 627
Postweaning multisystemic wasting syndrome (PMWS), 202
Poxviridae (poxviruses), 573–613
adaptive immune response to, 601
assembly of, virion, 578*t*, 591–594, 591*f*–592*f*
crescent and IV membrane formation in, 592–593, 592*f*, 593*f*
D13 scaffold removal from IVs in, 594
genome, core protein and transcription complex association with IVs in, 593
intramolecular disulfide bond pathway in, 578*t*, 594
mature virion occlusion in, 594
overview of, 591, 591*f*–592*f*
virion protein proteolytic processing in, 594
cell entry in, 578–582
cell–cell fusion, 582
extracellular virion and virus spread, 580*t*, 582, 582*f*
general considerations in, 578–581, 578*t*
mature virion entry in, 578*t*, 581–582, 581*f*
classification, 574–575, 574*t*
defense molecules in, viral, 596–601
extracellular defense proteins in, 596–598, 597*t*
chemokine inhibitors, 598
complement regulatory protein, 596
IFN-binding proteins, 597
IL-18 BPs, 597
other cytokine-binding proteins and homologs, 598
secreted NK-cell inhibitor, 598
soluble IL-1β receptor homologs, 598
soluble tumor necrosis factor BPs, 597–598
T-cell activation, 598
intracellular defense proteins in, 598–601
antigen presentation inhibitors, 601
apoptosis inhibitors, 601*f*, 600–601
cell pattern recognition receptor signaling pathway inhibitors, 598
IFN pathway inhibitors, 600
IFN-stimulated gene products inhibition, 600
IRF-3 pathway, 600
NF-★B signal transduction inhibitors, 599*f*, 599–600
POXV defense proteins, additional, 601
RNA inhibitors and DNA sensing, 598–599
overview of, 596

extracellular EV formation in
actin tail formation in, 583*f*, 595
intracellular movement and exocytosis in, 592*f*, 595
overview of, 594
wrapping in, 580*t*, 591*f*, 594–595
gene expression in, 582–587
early-stage
promoters and termination signals in, 584*f*, 583
transcription enzymes and factors in, 585*f*, 584–585
transcription regulation in, 577*f*, 584*f*, 582–583, 579*t*
intermediate-stage
enzymes and factors in, 586, 586*t*
promoters in, 584*f*, 585–586
transcription regulation in, 584*f*, 585
late-stage
promoters and RNA processing signal in, 584*f*, 586–587
transcription enzymes and factors in, 587, 580*t*
transcription regulation in, 577*f*, 584*f*, 586
POXV gene programmed expression in, 577*f*, 582, 583*f*
translation regulation, 587
history, 573–574
novel unclassified, 636
replication in, DNA, 587–591
concatemer resolution in, 590
DNA precursor metabolism enzymes in, 588–589
general features, 587–588, 587*f*
homologous recombination in, 590–591
models of, 588, 588*f*, 589*f*
viral proteins in, 589–590
structure of, virion, 575–576
chemical composition in, 575
genome in, 575–576, 576*f*, 577*f*
morphology, 575, 575*f*
polypeptide components in, 576, 579*t*–580*t*
treatment of, antivirals in, 601
vertebrate, 614–640
avipoxvirus, 636
capripoxviruses, 615*t*–616*t*, 634–635, 635*f*
leporipoxvirus, 615*t*–616*t*, 635–636, 635*f*
molluscum contagiosum, 615*t*–616*t*, 631–632, 631*f* *see also* (Molluscum contagiosum (MOCV))
orthopoxviruses in, 633–634 *see also* (Orthopoxviruses)
parapoxviruses in, 615*t*–616*t*, 617*f*, 629–631

suipoxvirus, 615*t*–616*t*, 635, 635*f*
yatapoxviruses, 615*t*–616*t*, 617*f*, 632–633, 633*f*
virus–host interactions, 595–596
cell pathway stimulatory effects in, 596
cytoskeleton effects of, 595
host macromolecular synthesis effects in, 595–596
tropism and host range in, 595
with ubiquitin-proteosome system interactions, 596
Poxvirus vectors, 573–574, 601–602
Pregnancy, adenoviruses in, 147–148
Premature infants, cytomegalovirus infection in, 422, 428
Pre-mi-RNAs, in adenoviruses, 121
Primary effusion lymphoma (PEL)
with Epstein-Barr virus and human immunodeficiency virus, 371
Kaposi's sarcoma herpesvirus in, 559
CD138/Syndecan-1 expression, 559
cell lines, 514
classification, 514
clinicopathologic features, 559
complex cytogenetics, 560
discovery, 514, 559
and Epstein-Barr virus, 514, 559
gene expression in, 546–547
immunoblastic–anaplastic large-cell morphology, 558*f*, 559
molecular pathogenesis of, 546
treatment, 560
Primary effusion lymphomas, 371
Primary/initial/recurrent genital disease, herpes simplex viruses, 308–309, 308*f*
Primary/recurrent oropharyngeal disease, herpes simplex viruses, 306–308, 307*f*
Progressive multifocal leukoencephalopathy (PML), 1–4, 505
AIDS and increase in, 3–4
clinical diagnosis of, 32–33
clinical presentation of, 32
emerging therapeutics, 31
histology of, 30–31, 31*f*
in HIV/AIDS, 24–25, 31
incidence, 31
JCPyV-associated diseases, 30–34
magnetic resonance imaging, 32, 32*f*
pathogenesis of, 32
prevention of, 33
treatment of, 33
Progressive vaccinia, 626, 627*f*

Promyelocytic leukemia (PML) protein, 252–253
Promyelocytic leukemia protein nuclear bodies (PML-NBs), in varicella–zoster virus, 464
Protein synthesis inhibitors, 403
Pseudocowpox virus (PCPV), 615*t*–616*t*, 617*f*, 628*f*
Psittacine beak and feather disease (PBFD), 197, 199*f*, 202, 204
Psittacinepox virus, 636
PTLD. *See* Posttransplant lymphoproliferative disease (PTLD)
Pyothorax-associated lymphoma, 369
    with Epstein- Barr virus, 369

Q

Quailpox virus, 636
Quantitative polymerase chain reaction assays (qPCR), 506

R

Rabbit oral papillomavirus (OcPV1), 62–63. *See also* Papillomaviruses
Rabbit parvovirus, 188
Raccoonpox virus, 615*t*–616*t*, 634
Radiculitis, HSV infection, 311
RAP, in Kaposi's sarcoma herpesvirus, 536–537
Rat CMV (RCMV), 390
Rb inactivation, DNA virus oncoproteins in adenovirus
    HPV E6 protein, 56–59, 57*f*, 58*t*
    HPV E7 protein, 59–61, 59*f*, 60*f*, 61*t*
RBP-J★ protein, 535
Reactivation, of varicella–zoster virus, 467*f*, 469*f*, 470*f*, 470–471
Recombination, in poxviruses, 590–591
Recurrent aseptic meningitis (Mollaret syndrome), HSV infection, 311
Recurrent respiratory papillomatosis (RRP)
    human papillomavirus in, 78–79
    laryngeal cancer with, human papillomavirus in, 78–79
Reinfection, in varicella–zoster virus, 471
Rep68 protein of adeno-associated virus type 2 (AAV-2), 500
Replication-associated protein (RAP), in Kaposi's sarcoma herpesvirus, 536–537
Respiratory diseases, adenoviruses, 145
    acute
        in adults, 145
        in military recruits, 145
    endemic infections, in young children, 145
Retinoblastoma protein (pRB), 406
Retinoic acid–inducible gene I (RIG-I), 272
Retroperitoneal fibromatosis herpesvirus (RFHV), 514
Rhadinovirus (RDV, rhadinoviruses), 324–325, 514. *See also* Kaposi's sarcoma herpesvirus (KSHV)

classification of, 514, 515*f*
Rhesus CMV (RhCMV), 390
Rhesus monkey rhadinovirus (RRV), 514, 548
Rhesus papillomavirus (MmPV1/RhPV1), 63
Rheumatoid arthritis, with Epstein-Barr virus, 372
Ribavirin, for adenoviruses, 156
Ribonucleotide reductase
in poxviruses, 589
virion structure and physical properties in, 456
Ribosomal S6 kinases (RSKs), in Kaposi's sarcoma herpesvirus, 541*f*, 542
Rodent parvoviruses, pathogenesis of, 188
Rolling circle amplification technique, 3
Roseoloviruses, 489
properties of, 492*t*
RTA, in Kaposi's sarcoma herpesvirus, 534–536, 534*f*, 536*f*, 541*f*

S

Salmon gill poxvirus, 575
SAP mutation, 360
Secreted NK-cell inhibitor, in poxviruses, 598
Serologic assays, for human herpesvirus, 507
Sexually transmitted infection (STI), 426–427
SH2D1A, 360
Sheeppox, 615*t*–616*t*, 634–635, 635*f*
Shingles, 445, 446*f*. *See also* Varicella–zoster virus (VZV)
Short interfering RNA (siRNA), 500
Shut-off exonuclease (SOX), in Kaposi's sarcoma herpesvirus, 544
Siadenovirus, 98–99
Signal transduction pathways, NF-kB, in poxviruses, 599–600
Simian parvoviruses, 174
Simian virus 40 (SV40). *See also* Polyomaviruses
cytopathic effect of, 4, 19

syncytia formation in, 460, 461*f*
transcription and translation in, 453–454
VZV proteins regulating viral gene transcription in, 454–455
IE4, 452*f*, 455
IE62, 452*f*, 454–455
IE63, 452*f*, 455
ORF61, 452*f*, 455
vs. smallpox, 445
structure of, virion, 446–447, 447*f*
treatment of
general, 478
in varicella, 478
in zoster, 478–479
vaccines in
for varicella, 479–480
for zoster, 480–481
Variola virus (VARV), 573–574, 574*t*. *See also Orthopoxvirus* (orthopoxviruses); *Poxviridae*
diagnosis of, 618*t*, 628
epidemiology of, 622
history of, 614–616
host range and geographic distribution of, 615*t*–616*t*
vCyclin, in Kaposi's sarcoma herpesvirus, 526–527, 527*f*, 529*f*
Vectors
expression, poxvirus, 601–602
for gene therapy, adeno-associated virus, 189
Vegetative replication, of papillomavirus DNA, 55
Vesiculopustular response, to vaccinia virus vaccination, 626, 626*f*–627*f*
vFLIP, in Kaposi's sarcoma herpesvirus, 527–528, 529*f*
vIL-6, in Kaposi's sarcoma herpesvirus, 532*f*, 533, 533*f*
Viral chemokines (vCCLs), in Kaposi's sarcoma herpesvirus, 542, 543*f*
Viral G-protein coupled receptor (vGPCR), in Kaposi's sarcoma herpesvirus, 532*f*, 544
Viral interferon regulatory factors (vIRFs), in Kaposi's sarcoma herpesvirus
interferon evasion by, 539–542, 541*f*

vIRF3, 517*f*, 528–530, 529*f*
Viral IRF homolog 3 (vIRF3), in Kaposi's sarcoma herpesvirus, 517*f*, 528–530, 529*f*
Viral mitochondrial inhibitor of apoptosis (vMIA), 425–426
vIRF3, in Kaposi's sarcoma herpesvirus, 517*f*, 528–530, 529*f*
Virophages
classification, 719
coinfection with Mimivirus, 720
genomics of, 719
host–virus symbioses and defense systems involving giant viruses, 721
Lavidaviridae, 719
particles structure, 719, 719*f*
replication cycle, 719–720, 719*f*, 720*f*
Sputnik, 707–709, 718–719
Viroplasms, in poxviruses, 592–593, 620
Virosomes, in Epstein-Barr virus, 331–332
Virus detection by culture, 506
Virus–host interactions, herpesviruses, 227*t*
conquering the cell, 226–227
modulation of host defenses, 227–229
pathogenesis, 229–230
Virus-like particle (VLP), 48
in circovirus, 200–201
in cytomegalovirus, 390
in human papillomavirus, 48*f*
PCV2, 198–199
in vaccines
for Epstein-Barr virus, 376
for human papillomavirus, 88–90, 88*t*–89*t*, 90*f*
Volepox, 615*t*–616*t*, 618–619, 621, 634
Vulvar malignancy, human papillomavirus in, 76
VZV. *See* Varicella–zoster virus (VZV)

W

Warts, human papillomavirus. *See also* Papillomaviruses
anogenital, 76
nongenital skin, 79
Wild cottontail rabbits *(Sylvilagus floridanus)*, 62
Woodchuck hepatitis virus (WHV), 642
Woolly monkey hepatitis B virus (WMHBV), 648
envelope proteins of, 691–693
Wu polyomavirus (WUPyV)
epidemiology, 24
history of, 3

pathogenesis and pathology of, 20
respiratory tract infectious diseases, 24, 37–38
sites of persistence for, 20–21
taxonomic classification, 2*t*, 3*f*

X

xCT, in Kaposi's sarcoma herpesvirus, 517–520, 520*f*
X-linked inhibitor of apoptosis (XIAP) mutations, 375
X-linked lymphoproliferative disease (XLP), 359–361, 360*f*
with Epstein-Barr virus, 359–361
type 1, 359–361
type 2 (XLP-2), 361

Y

Yaba monkey tumor virus (YMTV), 632
Yaba-like disease of monkeys, 632
Yatapoxviruses, 615*t*–616*t*, 617*f*
clinical features, 632, 633*f*
diagnosis, 633
epidemiology, 632
history, 632
pathogenesis and pathology, 632

Z

Zoster sine herpete, 477
Zoster vaccines, 480–481
